It is not necessary to conclude, however, that occasional acute attacks of tonsillitis in a child will result in permanent crippling of the organ. It is not easy to decide how many such attacks he may be allowed before becoming a candidate for tonsillectomy, but it certainly happens that children pass through such phases and then cease to be troubled by further attacks. According to Hajek's teaching, if a person has three attacks of follicular tonsillitis, with joint pains, in the course of a year or two, the tonsils should come out. Reddening of the faucial pillars does not necessarily signify chronic tonsillitis; it is frequently seen in healthy persons after meals.

Chevalier Jackson in his contribution to the text-book of Jackson and Coates exhibits two coloured illustrations of reddening—which, however, may be pathological; one shows a limited margin of redness, indicating that tonsillectomy will be followed by cure of associated remote disease; *in the other the reddening is more diffuse,* does not show a limited margin, and is the result of a general pathological condition which will remain unaltered if operation is carried out.

Œdematous infiltration of the tonsil with associated redness and swelling of the palatal arches is a definite indication of disease. Glandular enlargement in the tonsillar chain in the neck may be commonly felt; but the diagnosis of a harmful enlargement may vary with the personal opinion of the observer, especially when the patient is a child. Conservative treatment is therefore advisable. But when a frank glandular enlargement is noticed to persist, tonsillectomy is indicated, no matter what may be the appearances of the tonsil itself. Kaiser describes cervical adenitis in children as a clinical entity, deserving of the name, when glands actually become visible as a result of enlargement. Howarth and Gloyne have shown that such enlargement of glands is not necessarily tuberculous; tubercle is probably a late infection. The value of a blood examination in certain cases must not be lost sight of. I have had some fortunate escapes from performing the operation of tonsillectomy in cases of lymphatic leukæmia.

Opinions appear to vary as regards the value of *bacteriological examination of material taken* from the surface of the tonsils or from the crypts, either with the platinum loop or by puncture (Ramsay and Pierce). We may look for help to the pathogen selective method, as practised in this country by Cronin Lowe; this method is similar to that used by Solis Cohen in America, and bears a close relationship to the virulence test of Rouge modified by Phillip. Halasz, however, considers the discovery of types of organisms known to produce serious disease as evidence of a pathological condition of the tonsil. Some *bacteriologists are not willing to accept* the view that Cronin Lowe's method would settle this problem in remote disease of suspected tonsillar origin.

THE TONSIL AS A FACTOR IN REMOTE DISEASE

Lillie and Lyons in America, writing at a time when the responsibility of the tonsil in rheumatic affections was thought to be considerable, recommended complete removal of the tonsil with plica in every frank case of myositis and arthritis. They expected 89 per cent. of improvements. A history of tonsillitis, though valuable, was not considered to be necessary. Crowe, Watkins and Rotholz, more conservative, did not advise tonsillectomy in stubborn cases of rheumatoid arthritis, but claimed favourable results from the operation in (1) infective arthritis with peri-articular signs, (2) myalgia, and (3) acute polyarthritis (rheumatic fever). Such indictments against the tonsil as a focus of infection in arthritis led Gording and Bjorn-Hansen [23] to seek further information from the blood picture for evidence of an infective process. A. L. Bloomfield remarks, in a late edition of Musser's text-book of medicine :—

---

† An abstract by Mr. Thomas Guthrie appeared in the Jour. Laryngol., 1930, xlv., 590.

> With regard to remote disorders such as arthritis or nephritis the evidence is not conclusive, but such statistics as are available bring no proof that tonsillectomy either prevents or has any special beneficial effect on remote or constitutional disease. In brief, the present practice of indiscriminate removal of tonsils on the slightest excuse or for no reason at all is certainly to be decried. The subject is an important one, since the operation, while not usually difficult, has its hazards as well as its economic complications. Every physician should give the matter serious thought, and one may fairly add "let your conscience be your guide."

Kaiser's work among the children of Rochester, U.S.A., illustrates the need for such serious thought on the subject.

RESULTS OF THE ADENOID OPERATION

We know that the results of operative removal of the respiratory tonsil, in properly selected cases, are brilliant. This applies especially to cases of naso-pharyngeal stagnation, with inadequate nasal ventilation and its evil consequences. It is time, however, to dispel the popular idea that when such an operation gives poor results the adenoid mass has returned and must be removed again. If the operation has been properly carried out such a recurrence is rare indeed. The development of a residual granular naso-pharyngitis should not call for the curette or the adenectome, but for an inquiry into the general condition of the child, and particularly into the condition of the nose; in treating the so-called nasal catarrhs of children, it should be remembered that vasomotor rhinitis is common ; if surgical treatment is needed the application of the galvano-cautery point to the relaxed and waterlogged inferior turbinates gives hopeful results. We should look also for hypertrophic rhinitis and deflection of the nasal septum, but should expect to discover a manifest sinusitis more rarely.

Cases of ear disease with intermittent deafness do very well, particularly when they occur in young children. Keen [24] and Kaiser both draw attention to this. In frank inflammatory disease of the middle-ear cleft, however, disappointment after the adenoid operation must be accepted with some resignation, particularly in older children. We need have few illusions on this point now. The hereditary factor too comes out unpleasantly often. It is a delicate matter to decide whether the palatine tonsil should be removed or not, and equal care must be exercised when the size and state of the respiratory tonsil of Luscha is under review. The presence of a respiratory tonsil within normal limits may be more protective to the middle-ear cleft than none at all, particularly when we have to consider the more serious attacks of acute middle-ear disease and their complications.

ANCYLOSTOMA ANÆMIA AND ITS TREATMENT BY IRON

BY A. G. BIGGAM, O.B.E., M.D. Edin., F.R.C.P. Lond.

MAJOR, R.A.M.C. (SECD. F.O.) : PROFESSOR OF CLINICAL MEDICINE
IN THE ROYAL UNIVERSITY, CAIRO, AND DIRECTOR
OF THE MEDICAL UNIT, KASR-EL-AINY
HOSPITAL ; AND

PAUL GHALIOUNGUI, M.D. Cairo

REGISTRAR OF THE MEDICAL UNIT, KASR-EL-AINY
HOSPITAL

ANCYLOSTOMA anæmia is common in Egypt. The cause of the anæmia in this disease being easily removable, the rapidity of blood regeneration can consequently be observed and the response to different drugs in similar groups of cases compared. We therefore considered that this disease would furnish a suitable type of case for the trial of various drugs in the cure of the group of secondary anæmias. Recently we have had the opportunity of carefully studying a group of more than a hundred of these cases.

Ancylostoma anæmia is a hypochromic, microcytic anæmia. In severe cases the number of the red blood-cells per c.mm. is markedly diminished, while the hæmoglobin is reduced to a much greater extent proportionately. In this series of cases the average red cell count was 2,900,000, the hæmoglobin 27·8 per cent., and the colour-index 0·47. The lowest red cell count was 1,400,000, while the hæmoglobin in some cases was as low as 10 per cent. and the colour-index reached 0·15.

Boycott,[1] using the carbon monoxide method of determining the total volume of blood, concluded that in these cases the percentage content does not correspond to the actual deficiency, owing to a considerable increase in the plasma and total volume of the blood ; the red cells and hæmoglobin are in a way diluted, so that the total diminution in hæmoglobin is less than would be suggested by a consideration of the hæmoglobin percentage alone, while the total number of red cells is frequently higher than normal, this being compensated for by a secondary fall in the colour-index.

On the whole, as seen from Table I., there is little shortage of hæmoglobin, and this would probably account for the mildness of the symptoms frequently associated with the severest grades of anæmia—for example, 10 per cent. of hæmoglobin, as estimated by the Sahli hæmoglobinometer—especially if compared with cases of pernicious anæmia of the same intensity of hæmoglobin deficiency. It is an everyday experience to see cases with 20 per cent. of hæmoglobin complaining only of slight dyspepsia or pains in the knees on walking. The fullness of these patients' soft tissues usually gives them a rather plump face and this, associated with their pallor and the blue discoloration of their conjunctivæ, produces a characteristic picture from which ancylostomiasis can be diagnosed almost with certainty even at a distance.

TABLE I.—*After Boycott* (*Milroy Lectures, 1911*)

	Hb. %	Total Hb. in g.	Blood volume.	Relative number of red cells in whole blood.
Normal ..	100	400	3000	100
Anc. 1 ..	44	311	5160	102
„ 2 ..	47	357	5520	106
	41	331	5880	
„ 3 ..	49	316	4620	128

Not infrequently actual œdema is present in sufficient amounts to give quite definite pitting on pressure, especially about the ankles. In some of these œdematous cases where examination of the blood proteins was carried out, it was found that the total protein and the albumin percentage were diminished—sometimes down to 5 and 2·6 per cent. respectively; but this was not constant. Occasionally a marked swelling in the region of the parotids is very apparent, but its exact ætiology is uncertain. In two cases marked spoon-shaped nails were observed, without associated achlorhydria.

In the cases investigated by us the van den Bergh reaction has always been negative, so that there can be no question of hæmolysis; also the reticulocytes have always been less than 1 per cent., usually about 0·5 per cent. at the outset of treatment, normoblasts being found only very exceptionally and then in extremely small numbers. Anisocytosis was common. The average size of the red cells, as estimated by Eve's halometer, was 7·44 μ, varying in different cases from 7·02 μ to 7·66 μ, the normal with this instrument being considered to be 7·6 μ. Not a single case showed the picture of a megalocytic anæmia.

Occult blood was nearly always found in the stools; we could not, however, always exclude other causes for bleeding in the gut apart from the presence of the worms. The lesions produced by the biting apparatus of these worms will almost certainly lead to some ulceration, from which bleeding will continue to take place for some time afterwards. Looss[3] considered that the main food of the parasite was serum and mucosa, any blood being ingested accidentally, and it remains to determine whether the bleeding is sufficient to account for the anæmia. De Langen,[4] carrying out quantitative estimations, has shown that these occult blood reactions are equivalent to 2 or 3 c.cm. of blood per day, a quantity he considers not nearly sufficient to produce such a degree of anæmia, as he failed to cause anæmia in sheep by withdrawing 100 c.cm. of blood weekly. It has, however, been shown by H. S. Wells,[5] working on *Ancylostoma caninum*, that each worm passes 0·84 c.cm. of blood through its digestive tract daily, so that 25 worms would cause a daily loss of about 20 c.cm. If this work be confirmed it would indicate that there is sufficient loss of blood to bring about by itself a severe degree of secondary anæmia.

Whether ancylostoma anæmia is hæmorrhagic or toxic and, if toxic, hypoplastic or hæmolytic, is still a debated point and must for the time being be left an open question. It may be pointed out, however, that in our cases, before treatment, evidence either of hæmolysis or of active regeneration was lacking in the blood and that after treatment had been commenced the blood showed signs of active regeneration—viz., reticulocytosis. A toxin is, however, certainly produced, as shown by the eosinophilia, but this is no proof that it, or a similar body, is the important factor in the production of the anæmia. Hæmolysins have been extracted from the head of the worm but such bodies can be extracted from practically every living organ or tissue. In our cases moderate or high eosinophilia was quite common.

Boycott,[1] in 1903, found that cases with high eosinophilic counts usually had a high total count. He calculated that the increase in the total leucocytes corresponded exactly to the increase in the number of eosinophils, these being added to the normal leucocytes of the blood and any change in the respective percentage of the other cells being merely secondary to the addition of eosinophils. In our cases there was little difference in the total counts, only the group having 20 per cent. or more eosinophils showing any increase (Table II.). There was also little difference in the response to treatment between the cases showing high and those showing low eosinophil counts.

TABLE II

Percentage of cases.	Eosinophils %	Average total leucocytes.
19	20 or more	9943
27	10 to 19	7230
27	5 to 9	7460
27	0 to 4	7528

The maximum recorded was 31 per cent., the average 13½ per cent.

Besides the direct action of the worms, toxic or hæmorrhagic, other factors no doubt contribute to the causation of the anæmia. The diet in our cases has generally been very low for years, meat, according to the patients' statements, being partaken of at most once weekly or sometimes as seldom as twice a year. Almost all patients state that they seldom eat uncooked vegetables, these being usually eaten in very much overcooked forms. The staple articles of diet are maize bread and preserved cheese, a diet obviously deficient in iron and vitamins. Pellagra is a frequent complication; this disease, however, will not be considered here.

Gastric juice analysis very rarely revealed achlorhydria, and it was most commonly found in cases complicated by pellagra. That hydrochloric acid deficiency when present plays a rôle in the causation of the anæmia is probable, the cases showing it, as will be seen later, responding more slowly to iron therapy; absorption is apparently impaired because the pH is higher than 3, instead of the normal 1·4 to 1·6.

An interesting clinical feature of these cases of anæmia was the systolic murmur heard over the pulmonary and mitral areas in the majority of cases. It differed from the usual description given of such hæmic bruits in being frequently very harsh and heard well out towards the axilla. It was sometimes much more marked over the apex than over the base, its character changing with any alteration in the position of the patient. Such a murmur usually disappeared or was considerably diminished in intensity when the anæmia had disappeared under treatment.

TREATMENT

First of all, worms were got rid of by administering carbon tetrachloride at weekly intervals until repeated examination of the stools by the floatation method revealed freedom from ova, and further treatment with carbon tetrachloride failed to produce evacuation of any more worms. Usually three or four doses were required to remove all the worms. Hexyl resorcinol was tried in a number of these cases, and the results, which were not satisfactory, have been reported elsewhere.[6]

In some cases, although no ova were found on stool examination, the anæmia and the appearance of the patient were so typical that carbon tetrachloride was administered, and not infrequently large numbers of worms were expelled. This difficulty in demonstrating ova may be due either to the presence of male worms only or to the failure of worms to find in the host a sufficiently nourishing pabulum to lay eggs. Experimental evidence in favour of the latter hypothesis may be found in the observation of Looss[7] who, after infecting himself, found that when his diet was reduced the development of larvæ from his stools was poorer than when milk or cheese was added. This effect may, however, be secondary to a change in the flora; Fleming and Allison have shown that addition of egg-albumin to a diet increases the number of *B. coli* in the stools, while McCoy[8] has shown how the larvæ thrive on bacteria.

The dietetic factor may also help to explain the very low worm loads found in some of the severest cases, the worms abandoning the host if he becomes very anæmic, and if his diet is very poor. Generally cases with only a moderate anæmia (40 to 60 per cent.) harboured only a few worms (up to 20), while the more severe cases of anæmia were frequently associated with higher loads of worms. As pointed out above, this however was not constant. The maximum number of worms found in our cases was 141.

The majority of the worms having been removed, the drug we proposed to try was administered. The red cells and the hæmoglobin were estimated twice weekly, using the Sahli instrument. This instrument, according to Wintrobe and Miller,[9] gives lower readings than most others. According to their calculations a reading of 100 per cent. with it corresponds to 17·2 g. of hæmoglobin per cent., while with the CO method of Haldane, 100 per cent. corresponds to 13·3 g. per cent. and with the Dare instrument to 13·8 g. per cent., so that when the Dare instrument shows 100 per cent., the Sahli will show 80 per cent. That this number should be taken as the normal in the average adult Egyptian is further confirmed by some estimations we carried out on a series of normal Egyptian adult controls with this apparatus. Out of 60 cases, two-thirds varied from 75 to 85 per cent., with a minimum of 64 and a maximum of 93, the average being 78·8 per cent.

These considerations must be remembered later, when the level reached by the hæmoglobin on different methods of treatment is considered, as a level of 80 per cent. (Sahli) was seldom surpassed, this corresponding to 100 per cent. (Haldane); further, when considering the colour-index, an index of 0·8 (Sahli) will be equivalent to 1·0 (Haldane).

We have tried various iron preparations, given alone or in combination with other drugs. The following have been used:

Oral.—Ferrum redactum, Blaud's pill, ferrous chloride, liver.

Parenteral.—Inj. ferri (B.P. given) intravenously and intramuscularly.

To the oral iron, copper, and manganese, vitamin B in large amounts, liver or thyroid were added in different cases.

ORAL IRON

Ferrum redactum.—This was given in cachets after meals. At first, a number of cases had small doses, 0·3 g. t.d.s., but later these were increased to 2 g. t.d.s. No untoward gastro-intestinal symptoms followed these doses, and the patients did not complain of any gastric discomfort or diarrhœa. It must be remembered, however, that these cases were almost universally constipated on admission, any irritating effect of the drug on the intestine merely being sufficient to neutralise this constipation. In certain non-hospital cases, especially women, this large dose had to be reduced owing to the onset of diarrhœa.

In some cases liver was added to the iron with no apparent improvement in the results, while neo-arseno-benzene (914) in moderate weekly doses of 0·15 to 0·45 g. enhanced the hæmopoietic regeneration and enabled the hæmoglobin to reach higher levels, even in cases with a negative Wassermann reaction.

The rapidity of blood regeneration can be seen in Fig. 1 which shows the results in 70 patients who had 2 g. ferrum redactum t.d.s. The count rose from an average of 2,900,000 red cells and 27 per cent. hæmoglobin to 4,900,000 red cells and 64·3 per cent. in five weeks, and reached an average of 5,500,000 red cells and 75 per cent. hæmoglobin in seven weeks.

Five cases showed achlorhydria and, as seen in the chart, showed a much slower response to treatment, rising from 3,280,000 and 38·5 per cent. to 5,100,000 and 54 per cent. in five weeks, reaching only 5,400,000 and 54·5 per cent. in seven weeks. Eleven patients who had only 0·3 to 0·6 g. of ferrum redactum t.d.s. showed a very poor response to treatment, rising from 3,000,000 red cells and 27 per cent. hæmoglobin to 4,100,000 and 41·6 per cent. The increase in red cells is usually accompanied by a moderate reticulocytosis, in our cases not exceeding 10 per cent. This rise in reticulocytes is slow and prolonged, lasting roughly from ten days to two weeks. Fig 7 illustrates the same results in another way. It shows the gain in hæmoglobin, under various forms of treatment.

In a number of cases which became stationary at about 60–70 per cent. hæmoglobin, copper and manganese were added to the iron, according to the following formula: ferr. redact. 2·0 g., pot. permang. 0·025 g., copper sulph. 0·005 g. Ft. cachet 1 t.d.s.

Some were given vitamin B, in the form either of marmite 2 g. t.d.s. or of fresh brewer's yeast 60 g., daily. In others 250 g. of liver by mouth daily, or thyroid extract, were added. On the whole, copper and manganese enabled higher levels to be reached, but, as these patients stayed longer in hospital and were still having the iron all the time, it is possible that this rise was due to the iron alone. Marmite was usually ineffective, while thyroid extract produced an initial slight fall of 5 to 10 per cent. in the hæmoglobin, followed later by a small rise above the former level.

Blaud's pill was given to ten patients in doses of grs. 150 daily, in freshly prepared, easily crushed tablets. No toxic symptoms were observed from these massive doses. The patients treated by this preparation were mostly cases of pellagra with ancylostoma anæmia and consequently, as is usual in such cases, a large proportion of them suffered from achlorhydria, only one of them having any free hydrochloric acid. The results obtained with this method of treatment showed no appreciable difference from a similar group of achlorhydric cases on reduced iron, the red cells rising from 2,800,000 to 4,300,000 and the hæmoglobin from 35·6 to 62·5 per cent. in six weeks, as can be seen from Fig. 1.

Ferrous chloride.—Four cases had ferrous chloride in a mixture, in doses of 0·3 g. daily. The results were very poor, the red cells and hæmoglobin rising from 3,000,000 and 33 per cent. to 3,950,000 and 47 per cent. in four weeks. In one case, shown in Fig. 2, reduced iron produced a quick response after ferrous chloride had failed to do so in four weeks.

Liver was administered alone in nine cases, in doses of 250 g. a day of fresh lightly cooked liver. The hæmoglobin showed a very poor response, rising from 16 to 37 per cent. in six weeks, this being no more rapid regeneration than would have resulted from mere removal of the worms without any special line of treatment, while the red cells showed a rise from 1,800,000 up to 5,000,000 in a corresponding time (Fig. 3).

In four cases no iron was given after the expulsion of the worms, in order to watch the progress of the case. Practically no improvement was seen after about four weeks' treatment (Fig. 4). If to these four cases we added the eleven cases which had only small doses of iron and which showed a very poor response, it becomes clear that iron in large doses is necessary to bring about a rapid recovery. These results agree with those of other observers (Toshizo Kobayashi[10]). In another eight cases ferrum redactum 2 g. t.d.s. was given, while no attempt was made to evacuate the worms (Fig. 1). Here a very rapid improvement in the blood condition took place, the hæmoglobin reaching 66·7 per cent. in five weeks; this result is in agreement with Keefer and Yang's findings.[11]

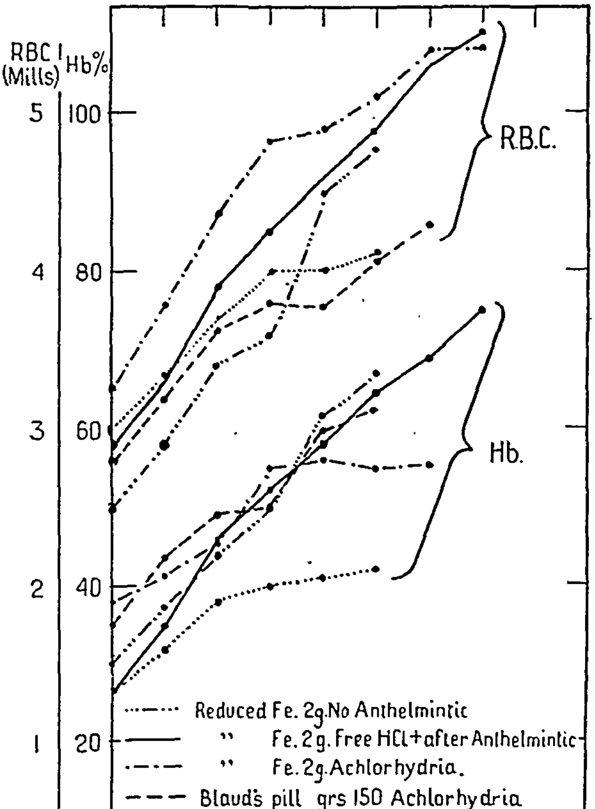

FIG. 1.—Showing response to various forms of treatment, and achlorhydria.

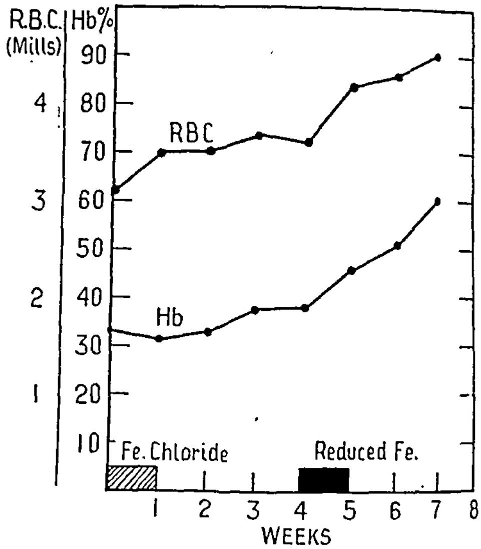

FIG. 2.—Showing weak response to ferrous chloride 0·3 g. daily for four weeks, followed by quick response to reduced iron.

The conclusion can therefore be drawn that large doses of iron can correct ancylostoma anæmia even when the patient is still harbouring the worms, but the probability is that such cases, if the iron were discontinued, would relapse to their former condition.

IRON BY INJECTION

By the kindness of Dr. R. S. A. Heathcote, professor of pharmacology in the faculty of medicine of Cairo, we were able to observe the effect of injecting large doses of iron intravenously in rabbits. The injectio ferri (B.P.) was used. It was first added to serum in vitro, no precipitation resulting. It was next injected undiluted into the ear veins of rabbits with no ill-effect even when 100 mg. of iron citrate were employed. Only one of the rabbits collapsed immediately after the injection, but it rapidly recovered and showed no subsequent ill-effect. In our patients we first used it intramuscularly. This method was exceedingly painful, the pain lasting very long after the injection had been completed; we therefore added 1 c.cm. of a 2 per cent. novocain solution to the contents of the ampoule at the time of the injection, and with this addition only very slight pain was experienced after the administration, and this rapidly disappeared.

In another group of patients we injected the drug into the vein daily. Some complained of an immediate feeling of flushing, giddiness, and nausea, but this was very transient and did not occur after the third injection. The ordinary B.P. injectio ferri was used at first, but as the results were poor this was considered to contain an insufficient amount of iron and another preparation was employed containing 50 mg. per c.cm., and of this preparation 1 or 2 c.cm. were given.

On the whole, iron by injection has produced only a very small effect, if any, on these anæmias. Six patients had intravenous injections in doses of 100 mg. daily of iron and ammonium citrate and showed a rise from 2,660,000 red cells to 3,000,000 and from 24·5 per cent. hæmoglobin to 33·5 per cent. in four weeks (Fig. 5). The effect of the intramuscular injections was not very different on the whole; the d cells rose from 2,900,000 to 3,900,000 and the emoglobin from 27 to 49 per cent. in five weeks, is being the average of eight cases who had 100 mg. day (Fig. 5).

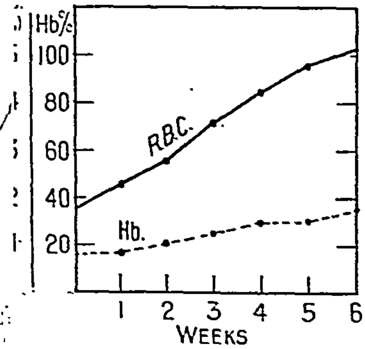

FIG. 3.—Effect of whole liver 250 g. daily on hæmoglobin and red blood-cells.

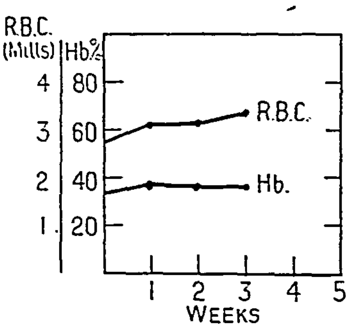

FIG. 4.—Showing no improvement, after removal of worms, in patients who had no iron.

On the other hand, taking the cases individually, we found that while the effect taken as a whole is nearly the same, some cases reacted very quickly and markedly to intramuscular medication, while this effect was never observed in those who had the iron intravenously Fig. 6 shows the red cells and hæmoglobin of a patient who was given 50 mg. of iron and ammonium citrate intravenously. The red cells and hæmoglobin, which on admission were 1,300,000 and 11 per cent. respectively, were still 1,700,000 and 24 per cent. after three weeks, although active anthelminthic medication had been given. Intravenous was then replaced by intramuscular injections of the same dose and his red cells and hæmoglobin showed a quick rise to 3,200,000 and 47 per cent. after four weeks. At this point the dose of iron and ammonium citrate given was doubled and the red cells rose in one week to 4,100,000 and the hæmoglobin to 60 per cent. (Fig. 7).

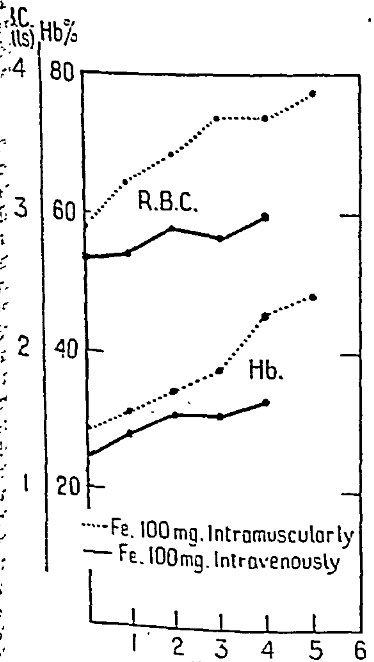

FIG. 5.—Effect of 100 mg. iron and ammonium citrate intramuscularly and intravenously, to same scale as Fig. 1.

This shows that, while iron by injection is as a whole of little use, the intramuscular route is more effective in some cases and in appropriate doses, and may produce quite an appreciable effect. In no case was there any ill-effect on the kidneys or any other organs during this parenteral administration.

CONCLUSIONS

1. Ancylostoma anæmia is considered to be a suitable anæmia in which to observe blood regeneration under different treatment after removal of the cause.

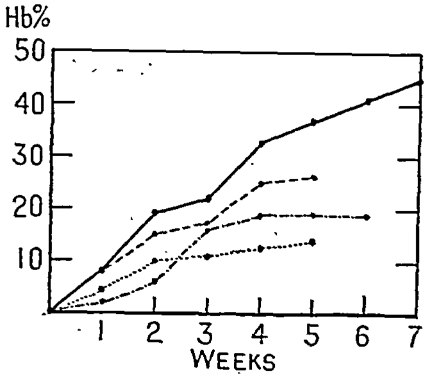

FIG. 7.—Comparative percentage rise of hæmoglobin above original level as compared with Fig. 1.

2. Reticulocytes were present in very small numbers before treatment. A rise to about 10 per cent. occurred under iron treatment. Eosinophilia up to 20 per cent. or more was noticed in 19 per cent. of cases, from 10–19 per cent. in another 27 per cent. of cases, from 5–9 per cent. in 27 per cent., and below 5 per cent. in 27 per cent. The maximum was 31 per cent., and the average 13⅓ per cent. No relation was found between the eosinophilia and the total leucocytic count.

3. The hæmoglobin in the average normal Egyptian adult is considered to be about 80 per cent., using the Sahli hæmometer.

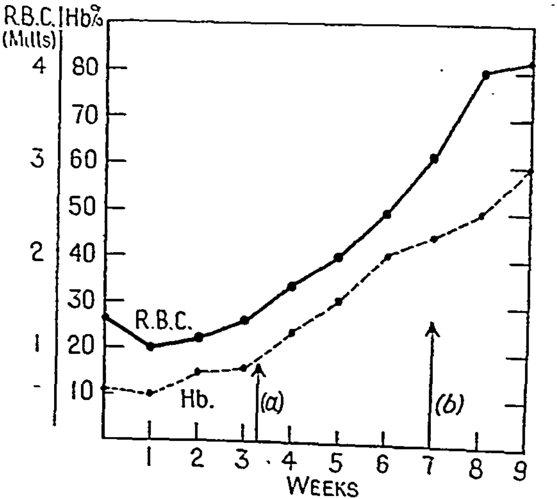

FIG. 6.—Showing effect of change from intravenous to intramuscular iron injections at arrow (a) and of doubling the dose from 50 to 100 mg. intramuscularly at (b).

4. The response of the red cells and hæmoglobin to reduced iron, Blaud's pill, and ferrous chloride by mouth, together with the effect of addition of liver, yeast, marmite, copper, and manganese in different cases is described and illustrated by charts. It is shown that doses of iron can correct ancylostoma anæmia even when the patient is still harbouring the worms, but that removal of the worms alone produces little or no change on the blood picture.

5. Observations on intravenous injections of the

injectio ferri (B.P.) in rabbits in very high doses showed no toxic manifestations.

6. The effect of 100 mg. daily of injectio ferri, i.e., three times the official dose, is discussed. The results are considered not to be satisfactory, although in certain cases intramuscular administration was sometimes effective. A case is described where intramuscular injections produced a good response after intravenous injections for three weeks had failed to do so.

SUBARACHNOID HÆMORRHAGE

IN GENERAL PRACTICE*

BY J. N. GALE, M.D. Sheff.

SUBARACHNOID hæmorrhage must be recognised in the patient's home. Unlike many other neurological conditions it does not allow of the patient being sent into hospital with perfect safety to await examination. A missed diagnosis, therefore, may easily lead to death; whereas with correct treatment in a suitable case complete recovery may be expected, since the brain substance has not been ploughed up and damaged as it is in an intracerebral hæmorrhage.

Spontaneous subarachnoid hæmorrhage refers to cases of hæmorrhage in the space between the arachnoid and the pia mater which are not caused by violence in the ordinary sense of the word. The cases fall roughly into two groups: the younger, in which it is usually due to a congenital aneurysm or a defect in the vessel wall; and the older, in which it is due to arterial disease or degeneration.

DIAGNOSIS

In general practice it is always convenient to have a condensed version of the signs and symptoms of the less severe cases in one's mind, and my own mental picture is as follows. The patient is suddenly seized with an intense headache and feels as if something has snapped in the head. He reels about and may become unconscious for a short time. He always has a severe headache over the occipital or more rarely the frontal area, with stiffness of the neck and usually photophobia. At the risk of being dogmatic I venture to say the headache of instantaneous onset with transient giddiness or unconsciousness, and stiffness of the neck and photophobia demand lumbar puncture as certainly as hæmaturia demands a cystoscopy. I may mention also that photophobia has been present in every case with which I have been associated and in every attack in a patient who has had five attacks. Although Barber and Taylor[1] and Lescher[2] have all noted this symptom previously, there is no mention of it in the classical monograph of Symonds,[3] and since it seems to depend on the irritation of the extravasated blood, as does the stiffness of the neck, it appears reasonable to expect to find it in nearly every case.

Other signs which seem to be due to the *irritation of the extravasated blood* are *Kernig's sign, pains in the body* and limbs due to stimulation of the nerve-roots, massive albuminuria due to irritation of the centre in the floor of the fourth ventricle—and not to any renal lesion—and a temperature of 99° to 100° F. This temperature is similar to that seen in cases of ruptured ectopic gestation and is likewise due to the effect of the extravasated blood.

The *occipital headache* is probably due to the increased intracranial pressure and is usually relieved immediately by a lumbar puncture. The other symptoms of increased pressure such as cerebral irritation may be followed by coma, and death may supervene.

Korsakoff's syndrome is present in most cases in greater or less degree. Although this syndrome is also present in alcoholic polyneuritis, infective conditions of the brain, in progressive paralysis, senile dementia, and cerebral contusions, it has not, I believe, been observed in intracerebral hæmorrhage. It may be pointed out that where the prognosis in many of these conditions is bad, in subarachnoid hæmorrhage it is relatively good.

Papillœdema and *hæmorrhages in the fundus* are recorded in a number of cases, and Doubler and Marlow[4] have cut transverse and longitudinal sections of the optic nerve which showed that the blood has forced its way along the optic nerve sheath into the eyeball, which may account for the pain in the eye of which some patients complain. In my own cases the discs have been normal, though photophobia and reddening of the conjunctiva were marked.

These signs and symptoms only add weight to the definite indication for lumbar puncture given by the headache of instantaneous onset, stiffness of the neck, and photophobia, and it is usually not wise to waste time by looking for them until after the lumbar puncture, since the latter will complete the information necessary for diagnosis, besides relieving the patient's headache. The cerebro-spinal fluid must be received into two (or preferably three) sterile test-tubes, since an accidental injury to a blood-vessel during the puncture may cause blood in the first test-tube only, whereas in subarachnoid hæmorrhage it is present in all of them in the same proportion. The colour may vary from a pinkish tinge to a pure blood colour. The blood is soon broken down and after a time the original colour may yield to a golden yellow or brownish tinge.

A large and rapidly fatal subarachnoid hæmorrhage is indistinguishable except at autopsy from a cerebral hæmorrhage which has ruptured into the ventricles or externally into the subarachnoid space. The history of instantaneous onset of the headache, when it can be obtained, is very helpful. The transient unconsciousness with pain, stiffness of the neck, and photophobia, combined with the detailed examination of the cerebro-spinal fluid, usually settles the diagnosis immediately and will exclude conditions such as meningitis and polio-encephalitis. In hæmorrhagic encephalitis lethargica the history is different, and the temperature is usually higher and more sustained; the absence of abdominal reflexes and the ocular symptoms help to differentiate the condition and the subsequent course is not the same.

PROGNOSIS

Excluding the cases where the hole in the artery is large and the patient dies in a few hours, the prognosis is very different in the older group due to arterio-sclerosis and in the younger group due to congenital defect or aneurysm, the mortality being nearly twice as high in the older group. From what have been able to read it seems that the importance of blood pressure in prognosis has been strangely neglected. While it is not possible to observe the condition of the cerebral arteries during life, it is possible to obtain with ease some measure of the strain to which they are subjected in the living subject. The blood pressure will give a definite answer to one-half of the problem of prognosis. Added to this we know already that in cases of spontaneous subarachnoid hæmorrhage the vessel wall is diseased or defective in some way, and this gives the blood pressure an added importance in prognosis and treatment. In most of the younger group of cases there is no permanent elevation of the blood pressure, and the hæmorrhage is due to some defect in the vessel wall or to a tiny aneurysm. In this group the immediate prognosis is relatively good, since with proper treatment and avoidance of anything which tends to raise the blood pressure the patient usually gets well; there is a great tendency to recurrence, as many as five or six attacks having been reported without a fatal termination. It is usually advisable to have a Wassermann test. Hall [5] has reported hæmorrhage from syphilitic arteritis in a man of 28.

---

* Based on a paper read before the Derby Medical Society.

In the older group due to arterial degeneration, with or without increased blood pressure, the prognosis is not so good, since the fragility of the vessel wall is usually progressive and the raised blood pressure throws a severe strain on a vessel which is gradually getting weaker. As a somewhat arbitrary rule it appears from the few cases in which the blood pressure has been recorded that a blood pressure of 200 mm. Hg or over is of very grave significance, although there is no certain safety even if the blood pressure is less, because the vessel wall may be unduly fragile.

TREATMENT

In every case there are certain natural factors which tend to cause a cessation of the hæmorrhage. These are the clotting of the blood at the bleeding point and the rise of pressure in the cerebro-spinal fluid. Treatment should take into consideration four factors: (1) the blood pressure; (2) repair of the vessel wall; (3) pressure of cerebro-spinal fluid; and (4) prevention of further attacks.

Blood pressure.—There is possibly a momentary fall in blood pressure due to collapse of the patient at the moment of onset; but almost immediately there is a reflex increase of pressure in order to maintain the cerebral circulation. If the case is seen soon after onset when the bleeding is probably in progress the patient should be rigidly recumbent, the neck must not be kinked, nor should he have any tight clothing round his neck. The rise of intracranial pressure due to the lightest pressure on the jugular vein of one side, as seen in Queckenstedt's test, is instantaneous and gives a very obvious reason for these directions. After performing diagnostic lumbar puncture and finding the pressure of the cerebro-spinal fluid is not unduly high, it is probably advisable to perform a venesection, if the patient has a high blood pressure. It has been argued that venesection is dangerous owing to the risk of reducing the venous blood pressure in the cerebral veins below the intracranial pressure of the cerebro-spinal fluid, but the necessity for venesection can be judged after consideration of the pressure of the cerebro-spinal fluid and also considering the degree of hyperpiesis. I have myself frequently performed venesection and withdrawn 15–20 ounces of blood in cases of apoplexy without any harmful results, although here also there is the same theoretical objection to an immediate reduction of the blood pressure.

There can, at least, be no doubt that it is supremely important to keep the blood pressure as low as possible during convalescence. To guard against the further attacks which are so likely to follow, it is essential to lessen the strain on the vessel wall which is known to be defective. When diphtheria has attacked the heart it is customary to maintain the patient in a rigidly recumbent attitude for some weeks; and I suppose we all keep our cases of thrombophlebitis in bed for six weeks with the limb at rest. I am confident that it is far more important to keep cases of subarachnoid hæmorrhage in bed and rigidly recumbent for at least six weeks, when the rent in the vessel wall should be firmly healed. Purves-Stewart [6] has suggested ligation of the common carotid artery on one side, but many patients would demand some record of success before submitting to a rather drastic operation, and to me personally their attitude seems not unreasonable.

Repair of vessel wall.—Anything which tends to increase the rate of clotting of the blood will tend to limit the hæmorrhage and prevent further leaking. Since local application is impossible the hæmostatics given by intravenous or intramuscular injection may be tried. There is abundant clinical and experimental evidence to show that Hæmoplastin, Coagulen, and Thromboplastin have an immediate and profound effect in increasing the coagulability of the blood, and they should therefore be injected at the earliest possible moment together with some form of calcium.

Pressure of cerebro-spinal fluid.—Indiscriminate and repeated lumbar puncture is not advisable in the earlier stages, since the sudden lowering of the intracranial pressure has resulted in renewed hæmorrhage and death of the patient. Ingvar, quoted by Symonds,[3] has summarised the position as follows:—

> "In subarachnoid hæmorrhage there are two stages to be observed:—First: When the hæmorrhage is actually proceeding the raised intracranial pressure has a protective value as tending to reduce the rate of leakage and so promote coagulation. In this stage, therefore, though it may be necessary to remove a small amount of fluid for diagnosis, therapeutic drainage is contra-indicated—with one very important exception, which is when the rise of intracranial pressure threatens life. In such cases the risk of death by compression outweighs the risk of further hæmorrhage, and lumbar puncture with free drainage may offer the only hope of saving life. In the earliest stages of subarachnoid hæmorrhage therefore, the indications for therapeutic lumbar puncture are the signs of dangerous increase of intracranial pressure especially if these be progressing. In the second stage, when the bleeding has ceased the pains may undoubtedly be relieved by repeated lumbar puncture. The patient should be lying down, a manometer should be used, and the pressure of the cerebro-spinal fluid should not be allowed to fall below 100 mm."

The figures of 100 mm. seems a rather low level for the pressure of the cerebro-spinal fluid and in many cases so big a drop in pressure will not be needed. In this connexion it is interesting to note the type of headache which one can expect to relieve at once by means of lumbar puncture.

The patients usually complain of pain in the occipital region combined with a feeling of intense pressure or numbness. Sometimes they describe the pressure as feeling "like a block of ice" or "being held in a vice," pointing to the occipital region. This headache is not relieved by anything I have tried, excluding morphia, which relieves it for a time. Some time ago I performed four lumbar punctures in five weeks for headaches of this type with instant relief to all. One case was subarachnoid hæmorrhage, one apoplexy, and two were what I believe to be mild cases of encephalitis lethargica, since they occurred along with six or seven others in the course of a small epidemic in which two patients died.

The occipital headache may, of course, be replaced by a temporary headache of a frontal nature, but the knowledge that the lumbar puncture will relieve the occipital headache is often enough to persuade the patient to submit to the lumbar puncture which will also furnish the physician with such valuable information.

Prevention of further attacks.—As there is a great liability to subsequent attacks which are usually brought on by some temporary elevation of the blood pressure, sudden and violent exertion or emotion should be avoided. Constipation with consequent straining is dangerous, as also is repeated bending down. The blood pressure, if raised, must receive very careful attention with prolonged treatment, and it should be observed at least every month for the first year and every two months for the next two years, or oftener if it shows a tendency to rise.

PRESBYACUSIS AND ITS TREATMENT

By MACLEOD YEARSLEY, F.R.C.S. Eng.

THAT the infirmities of age include the affliction of deafness has long been common knowledge. Polixenes, when he, in disguise, chides his son for *failing to consult him in the choice of a wife* ("Winter's Tale"), refers to it in

> Is not your father grown incapable
> Of reasonable affairs? Is he not stupid
> With age and altering rheums? Can he speak? Hear?
> Know man from man?

and other allusions to age deafness abound in literature. But presbyacusis has been too long accepted, unquestioning, as the inevitable concomitant of "the sere, the yellow leaf," and few ageing persons know that the condition can be improved and to a great extent prevented.

Senile deafness, or presbyacusis, appears in two varieties, according to whether the degenerative changes occur in the middle or internal ear. The latter may be distinguished as the true presbyacusis, but I doubt whether the degenerative process in the middle ear is not always present in some degree. The changes in the internal ear have been considered to be due to a degeneration of the cochlear ganglion cells and the hair cells of the organ of Corti, although Mayer held that the cause lay in an "ossification" of the basilar membrane. Pathological investigations, however, are practically non-existent—at least I have met with none, and a confrère to whom I applied has found the literature equally sterile. There is one remarkable and, to my mind significant, case, published by L. Katz (*Arch. f. Ohrenheilk.*, May, 1906), of what that observer considered to be an instance of otosclerosis in a cat. The animal died at the extreme feline age of 23 years, having gradually become deaf during the last years of its life. Katz found rarefying osteitis of the bone surrounding the labyrinth, with partial degeneration and atrophy of the cochlear nerve and organ of Corti. Since the stapes was not ankylosed and the entire annular ligament was intact, otosclerosis is negatived, and the changes were much more probably due to age.

Systematic pathological research into the condition of both middle and internal ears of elderly and aged people is greatly needed. The very nature of the deafness ensures a plentiful supply of the necessary material.

The age at which presbyacusis first shows itself is usually between 55 and 65, but in all probability it commences at about 50, sometimes even earlier. Like all other forms of nerve deafness, it is characterised by a lowering of the upper tone limit of hearing and a shortening of the bone conduction; probably the former precedes the latter. It would appear that, seeing the little use we make of the hearing acuity for very high tones in modern civilisation, it is these extreme upper notes that would be the first to go, and this is borne out by experience. Bezold, in 1894, examined the hearing in 200 ears of patients over 50 years of age. He found that in the decades following that from the 50th to the 60th years there is not only a successive decrease in the number of those with nearly normal hearing, but there is also a successive increase in the degree of deafness. About the same period, Zwaardemaker deduced from his own investigations a *presbyacusis* law, as follows:

(1) The compass of the human hearing contracts half an octave at its upper limit to the period of advanced old age. The average is a major fourth, the maximum being a major fifth.

(2) During advanced age proper, the contraction of the scale increases.

(3) The upper limit is in youth at *e*7, in advanced age at *a*6 (average values). The extreme lower limit for normal hearing in old people is *g*6.

About ten years later Pflimlin examined 140 cases over 60 years of age in the Freiburg ear clinic, and found the most frequent condition in advanced age to be nerve deafness, or an affection of the labyrinth, perception for high tones suffering most, and bone conduction being considerably reduced. He considered that Zwaardemaker's law holds good for 60 years and over, and that a part of the cases of deafness may be regarded as an increase of physiological presbyacusis, whilst a relatively frequent cause of deafness in advanced age is fixation of the stapes. In this latter statement I am of opinion that Pflimlin was confusing true presbyacusis with deafness due to changes in the middle ear, probably of arthritic nature, and due to the effect of toxæmia, most likely of intestinal origin. In a work upon "Otosclerosis" recently published, I have suggested a serial connexion between certain forms of congenital deaf-birth, otosclerosis, certain anomalous cases of insidious chronic deafness occurring in middle age, and true presbyacusis, and if this connexion proves to be a definitely established fact it will open up a new field in the treatment of chronic and progressive forms of deafness. Unfortunately, I repeat, research is wanting in the pathological anatomy of presbyacusis. One thing is, however, very significant—the association between presbyacusis and intestinal toxæmia. My experience of the past 35 years suggests that if people paid more attention to what they ate and drank, and to the necessity of regular evacuations of the bowels (to the number of two a day), they would delay their degenerative processes and preserve their hearing much longer. It is certain that unless old people with early presbyacusis pull themselves up and take more care of their digestive apparatus from the points of view of a more appropriate diet and less consumption of what are called, with doubtful veracity, the "good things of life," their commencing deafness will assuredly go from bad to worse. This s probably why the treatment of presbyacusis is considered as unsatisfactory and its prognosis usually pronounced to be hopeless. Until about seven years ago, my advice to persons suffering from true presbyacusis was directed to certain radical alterations as to mode of life and the avoidance of too much local treatment, and, in a large proportion of cases, the advice proved unpalatable. But an intimate acquaintance with the electrophonoïde method of Zünd-Burguet in the treatment of other forms of deafness led me to try it in presbyacusis. Since then I have used it in 31 cases with success, especially in the earlier stages of the deafness. The accompanying Table affords a brief record of these cases as to sex, age, duration of deafness, and the state of the hearing for the voice, spoken or whispered, before and after treatment, the distance being given in inches. These cases speak for themselves. Tuning-fork tests are not given, because, for practical purposes, improvement in hearing for the voice in conversation and social intercourse is the aim with which these patients sought treatment. Four of them stated that if they could hear the calls at bridge better they would be perfectly satisfied. In one case the improvement caused a domestic upheaval, as the patient began to hear disparaging things said about him by his family at table.

W. = whispered voice. ‡ 15 treatments only.

Nos. 9, 12, and 19, marked with an asterisk, were early cases. Three patients, all men (marked with a dagger), were prematurely aged. Of these, Nos. 10 and 14 died at 52 and 58 respectively from apoplexy. Both were hard livers, hard eaters and drinkers. No. 30 was prematurely aged by hard work. All three had passed many years in the tropics. No. 23 was a careful man, abstemious without bigotry. He retained his improved hearing almost to his death, at 81 years.

The degeneration of the nerve arrangements of the organ of hearing is due largely to the fact that its blood-supply is one of the circulatory back-waters, or "dead-ends," in the body. The cochlear artery is small, and with a lessened force to pump the blood through it the organ it supplies must suffer in nutrition. The effect of the electrophonoïde method on the ear is the ideal means for dealing with such a condition. The massage by sound, which is its essential basis, and which is the normal stimulus for the ear, causes an active hyperæmia throughout the whole organ, resulting in an increased nutrition which greatly improves the cochlear tissues. Even when, after the lapse of some time, the improvement wears off, a further short course of the treatment will restore it. Of course, if the patient can be, at the same time, induced to reconsider his diet and other indulgencies, and keep his bowels in order, the effect is very much better.

THE PAIN OF HERPES ZOSTER TREATED WITH PITUITRIN

By Francis H. Gillett, M.B. Camb.

Dramatic results with the injection of pituitrin for the treatment of herpes zoster have been reported in the American and continental medical press during the last few years, and considering the remarkable relief which sometimes is given to the patient by these injections, it is surprising that the treatment receives so little attention. The report of the following selected cases may help to stimulate further inquiry.

Case 1.—A male aged 40. Came to me on July 19th, 1932, suffering from herpes zoster, the rash covering the two segments below the left nipple. The pain had been present for ten days, and he described it as agonising. Analgesics including morphia had scarcely given him any relief. I gave him 1 c.cm. of pituitrin, and even before the injection was completed he told me that the pain had quite disappeared. A few minutes later he turned very white and had a sudden forceful opening of his bowels. The pain was completely relieved, and 17 hours elapsed before it recommenced and then it became steadily worse. Nineteen hours after the first injection I gave a second 1 c.cm. of pituitrin, and the pain disappeared about one minute later. On July 21st he returned to me with a dull ache present, and a third injection made him quite comfortable for two days. On July 23rd the ache having returned I gave him a further 1 c.cm. of pituitrin. This was followed by the most acute pain, which lasted for about five minutes, and then ceased as abruptly as it had commenced. I saw him again on July 28th, and except for the irritation of the drying scabs he was absolutely comfortable.

Case 2.—A woman aged 61. Pain in the right flank had commenced on Sept. 6th, 1932, and had gradually become worse. I saw her for the first time on the 11th, when the spots had just appeared extending in a band 1½ inches deep, from the spine to the pubes. The pain she described as excruciating, and she had been taking two aspirin tablets every two hours without relief. I gave her 10 units of pituitrin at 10.15 A.M. on Sept. 11th into her deltoid and about one minute later she was freed from all pain in a most dramatic fashion. After a few minutes the bowels were opened, and then the patient went to sleep "for the first time for three days." Seventeen hours after this injection the pain returned, gradually becoming worse, and 4½ hours later I gave her a second injection, which relieved the pain even before the needle was withdrawn. During the next few days she felt what she described as "numbed pain"; she suffered from flatulence and difficulty in opening her bowels. Further injections were given on Sept. 15th and 16th in order to relieve this discomfort, but only a transient relief for a few hours was obtained, and aspirin was found to be sufficient.

Case 3.—A man, aged 63, received complete relief from the pain associated with herpes zoster after I gave him 1 c.cm. pituitrin on July 26th, 1932. The injection made him feel queer and faint. The pain came on again very severely 10 days later but was relieved promptly by

0·5 c.cm. pituitrin without any ill effects. Six weeks later he reported that he had had no return of the pain.

Sidlick[1] in 1930 described 4 cases from a series of 54 patients suffering from herpes zoster treated with pituitrin. These four suffered agonising pain and the treatment was most efficient. Niles[2] in 1932 also described a series of 16 cases treated with pituitrin, and considers that the most brilliant results were obtained in the very early cases and that the course of the disease was shortened by about 2½ days. He found that the severe pain was usually rapidly relieved.

I have found that the injection of pituitrin is an uncertain and by no means an infallible treatment. It appears to act most dramatically when the pain is most intense. I can at present offer no explanation of why this should be so, but the treatment is a valuable asset to the practitioner in his attempt to relieve a patient from the pain accompanying herpes zoster.

Eastbourne.

EVIPAN SODIUM AS AN ANÆSTHETIC IN PULMONARY TUBERCULOSIS

By M. Lask, M.B. Leeds
MEDICAL OFFICER, PRESTON HALL SANATORIUM, AYLESFORD, KENT ; AND

J. H. Crawford, M.B. Leeds
ASSISTANT MEDICAL OFFICER AT THE SANATORIUM

In view of the considerable interest which has been aroused in the use of evipan sodium as a general anæsthetic, it may be of some interest to record our experience in the use of this anæsthetic in pulmonary tuberculosis. During the past four months we have administered evipan sodium in 85 cases of pulmonary tuberculosis, all of whom had open lesions and were drawn from all three classes of Group B (London County Council classification). The cases can be grouped as follows :—

(1) Dental extractions	35 cases
(2) Minor operations	20 cases
(3) Operations involving direct surgical treatment of pulmonary tuberculosis—*viz.*, apicolysis, partial thoracoplasty, section of pleural adhesions, and bronchoscopy for drainage of cavities (8 cases)	30 cases

Of these, 25 cases in Groups 1 and 2, representing 29 *per cent. of the total series (or 45 per cent.* of the two groups alone) were undergoing artificial pneumothorax treatment and had already attained satisfactory collapses, while the remainder in these two groups were ambulant, non-febrile cases. In Group 3, 11 cases, representing 13 per cent. of the total series (or 37 per cent. of this group alone) had more than three lobes affected with cavitation at one or both apices.

No premedication was given for the patients in Groups 1 and 2, but those in Group 3 were all given the Hoffmann-La Roche preparation containing omnopon gr. ⅔ and scopolamine gr. 1/150, one hour before operation. In this group the full dose of evipan sodium (1 g. dissolved in 10·5 c.cm. sterile water) was injected, but for Groups 1 and 2—i.e., for dental extractions and minor operations—quantities varying from 4·5 to 10 c.cm. were injected.

As cases of pulmonary tuberculosis in any stage are notoriously bad risks from the point of view of inhalation anæsthesia, a safe and satisfactory alternative is desirable. As a result of these observations, our conclusion is that evipan sodium is the anæsthetic of choice for all minor surgical conditions in pulmonary tuberculosis whenever local anæsthetisation is impracticable. In our series there was only one case which occasioned any anxiety, that of a man aged 55, who stopped breathing for four minutes in the course of a dental extraction. Artificial respiration, the injection of coramine, and the application of hot fomentations to the back of the neck were entirely successful in restoring function. This conclusion is maintained despite the fact that there was always a fall of some 20 per cent. in the blood pressure and that evipan is a respiratory depressant,[1] two factors that would seem to mitigate against its use in pulmonary tuberculosis.

Our observations on the cases comprising Group 3 of this series point to the fact that evipan sodium has a wide field of usefulness in thoracic surgery. It can be used alone where excessive nervousness on the part of the patient precludes the use of a local anæsthetic, or in combination with local anæsthesia for operations such as rib resection, cauterisation of pleural adhesions, and partial or localised thoracoplasty. No ill-effects were observed after the use of evipan sodium ; in fact, there was a remarkable unanimity of opinion among the patients operated upon as to the well-marked feeling of freshness experienced on coming round from the anæsthetic. For the larger operations of apicolysis and thoracoplasty we have, at Preston Hall, been using a combination of regional anæsthesia combined with very mild general narcosis with the Tiegal-Henle positive pressure ether apparatus, and it would seem that this is the most satisfactory form of anæsthesia whenever a thoracoplasty is to be performed in one or two stages, as by this method the dangers and post-*operative risks peculiar to thoracoplasty* are to a large extent obviated.

It may be noted that eight cases of bronchoscopy are included under Group 3. Although anæsthesia was quite satisfactory in each of these cases, we cannot advise the routine use of evipan for this operation, as we consider that in the hands of properly trained operators, bronchoscopy is a safe procedure and should not require general anæsthesia.

Many workers[2] with evipan anæsthesia have stated that for minor surgical operations such as dental extractions, a small dose of evipan (2·5—5 c.cm.) is sufficient. *This is not in accordance with our experi*ence ; we find that out of a total of 55 minor operations (dental extractions, removal of ingrowing toe-nails, opening of whitlows, abscesses, &c.) in phthisical patients, 51, representing 93 of the total, required a minimum of 4·5 c.cm. for satisfactory anæsthesia. We do not wish to commit ourselves to an explanation of this phenomenon and suggest that further work is necessary to elucidate this matter. It is possible that the explanation lies in the fact that these patients have been subjected to toxic influences over such long periods of time, that they may have acquired a certain degree of tolerance to any respiratory depressant. We should like to hear the views of other workers on this point.

The technique of injection used was that advocated by Bayer Products Ltd., but after experimenting with different rates of injection we have come to the conclusion that this is not a point of paramount importance.

[2] Niles, H. D. : New York State Jour. Med., 1932, xxxii., 773.

SUMMARY

(1) An analysis of 85 cases of pulmonary tuberculosis in which evipan sodium was used as an intravenous anæsthetic is presented. (2) The use of evipan anæsthesia in pulmonary tuberculosis has proved to be entirely safe. (3) It does not, however, effectively take the place of mild inhalation anæsthesia for major thoracic operations. (4) Generally speaking, though not always, the dosage of evipan required for minor operations in phthisical patients seems to be higher than that required to produce an equivalent degree of anæsthesia in non-phthisical subjects.

We are indebted to Dr. J. B. McDougall, the medical director, for his kind permission to carry out this investigation.

REVIEWS AND NOTICES OF BOOKS

Swimming Bath Water Purification

Second edition. By F. WILKINSON, M.Inst.C.E., M.I.Mech.E., and F. J. FORTY, B.Sc., A.M.Inst.C.E. London: The Contractors' Record Ltd. 1934. Pp. 262. 12*s*. 6*d*.

THE authors of this timely book are respectively borough engineer of Willesden and deputy borough engineer of Ealing. Swimming has for some years been an increasingly popular exercise, and if a succession of hot summers may be expected the demands for good baths will still increase. The best design and arrangement of a swimming bath has, in the past, hardly been part of the normal stock of knowledge of either borough engineers or medical officers, and many good baths would have been better had such a book as this been available. As Prof. H. R. Kenwood remarks in his foreword, the public health side of the subject is given in this book the prominent place which its importance warrants.

Reference is made to the pioneer work of Dr. F. W. Alexander who chlorinated the water of the swimming baths in the borough of Poplar 25 years ago, and to the early investigation of the bacterial flora of a small swimming bath by Dr. J. Graham Forbes, who found among 4000 organisms per c.cm. of the bath water *Staph. pyog. albus*, *S. epiderm. albus*, and members of the proteus group (from skin contamination), *Strept. salivar.* and others (from saliva), and *B. coli*, *B. pyocyan.*, *Strept. fæcal.*, and proteus (from fæcal contamination)—a formidable but easily explained group of organisms, highly suggestive of the occasional presence of others still less desirable. The authors cite this and other evidence which makes it "abundantly clear that swimming bath water which has been subjected to use by many bathers, without any attempt to ameliorate its condition is objectionable not only from the most obvious—namely, the æsthetic standpoint—but also from the points of view of sheer danger to life through risk of drowning (opacity of the water) and the risk of transmission of diseases, mild, serious, or fatal."

Can these grave risks be avoided in a simple, safe, and economical manner? The authors' reply is "Definitely yes," and they go on to describe the processes of incomplete purification as used by Alexander at Poplar and the later processes of continuous purification—straining, aeration, coagulation, filtration, and chlorination—giving sufficient detail to make the book useful to bath superintendents. Processes of sterilisation other than chlorination—ultraviolet rays, catadyn silver, ozone—are lightly touched on. They have not received the full trial which chlorination has and may be considered as in the experimental stage, although worthy of consideration by those who are starting new baths, and who are willing to give more skilled attention to the sterilisation of the water than is required by a chlorination plant. These agents have the advantage of not leaving an irritant substance in the water.

The arrangement of the bath and the control of bathers are dealt with in a way which shows that the authors have practical knowledge of their subject. The book can be recommended without hesitation to all those who may have to give advice to public bodies or private owners on the management of swimming baths, as well as to those who have to inspect such baths and report on the suitability of lay-out and the efficiency of working.

The Ancestry of the Long-Lived

By RAYMOND PEARL and RUTH DEWITT PEARL. Baltimore: Johns Hopkins Press; London: Humphrey Milford. Oxford University Press. 1934. Pp. 168. 13*s*. 6*d*.

THIS publication sets out in book form an interesting study of the inheritance factor in duration of life, an account of which was originally issued by Prof. Pearl and his daughter in *Human Biology* (February, 1934), and was discussed in a leading article in our own columns (1934, i., 745). One or two sections have now been expanded, more especially those dealing with the group of persons who were chosen to serve as the standard of comparison with the longeval. The rules of selection that governed the composition of this group certainly need very careful consideration, for it is upon the adequacy of this standard that depends the validity of the evidence favouring the extra longevity experienced by the ancestry of the long-lived group. The development of their case for inheritance does not, as the authors admit, make easy reading, but it is presented in as clear and interesting fashion as possible.

The Doctor and His Patients

By ALBERT KRECKE. London: Kegan Paul, Trench, Trübner and Co. 1934. Pp. 301. 10*s*. 6*d*.

THIS book is a series of essays by the late Dr. Albert Krecke, which in the original German ran through several editions. The subjects are well chosen for the purpose of bringing before the practitioner the pros and cons of many fundamental questions which must arise in the course of his professional life. The real value of plain speaking to certain patients, and the practical necessity of deciding what the patient and the patient's relations should be told, are discussed, and wise advice is given on how to deal with the fear of cancer among the public. Other chapters touch on the conduct of practice, giving counsel as to the proper attitude of the doctor towards his colleagues, and towards patients, while the way to maintain just relations between the consultant and the family doctor, and the principles involved in the payment of doctor by doctor are set out. In another chapter warning is given as to the responsibilities which the young doctor has to undertake, and in yet another we have suggestive reflections upon the situations which follow unsuccessful operations. Albert Krecke conducted an excellent private clinic for nearly 20 years in Munich; his annual reports were read by the majority of German surgeons, and he was a prominent contributor for a long period to the *Münchener medizinische Wochenschrift.* His obiter dicta were very sagacious, and here many of them will be found.

Injection Treatment in General Practice

By M. L. GUJRAL, M.B. Punjab, M.R.C.P. Lond. Publishers: Practical Medicine, Nai Sarak, Delhi, India. 1934. Pp. 209. Rupees 6.

THIS book attempts within a very small space to cover the technique of all branches of injection treatment. It ranges from the application of the method to surgical conditions such as hernia, hæmorrhoids, and varicose veins on the one hand, to vaccine and non-specific protein therapy on the other. To achieve such an object in so slender a volume would require, in addition to knowledge of the facts, a measure of considered judgment in interpreting and assessing them. The author has not shown evidence of such critical judgment. The book, apart from being sketchy, contains much information which is not accurate, much advice that could not safely be followed, and what must be almost a record number of typographical errors for a twentieth century medical work. It cannot in any sense be regarded as a trustworthy or sure guide for the practitioner.

British Journal of Surgery

THE July issue (vol. xxii., No. 85) contains the following papers: The Examination of Fresh Tissues by the Wet-film Method, by Leonard S. Dudgeon and N. R. Barrett (London). Through experience gained in examining 1000 cases a high degree of accuracy in diagnosis has been attained. As the process takes a few minutes only its value in operating-room technique is obvious.—Reconstruction of the Forearm after Loss of the Radius, by R. Watson Jones (Liverpool). Following a previous diaphysectomy involving almost the whole length of the radius, the distal end of the ulna was implanted into the small distal fragment of radius, thus constructing a single forearm bone. The function and cosmetic result are excellent.—Localised Hypertrophic Enteritis as a Cause of Intestinal Obstruction, by W. A. Jackman (Bristol). Two cases are described. The onset in each instance was sudden, and produced an "acute abdomen." Recovery followed resection and ileo-cæcostomy.—Gastro-jejunal Ulceration, by A. James Walton (London). Based on 79 cases operated on by the author. The conclusions are that gastro-jejunal ulceration is almost always a sequel of gastro-enterostomy performed for duodenal or pyloric ulceration, and should be treated by partial gastrectomy. Its incidence is not high enough to preclude the use of gastro-enterostomy as the operation of choice for duodenal ulceration.—Protrusio Acetabuli (Central Luxation), by F. Campbell Golding (London). The condition is defined as a "disease process and not an entity." Ten cases are described. In the ætiology disturbance of growth of the Y-shaped cartilage and rheumatic processes are considered of most importance.—Bone-Graft for Non-union of the Carpal Scaphoid, by Gordon Murray (Toronto). The method is used for old fractures showing no evidence of union, and has given good results with complete restoration of function.—X Ray Investigation of the Upper Right Quadrant, by the late W. H. Dickson (Toronto). A comprehensive account of the investigation of gall-bladder disease and of its differential diagnosis by the use of dyes and of opaque meal and enema.—Changes in the Blood-Sugar Level associated with Surgical Operations, by A. G. Weddell and H. E. D. Gale (London). Pre-operative anxiety did not seem to be a factor in raising the blood-sugar level, nor did the length of the anæsthesia. The nature of the operation did influence it. Post-operative glucose salines had no specific effect; the glucose was absorbed and was probably useful as a food.—Diverticula of the Vermiform Appendix, by Harold C. Edwards (London). Ten cases are described, seven of which had been associated with symptoms of appendicitis. The literature is reviewed.—Acute Enteric Intussusception in an Adult, caused by a Lipoma, by R. I. Poston (Oldham). Excision of a gangrenous part of small intestine was successfully performed. The mechanics of intussusception are discussed.—Cysts of the External Cartilage of the Knee with Erosion of the Head of the Tibia, by H. A. T. Fairbank and Eric I. Lloyd (London). Both cases followed injury, and were cured by excision of the cartilage with i[illegible] Kyphosis, by J. M. Edelstein [illegible] cases are reported of a progressive type of deformity resulting from disturbances of normal vertebral ossification.—Enterogenous Cysts, by W. E. A. Hughes-Jones (Melbourne). Ætiology, site and structure, and various forms of treatment are discussed.—The Origin and Evolution of Colostomy, by Tilson Dinnick (London). A historical survey.—The Relation of the Extrinsic Nerves to the Functional Activity of the Œsophagus, by G. C. Knight (Buckston Browne Surgical Research Farm). Observations on the vagal and sympathetic nerve supplies to the œsophagus of the cat.—The Growth of Periosteum in Long Bones, by W. Turner Warwick and Philip Wiles (London). A record of experiments carried out on rabbits at the Courtauld Institute of Biochemistry. The *interstitial* growth of periosteum was proved, and the relation of this particular type of growth to the limiting and modelling of bone is suggested.—Shorter notes on cases are also included.

REPORTS AND ANALYSES

NORWEGIAN CHEESE

NORWEGIAN DAIRIES EXPORT CORPORATION, OSLO, NORWAY.
SOLE AGENTS: MESSRS. W. C. LAMING AND CO., LTD.,
29, TOOLEY STREET, LONDON BRIDGE, S.E.1

THIS cheese is stated to be made from goat and cow's milk; it is described on the package itself as a whey cheese made in Norway. The makers claim that all indigestible milk solids are extracted from the cheese in process of manufacture; it should therefore follow, they state, that "the tissue-building material is available without the indigestible casein content, and that it should be of considerable benefit to most invalids." The Norwegian Official Research Bureau for Dairy Products furnish the following analysis:—

Water	13·41%
Dry matter	86·59%
Containing—	
Ash	4·75%
Fat	29·61%
Protein (mainly milk albumin) ..	10·30%
Sugar (milk sugar)	41·85%

Our analysis of the cheese agrees closely with that given by the Research Bureau, the figures found being the following:—

Water	12·94%
Dry matter	87·06%
Containing—	
Ash	4·33%
Fat	32·00%
Protein	9·00%
Sugar (lactose hydrate)	41·10%

The cheese is of the soft, crustless variety, and of a somewhat dark yellow colour. The percentage of water is unusually low, and the product should thus prove economical in use as well as nutritious. The high content of milk sugar—an unusual ingredient in cheese—will be noted.

THE LANCET

LONDON: SATURDAY, AUGUST 11, 1934

A QUESTION OF NEEDS

THE object of unemployment insurance is to tide people over short periods when work is unobtainable or unobtained. Substantial contributions are made by the worker himself (as well as by the employer and the State) and having paid his share of the premiums he is legally entitled to definite benefits, for himself and his dependants, over a definite number of months. These benefits are not assessed according to his needs; they vary according to the funds available for division. In its new Unemployment Act the Government has put these funds on a self-contained or business basis: hence, if unemployment decreases the benefits should soon become more generous; if, on the other hand, the situation gets worse they will be reduced. The present rates of benefit, which include 2*s.* a week for a child, are not defended as adequate for long periods when there are no other resources; they are meant to prevent temporary destitution till other work is found by the breadwinner. The larger problem of unemployment concerns those who have exhausted their right to insurance benefit and those who have never been covered by any contributory scheme. Under part II. of the Act workers who have fallen out of insurance, and those (e.g., the lower-paid black-coated and the agricultural) who are outside insurance altogether, will come under the care of a new body, the Unemployment Assistance Board. The chairman of this Board is Sir HENRY BETTERTON, under whose able guidance, as Minister of Labour, the Bill went through the House of Commons, and its task is to provide for the vast body of unemployed *according to their needs.* It will be seen at once that the distinction between the two parts of the Act is fundamental. Part I. governs the distribution to insured workers of the benefits to which they are statutorily entitled. Part II. established a new body, now under Sir HENRY's control, which must see that no one, because of unemployment, lacks the necessities of life. The scale of the Board's relief need bear no relation to the scale of ordinary unemployment insurance as we have known it; it is to be dictated solely by what is necessary to "promote the welfare" of the unemployed.

In our correspondence columns last week a distinguished group of physiologists and physicians [1]—whose authority has since been enhanced by the adherence of Dr. A. K. CHALMERS, Prof. J. J. R. MACLEOD, F.R.S., and Prof. LEONARD PARSONS—urged that the Board should now proceed to lay down a scale of needs in accordance with physiological and other requirements. Their experience, they said, leads them to believe that there will be "grave danger of widespread physical deterioration, especially among the growing generation, if a considerable section of the population, obliged for reasons beyond its control to depend for maintenance on public funds, is unable to purchase sufficient food and other necessaries for healthy existence." "We suggest," they added, "that a standard of needs which will fulfil the intention of the Act can only properly be arrived at in consultation with medical and other expert opinion qualified to estimate the minimum requirements of healthy living and the cost of satisfying them for families of various sizes." A similar suggestion is made in more detail in a memorandum submitted to the Board by Miss ELEANOR RATHBONE on behalf of the Children's Minimum Campaign Committee.[2] By Ministerial statements the Board is committed to adopt scales which provide for healthy subsistence, and the Committee points out that the basis of these scales "should be publicly known and capable of being publicly defended by reference to scientific data established in conference with experts." So far as food is concerned it proposes that the Board should use the statement of basic requirements [3] finally agreed upon last spring by representatives of the Ministry of Health and British Medical Association committees on nutrition—translated into terms of cost according to the calculations in the B.M.A. report. The standardisation of needs other than food must rest rather on practical experience than on scientific theory, but the estimates used in the Social Survey of Merseyside (reviewed in our columns last week) and of London would serve as a starting point. For rent the best rule, it is thought, would be to allow for the rent actually paid, unless this was evidently extravagant and cheaper accommodation was available elsewhere in the neighbourhood.

According to none of the current estimates can the needs of large families be met out of ordinary insurance benefit, and when the Unemployment Bill was debated in the House of Commons many members of all parties supported an amendment which would have bound the Unemployment Assistance Board to pay at least 3*s.* for every child. This and other amendments were opposed by the Ministry on the ground that the Board was already under contract to meet all the needs (other than medical) of the unemployed, and that this contract implied something more than merely providing for their physical requirements. Such an obligation, interpreted according to the B.M.A. report, would mean a big advance on the standards hitherto adopted by insurance or poor-law authorities, and the question is whether the Board will really be prepared to go so far. It will be tempted in the first place to accept the argument that scales constructed by sociologists and physiologists are negligible because in fact large numbers of people manage to exist on less. But as the Committee says, "if the Board's scale is not to be based on any scientifically worked out standard of needs, what will it be based on? It will in any case be challenged by reference to such a standard." Again, it may be felt that the Board's rates of relief must not exceed the ordinary unemployment insurance benefit; but this thesis can scarcely be upheld, since the Board is primarily concerned with the victims of prolonged unemployment; moreover, it is specifically empowered to supplement benefit paid under part I. of the Act in cases where this is insufficient even for brief periods out of work. The real difficulty facing the Board is that the sum required to meet the needs, as nowadays understood, of a family of human beings will sometimes be greater than the earnings of the head of the household when employed. It is a cardinal principle that relief must never equal (let alone exceed) wages; on the other hand, it is obvious that relief should vary with the size of the family, whereas wages do not. In these circumstances it is suggested that school meals or milk or other assistance in kind provided for the children by public assistance or charity should not be reckoned in the family resources.

M'Gonigle, Prof. Charles McNeil, Prof. V. H. Mottram, Dr. J. Boyd Orr, F.R.S., Dr. Charles Porter, and Sir Humphry Rolleston.

[2] Memorandum on the Scale of Needs. Submitted on behalf of the Committee by Miss Eleanor Rathbone, M.P. July, 1934. Obtainable from the Committee, Room 116, Thames House, Millbank, London, S.W.1. Pp. 16. 4*d.*

[3] THE LANCET, 1934, i., 1098.

On the general question whether the nation can afford more adequate methods of relief there will no doubt be more than one opinion. Plain assurances, however, have been given about the scope of the Bill which has now become law, and Miss **Rathbone** and her colleagues are right in saying that these assurances, if implemented, "foreshadow a bold, far-sighted and generous policy, which will revolutionise the standard of assistance to the unemployed in this country."

THE SEX HORMONES

Prof. **Butenandt**, who has played a distinguished part in advancing chemical knowledge of the sex hormones, reviews the present position in a lecture lately given in Vienna.[1] In the course of it he expresses his own point of view very clearly and definitely in the following terms:—

> "The chemical investigation of hormones begins with attempts to prepare the hormone under investigation in the form of a chemically pure, simple substance. The solution of this problem is bound up with the existence of a suitable starting material and of a quantitative test for the hormone. and its goal is reached when the hormone is obtained in well-formed crystals the simple nature of which can be settled beyond doubt with the help of modern physical and chemical methods. When the preparation of a pure hormone is accomplished, then the necessary preliminary conditions are satisfied for determining by a thorough physiological and pharmacological analysis of a simple substance its function in the organism. The problem of the number of hormones taking part in the course of a physiological process can only be solved in this way. From these investigations are then obtained the exact indications for the therapeutic application of the hormone on the basis of an exact measured dosage."

From physiological investigations it has been established that sexual processes are primarily controlled by the hormones of the anterior hypophysis, which is in the position of governor, and by the gonadal hormones, elaborated by the testis and ovary. The hormonal nature of the control by the anterior hypophysis is established, but we are still in the stage of dealing with "factors" characterised by their physiological action and far from the ideal of "well-formed crystals." **Bernhard Zondek** has postulated the existence of two such gonadotropic factors, prolan A and prolan B, promoting, respectively, ripening of ovarian follicles and their luteinisation, but the existence of two separate substances is not yet settled beyond doubt. A third "accessory" or "synergic" factor has also been postulated, which activates the other two, and the disappearance of which entails the decay of sexual function associated with senility. The relation of the physiologically active materials excreted in urine of pregnancy to the materials extracted directly from the anterior hypophysis is still a matter of some discussion, but the evidence is, on the whole, in favour of the urinary factors being different and derived from the placenta during pregnancy. The chemistry of these substances, allied as they are to the proteins, is extremely difficult, and it may be long before the criteria suggested by **Butenandt** can be approached. It is at least necessary to proceed with caution and a due realisation of our ignorance in using these materials in physiological experiments. In the past not a few physiological investigations have been made with materials which were later recognised to be mixtures in varying proportions of substances with different characteristic properties.

It is clear, however, that the function of the hormones of the anterior hypophysis, whatever their number, is that of stimulating the gonads to activity and excretion of their specific hormones. In the case of these latter hormones the position is more satisfactory. The isolation of œstrin (œstrone) and of the testicular hormone, now named androsterone, will be familiar. Chemical investigation has shown that there is a family of natural products containing the *cyclo*penteno-phenanthrene ring-system. As Prof. **Dodds** lucidly explained in his Goulstonian lectures[2] a few months ago, the sterols, the bile-acids, pregnandiol, androsterone, dehydroandrosterone, œstrone, and equilenin form a series in which one member may, on paper, be converted into the next by processes of successively shortening the sterol side-chain, replacing it by a ketonic group, and dehydrogenating; and the suggestion is obvious that such a metabolic chain exists in the body itself. Of equal interest from the chemotherapeutic point of view are the modifications which have been produced in the laboratory. It is possible to prepare from œstrone by vigorous hydrogenation substance with male hormone activity: on the other hand, reduction of the ketonic group of both œstrone and androsterone yields substances in which the original sexually specific activity is greatly enhanced. To the œstrone group may now be added the corpus luteum hormone, responsible for the progestational secretory phase of the uterus; for Prof. BUTENANDT announces that, in collaboration with Prof. W. SCHOELLER and others, he has achieved the isolation of a crystalline active substance of the formula $C_{21}H_{30}O_2$ or $C_{20}H_{28}O_2$, which is a diketone evidently belonging to the same chemical series. Almost simultaneously two other groups of workers[3] have announced the isolation of active substances. There is some inconsistency in these reports, but it cannot be long before another sexual hormone of definite properties is available in a state of purity.

[1] Butenandt, A.: Wien. Klin. Woch., July 20th and 27th, 1934, pp. 897 and 901; cf. Forschungen u. Fortschritte, 1934, x., 266, 276.

[2] Dodds, E. C.: THE LANCET, 1934, i., 931, 987, 1048.

Concurrently with these chemical advances, the physiological-chemical picture of the female sexual cycle is becoming clearer. It is now possible to visualise a mechanism in which the anterior hypophysis stimulates the ovary, which in turn stimulates mamma, vagina, and uterus, whilst, probably by a nervous path involving a sexual centre in the mid-brain, the gonads react on the hypophysis and inhibit its activity in the final phase of the cycle.

ON DEBT COLLECTING

ONE of the points in favour of contract practice is that there are no book debts, no accounts to send out, and little variability in income. Yet most insurance practitioners are also engaged in private practice; although they do exist, there are few doctors who refuse to see a patient because he is not an insured person. The question of sending out accounts and the getting in of book debts does therefore come into the purview of most practitioners whether they are on the panel or not. Judging from the number of circulars they receive from debt-collecting agencies this appears to be the time when they should be getting busy about it. One circular is headed "without offence"; there seems to be some idea that a patient who owes a doctor for attendance is offended if he is asked to pay up. This may be so in a few cases, but experience shows that even when debtors have been put through the county court they are apt to come back to the same doctor. This question of offence is much overdone. In earlier times practitioners sent their accounts out once a year: the patient might then have forgotten he had ever been attended or have moved elsewhere, and book debts were heavy. Some practitioners now send out accounts half-yearly, most of them quarterly; others do so as soon as the attendance is finished or at the end of the month. Whilst it is definitely bad for any practice to have the doctor in charge of it always worrying about his bills and talking to his patients about them, yet on the other hand he will find his unremunerative work increase rapidly if he never, through fear of giving offence, puts any pressure upon a patient to pay up who can afford to do so. This will have its effect, too, on the selling value of the practice which is based upon gross receipts. If a practice is being sold, for example, at one and a half years' purchase the collection of £10 in book debts will make £15 difference to its value in that year.

It is a good plan to send out accounts at regular intervals even to substantial patients, for they then know the amount of their indebtedness; less substantial patients will often pay at once a relatively small bill of £3 or £4, whilst they will feel £7 or £8 more than they can manage—and this type of person does not like to pay in instalments. If an account is not paid when sent out once it should be sent in again as an account rendered at the next regular interval. If it still remains unpaid the question arises what next to do. It may, of course, be sent in again, perhaps with some friendly remark added to the billhead or even underlined in red ink; but if it then still remains unpaid in a busy practice further help in its collection will probably be needed. Investigation may prove that the address is wrong, that the patient has moved away and letters have not been forwarded, that financial loss has occurred making payment impossible. Before instructing a collector some practitioners send out another form, in which it is stated that the account is considerably overdue and asking the patient to suggest terms for settlement in the course of a few days, failing which it will reluctantly be placed in the hands of X.Y.Z. for collection. X.Y.Z. may be one of the usual debt-collecting agencies or a private individual who takes a commission on the amount he collects. Such collectors visit the houses and trace removals; they arrange for payments on account and, if necessary, deal with county court cases if there is no dispute as to charges. But the results of their efforts are rarely good. They are apt to blame the doctors for not handing them their accounts sooner, and it has been suggested that the practitioner should supply the collecting bureau with a duplicate copy of his day-book from which to send timely reminder. If this bureau charges 5 per cent. on all the money collected, instead of the usual 15 per cent. on those ageing debts which are placed in its hands, the scheme is not likely to be adopted in a practice where there is any secretarial efficiency, although it would save the doctor who worries about his accounts. All he would have to do would be to send off one day-book when the other comes back, informing the bureau of the receipts he had taken in the period.

A woman was once heard to boast in a chemist's shop that she had consulted eight doctors in one small town and had not paid one of them. She would deserve all she got from the firm handling of a competent collector. But just as it is unfair to A, who does his best to pay up, to let B, who does not try to pay, go scot-free, so it is bad policy to put pressure on C, who has had a long spell of illness or has suffered some unforeseen misfortune. Such persons should be transferred to the local public medical service whose rates they can afford to pay.

ANNOTATIONS

REMOTE CONSEQUENCES OF GASTRO-INTESTINAL DEFECTS

THE causal relationship between abnormality of the gastric secretion and pernicious anæmia, foreseen by Samuel Fenwick, Faber, Hurst, and many others, is now firmly established by the work of W. B. Castle and his American collaborators. Tropical sprue, which is certainly a primary disease of the gastro-intestinal tract, often leads to the appearance of severe macrocytic anæmia or of tetany, whilst cœliac disease has been shown by Bennett, Hunter, and Vaughan to lead at times to several varieties of severe anæmia, to tetany, and to considerable bony softening. These examples illustrate the serious remote effects of certain gastro-intestinal disorders; consequences which may with complete accuracy be classed as deficiency diseases although they are occasioned not by defective diet but by obscure lesions of the alimentary canal, preventing the proper digestion or absorption of certain essential constituents of the normal diet. The manner in which the deranged alimentary canal can in this way create deficiency diseases is discussed in a recent article by Maurice B. Strauss.[1] After reviewing the various experiments responsible for the modern theory of the causation of pernicious anæmia, Strauss quotes the classical case of macrocytic anæmia described by Addison in a patient with ulcerative colitis, and similar cases associated with prolonged diarrhœa and chronic bacillary dysentery. Macrocytic anæmia which has been described in connexion with chronic gastric fistulæ is strictly comparable to the series which accompany strictures of the small intestine, colon, or cæcum. In his own experience he has seen such a condition arise in a child eight years of age in whom various short circuits between loops of small intestine had occurred following intestinal obstruction of inflammatory origin.

Pellagra when it occurred in endemicform is probably due to lack of vitamin B_2 (G), but cases have occurred in which all the manifestations of this disease appeared, with normal dietary, in patients with severe alcoholic gastro-enteritis. Pellagra has been reported in 15 cases of cancer of the stomach, usually associated with pyloric obstruction; it has also been encountered in cancer of the ileum and even in association with strictures of the rectum. Skin lesions identical with those of pellagra have been reported with diarrhœal diseases such as ulcerative colitis, dysentery, and various forms of rectal disease, and also in certain diseases of the small intestine and even of the œsophagus. Another effect of deficiency occasioned by gastro-intestinal disease is to be found in peripheral polyneuritis. Chronic alcoholism as a cause of neuritis has been known for upwards of 150 years, but it is only recently that Shattuck has formulated the theory that "alcoholic" neuritis is in reality a deficiency disease similar to the neuritis seen in beri-beri. This opinion is confirmed by the work of Minot, Cobb, and Strauss, who have relieved alcoholic neuritis by the oral and hypodermic administration of vitamin B whilst permitting the administration of alcohol to continue. Polyneuritis has been reported fairly frequently in cases of pyloric stenosis secondary to peptic ulcer, and it has also been seen in association with dysentery and ulcerative colitis. In fact a mass of evidence accumulates to show that a deficiency caused by defects of the alimentary canal may be responsible for this neurological picture quite frequently.

BRONCHOSPIROMETRY

REFERENCE has been already made in these columns[1] to a method by which the function of the two lungs may be studied separately. One of the authors of the original paper, Dr. S. Björkman, has now produced a small monograph on the subject.[2] The procedure is to pass a "double bronchoscope," consisting of two tubes one inside the other. The inner tube communicates with one main bronchus, where an air-tight junction is maintained by the inflation of a rubber armlet, and the outer communicates with the lumen of the trachea (and thus with the other main bronchus), a second rubber armlet being inflated just below the lower end of the larynx so as to prevent air passing in any way except through the bronchoscope. By means of recording spirometers connected with the two tubes, accurate measurements of the functional activity of each lung can be obtained. A certain number of normal people have been examined and supply readings which serve as a background for the results in nearly 60 patients suffering from pulmonary disease. Björkman says that, normally, the left lung accounts for 40 to 50 per cent. and the right lung 60 to 50 per cent. of the total ventilation, but this relationship is of course much altered, where there is disease of one lung. What is surprising is to learn that often the alteration from normal as regards the distribution of total oxygen intake and total carbon dioxide output on the two sides is not uniform; so that while the respiratory quotient for the two lungs together is normal, a different quotient was obtained for each lung separately. The suggestion is made that possibly carbon-dioxide is actively excreted by the mucous membrane of the bronchi and that this process is sometimes impaired by disease. The functional activity of the lungs in different postures has been studied, and also the effects of coughing, confirmation being obtained for the view that sputum from a diseased lung may enter a sound lung during this complicated act. Björkman admits that his method is applicable only to a small group of subjects, but his observations provide the clinical physiologist with fresh objectives.

A GALLERY OF "TROPICAL DOCTORS"

Dr. Gottlieb Olpp, who directs the Institute of Medical Missions at Tübingen and holds a chair in the University, has brought out a remarkable directory[3] of doctors, living and dead, whose names are associated with service in the tropics. He has spread his net very wide—to include Hippocrates, Imhotep, and Berkefeld, inventor of the filter—and has included some 300 biographies of which only quite a modest proportion, not more than one-third, are of German origin; and the collection is made more remarkable by the fact that he has collected a gallery of excellent portraits with only a few relatively unimportant omissions. Dr. Olpp went out to China as a medical missionary and began at once to collect material to perpetuate the memory of men for whom he conceived a profound admiration. For 20 years past he has gone on collecting with the help of correspondents in many countries—he acknowledges the help of Nuttall in Cambridge, Andrew Balfour and Manson-Bahr in London, Stephens in Liverpool—and accepting living experts at their own valuation although impeded by their inherent modesty. The several biographies are interesting in themselves; they have been put together with skill and there is considerable charm in the author's extreme simplicity of style. To the inexpert, approaching the history of tropical medicine for the first time, he recommends the reading of biographies in the following order—viz., Leeuwenhoek, Jenner, Meigen, Pollender, Griesinger, Bilharz, Obermeier, Koch, Laveran, Baelz, Pasteur, Metchnikoff, Manson, Ross, Reed, Gorgas, Carroll, Ehrlich—a list which does credit as much to his sense of proportion as to his freedom from national prejudice. Having been a medical missionary himself he has allowed himself to go strong in recounting missionary endeavour, and here again the reader will be grateful for his indication of seven biographies which deserve study. Happily in this case there are some survivors. To the biography there is in many cases a bibliography attached, and the author takes credit for giving the present address of these who are still alive. The production of the book is as distinguished as its authorship. The paper cover is attractive in design, the typesetting beyond criticism, and the index a model for other effort. The book is indispensable in any medical library.

PHOTOTHERAPY OF THE EYE

A DEPARTMENT for ultra-violet treatment was established at Moorfields Hospital in 1925, under Sir Stewart Duke-Elder, who summarise his work in reports issued in 1926 and 1928. In the book before us [1] his successor, Mr. F. W. Law, considers all the cases who had a full course of such treatment, general or local, in the clinic last year, and some of those treated in the three years preceding. To help towards assessing the permanence of results a letter was sent out to the patients or their parents as to their present condition. The effect of general phototherapy must be read in the light of the fact that the patients were attending hospital three times a week for a long period, and therefore received also other treatment in an unusually thorough way. This resulted in a high standard of cleanliness, for the undressing of a child three times a week before a nurse has its educative value on the mother. With these provisos Mr. Law endorses the favourable opinions expressed by other writers of the ultra-violet treatment of blepharitis, phlyctenular disease, and conjunctivitis in children. Most forms of keratitis derive some benefit; this applies, in Mr. Law's experience, even to interstitial keratitis. Syphilitic iridocyclitis and tuberculous disease failed to react, and, on the whole, his results do not reach the high level of some other workers. General phototherapy is, in fact, no more than an adjunct in treatment. Local irradiation in its own sphere has more to offer. Mr. Law reports 51 cases, nearly all of them corneal ulcers or different forms of keratitis, treated by focusing the rays exactly on the spot. Although he has himself never seen a cataract remotely connected with ultra-violet therapy, the application calls for continual care. Preferably the pupil should be small, although this is not always feasible. The usual initial dose is one of 2 to 2½ minutes, but if the duration of the beam has to be as oblique as 45° the time of exposure may be increased by one-half; if to 60° it may be doubled. Although corneal ulcers undoubtedly heal more quickly when irradiated there is not sufficient evidence that the density of the subsequent scar is less, nor is there any effect on established nebulæ. In tuberculous iritis there is often a suggestion of improvement, but the dosage needs careful watching. Throughout the monograph Mr. Law maintains a severely critical attitude towards his own results. In using radium and X rays for eye diseases the danger of inducing cataract must, he says, always be taken into account. Infra-red rays play no part as a therapeutic agent in diseases of the eye; they are a source of possible injury to cornea, lens, and retina—e.g., eclipse blindness.

THE ENGLISH TONGUE

THE history of the English language is not a matter for philologists; all persons with claims to education, in the countries where English is spoken, should have some acquaintance with the origin and development of their own tongue. In the United States of late this feeling has certainly been active, and a short article on the subject in the *Medical Record* for July 4th is worth attention. The writer says that few persons know the origin of "the King's English," evidently thinking that fuller appreciation of the lineage of language would minimise its frequent abuse. His pithy sketch of the Saxon invasion and the settlements of parts of England at different epochs gives reasons for the gradual evolution of English to its present standard. According to him it was not until 1385 that the language of the English-speaking peoples stepped out of its dialect petticoats to become an adult tongue, since when it has taken its place as the most universal means of intercommunication. On the cover page of the same issue of the *Medical Record* there is a picture of Dr. Thomas L. Stedman, for many years the editor of the journal, and this is opportune, for Stedman is a master of English, as well as a versatile linguist. Largely through this fact he has made a reputation as a lexicographer, where an accurate knowledge alike of the subject in hand and of languages is essential.

EPIDEMIC MYALGIA IN SWEDEN

IN a note presented to the permanent committee of the Office International d'Hygiène publique, Dr. R. Huss [1] outlines the salient features of the epidemic of myalgia which, in the summer and autumn of 1931, claimed many victims in the southern coastal areas of Sweden and in Denmark.[2] Though not a single case was fatal, the manifestations of the disease, when it was of the abdominal type, led occasionally to an exploratory laparotomy which proved nothing but the mistake in making it. There was also a thoracic type with bilateral symptoms referable to the lower chest. The most common complications were orchitis (some 50 cases) and dry pleurisy (about a score). Catarrhal symptoms referable to the respiratory tract were rare. Some cases were characterised by euphoria and flushing of the face. It seems that the epidemic had had its forerunners in 1[illegible]27, 1929, and 1930. The outbreak of 1931 began in the middle of June in the seaport of Marstrand, at which t[illegible] Swedish warships were stationed from Jun[illegible] 8th to 26th. The sickness-rate on these ships a [illegible] days after they had left Marstrand was such th[illegible] about a third of the crews was involved. Bet[illegible] the ages of 14 and 17 there were 190 person[illegible] of whom [illegible] ill. Between the ages of 20 and 30 there [illegible]

---

[1] Bull. de l'Off. Internat. d'hyg. pub., June, 19[illegible]

[2] See THE LANCET, 1933, i., 70[illegible]

12 patients out of a possible 44, and none of the 14 members of the crews who were over the age of 30 developed the disease. Apparently, therefore, it has a predilection for adolescents. As for the mode of propagation, Huss is inclined to defer final judgment till more tangible evidence is available. In favour of a contact infection was the behaviour of the epidemic on board the two warships; but the theory of a contact infection was not supported by the tendency of the disease to flare up in certain well-defined areas on the seaboard, and to leave whole communities here and there in the same area untouched. The occurrence of the outbreak in the hottest months of the year was suggestive of an insect-borne disease, and its explosive character on certain occasions gave support to the theory that it was conveyed by water.

EXHIBITS AT THE COLLEGE OF SURGEONS

THE Royal College of Surgeons of England has received an important addition to the historical section of its museum by a gift from Miss K. R. Image of over 300 surgical instruments belonging to her father and grandfather. The collection, which was formerly in the possession of the faculty of medicine at Cambridge, was made by William Edmund Image, an honorary fellow of the College, and his son, Francis Edward Image, M.B. They practised at Bury St. Edmunds between 1830 and 1913, and the instruments may be said to represent the complete armamentarium of a country general practitioner of the last century. They are now on view and include more than 40 varieties of scalpels, bistouries, and dressing instruments, together with knives for amputation and lithotomy. The gynæcological and obstetric instruments comprise several types of vaginal specula, from the old bladed patterns to Fergusson's silvered glass instrument, the midwifery forceps of Robertson, Waller, and Simpson, and cephalotribes and forceps in great variety. Lithotomy instruments are also well represented and include the lithotrites of Fergusson, Thompson, and Weiss, as well as stone-crushers, gorgets, and the lithotomy knives devised by Liston and Thompson. There is a comprehensive collection of ophthalmic, aural, and nasal instruments which illustrate the period of development between 1830–70, and the instruments for amputation include Liston's and Lisfranc's knives, saws, and several types of bone-forceps.

Among the earlier exhibits are a number of dry-cupping sets, scarifactors, and glasses complete with spirit lamp; cauteries, stethometers, otoscopes, and one of the earliest types of Dudgeon's sphygmograph. There is also a pair of the long clinical thermometers, introduced by Prof. William Aitken of Netley, used in hospitals in 1866. Another gift to the College, which is of special interest in this connexion, is a thermometer that originally belonged to Dr. John Aikin, of Warrington, the medical biographer, who was born in 1747 and died in 1823. It is 6¾ in. in length and is bent at a right angle of 25° at one end terminating in the mercury bulb. The index is of ivory which is clipped on to the stem and is graduated in half inches from 1 to 12, and is divided into tenths. It is marked "Cary. London," and is enclosed in a velvet-lined leather case. It was probably used before the end of the eighteenth century, and is similar to one described as having been used by Sir Astley Cooper in 1802, which also had an ivory scale. This authentic specimen is probably the earliest type of clinical thermometer known, and descended in direct line from Dr. Aikin to Mr. C. W. Brodribb, who presented it to the museum.

Instruments of more recent date now on exhibition at the College are represented by the original model of Kocher's artery forceps made for the inventor and presented by his son, Dr. Albert Kocher; also a set of four instruments devised and used by Prof. Trendelenburg for performing embolectomy,[1] which were given to and presented by Sir Charles Ballance. Objects of more general interest include a mummified hand said to have been that of Dick Turpin, the highwayman, who was hanged at York in 1739, and some relics of the Roman occupation discovered last year near the Poultry and presented by Dr. Mervyn Gordon, F.R.S. They consist of two spoon-sounds, two ear-scoops, a pair of forceps with ear scoop, and a long needle, all in an excellent state of preservation. They are believed to date from the first century.

INJECTIONS OF CARBON

SOME observations by Gaudier and Démarez[2] on the treatment of infections by means of injections of animal carbon arise out of an earlier communication to the French Academy of Medicine by Saint-Jacques, of Montreal.[3] They have given this treatment to 25 patients suffering from various infections, surgical, medical, and obstetric. Each dose consists of 2–5 c.cm. of a suspension of animal carbon in isotonic glucose serum, containing from 1 to 3 per cent. of carbon, and the injections were given every or every other day or at longer intervals, the maximum total dosage being 42 c.cm. of a 2 per cent. solution. The injections were painless even when some of the solution was deposited outside a vein, and there was no violent reaction at the time such as pallor, flushing, shivering, dyspnœa, or any change in the pulse and blood pressure. There was not even a febrile reaction, and the treatment could not, therefore, be considered as a variety of shock treatment. Gaudier and Démarez believe that as a rule the injection was followed by a fall in temperature of at least 0·5° C.—a fall which in the favourable cases was maintained and even continued in association with clinical improvement which was sometimes startling. The carbon did not seem to have a direct antipyretic action, and it was ineffective when escape was not provided for collections of pus. The best results were achieved in diffuse, inflammatory processes, when the reaction of the organism to the infection hung fire, or when it ran an acute and serious course without free suppuration. It is said that pneumonia and acute articular rheumatism also responded satisfactorily to the remedy, but its mode of action remains obscure.

CANCER OF THE LARYNX

Dr. J. H. Douglas Webster reports[4] two cases of laryngeal cancer in which the patients have been well for nearly 12 months after treatment with X rays, according to the protracted fractional method described by Dr. Coutard, of Paris, in our issue of July 7th. Dr. Webster's previous study of 42 cases of cancer of the larynx shows clearly that the disease can rarely be controlled by the methods of X radiation which have been successful in other situations. All methods he has employed have ultimately led to failure, except occasionally in post-operative "prophylactic" cases, in which it is not known whether any malignant cells have been left in the tissues. Exact clinical details of the two cases now reported are not given, but it is stated that the first had a large fixed mass over the right side of the larynx and œdematous swelling of the right arytenoid and false cord; a specimen removed from the larynx was only œdematous tissue, but one from the external tumour showed an undifferentiated squamous-celled cancer with much fibrous reaction. The second patient had undergone a partial laryngectomy, with removal of the left cord and all visible growth, after he had refused total excision of the larynx; the tumour was of Grade 3 in Broders's classification. In neither case is there any sign of recurrence almost a year later, and Dr. Webster believes that the method gives great promise for the future usefulness of X ray therapy in squamous-celled carcinoma of the larynx, pharynx, and tonsil. The technique unfortunately is very laborious, so that each patient requires an expenditure of time and energy which would suffice for about 20 treated by ordinary "short-time" radiation. The essentials of Coutard's plan is that each dose is *protracted*, or of low intensity, 3 to 4 r per minute instead of 30 or 40 r as often given, and that the doses are highly *fractionated* compared with other fractional methods; the entire dosage is divided up over 2–4 or more weeks, and the patient should not be treated for more than three or four hours a day if undesirable reactions are to be avoided. As the result of these low-intensity treatments, spread over a long period, an extraordinarily high total dosage can be applied with safety, and the success obtained seems to depend on this fact.

SCHOOL-CHILDREN IN CENTRAL EUROPE

A GENERAL idea of the conditions of childhood in a central European city is given by Dr. E. Neuber's survey[1] of school-children from 6 to 8 years old in the elementary schools of Debrecen in Hungary. Neuber himself is actively concerned with the campaign against venereal disease, and among the 1612 children studied he found 36 who were definitely syphilitic, while a further 43 were probably infected. A gynæcological investigation carried out in nearly 70 per cent. of the girls showed, among other things, the presence of a vaginal discharge in 68 out of 538, and 3 of these proved to have gonorrhœa. It is thought that more elaborate examination would have raised this figure to a much higher level. A tuberculin reaction was positive in 30 per cent. of the children, and radiography of the lungs, carried out for 1583, revealed definite changes in 648 (that is, over 40 per cent.), though only about half of these were of such a nature as to suggest tuberculosis. Roughly speaking, therefore, one-fifth of the children showed changes in the chest suggesting tuberculosis, but it was thought that in only one in five of these was the disease in an active state. Intestinal parasites were found in about a quarter of the children, the commonest being *Trichocephalus dispar*; nits and pediculi capitis were present in just over 30 per cent., and the predominance of girls among them leads Neuber to plead for a compulsory Eton crop (Etonfrisur). The results of ophthalmological investigation revealed what seems, in comparison with standards in this country, very few defects, for out of the 1325 children examined 1250 were passed as completely normal. Of those with refractive errors, myopia accounted for 4, hypermetropia for 14, and astigmatism for 20. On the other hand, dental disease appears to be as common in Hungary as in this country, since nearly 70 per cent. of the children out of the total of 1612 had defects in their teeth. Their incidence was considerably less among children coming from the country than among those who were town-bred.

Neuber's survey was made in 1931–32, before the economic depression reached its greatest depth. A report by Dr. R. Paula Lopes to the International Labour Office[2] suggests that in Germany, Poland, and elsewhere there has been a serious deterioration since that time. In an inquiry into the situation of 383 unemployed families in the Silesian mining industry and the Lodz textile industry it was found that no less than 311 of the 382 children of school age could not attend school regularly, the chief reason being lack of clothing. A report of the Prussian Ministry of Social Welfare records that in all the Prussian schools there has been a striking increase since the end of 1931 in the number of cases of anæmia, scrofula, dental caries, diseases of growth, and nervous states which reveal themselves in early fatigue and inattention. "Numerous reports from clinics, health centres, and school medical officers confirm these facts; some of them also mention a notable increase in the incidence of rickets and tuberculosis." The gravity of all these facts, Lopes points out, is increased by the inability of the municipalities to devote large sums to the relief of poverty. Thus the free distribution of milk in Berlin was cut down by 50 per cent. in 1932, and in the same year an inquiry made by the Verband der Kommunal-Schulfürsorgeärzte showed that similar restrictions had been introduced in the 43 towns covered.

DISTRIBUTION OF BOVINE TUBERCULOSIS IN MAN

DURING the past two years the tuberculosis division of the State Serum Institute in Copenhagen has followed a uniform technique in the differentiation of human and bovine strains of tubercle bacilli derived, for the most part, from human sources. Some idea of the extent of these operations is given by the statement, published by Dr. K. A. Jensen,[3] that during these two years 7031 specimens have been examined, and 1772 strains of tubercle bacilli have been isolated from the same number of patients. The interest of Dr. Jensen's work does not, however, lie so much in the volume of his work as in his geographical handling of it. In the past, as he points out, most statistics have been concerned only with the relative number of human and bovine strains found in a given laboratory, and with a grouping of these strains according to the ages of the patients from which they came. By referring each strain back to the area in Denmark whence it came, Dr. Jensen has succeeded in showing how impressively unequal is the distribution of tuberculosis of the bovine type in human beings throughout the country. In some counties it is practically non-existent. In others its incidence is much in excess of that indicated by the large collective statistics of any other country. Such a geographical survey of tuberculosis in human beings infected with the bovine type should prove of great practical value where the eradication of tuberculosis in cattle is under discussion. It will be remembered that Bang's system for the eradication of tuberculosis in cattle has for many years been put into practice in Denmark with the result that it is almost completely stamped out in certain areas. No greater spur to the completion of this work could be found than Dr. Jensen's investigations, which so clearly link up tuberculosis in cattle with tuberculosis of the bovine type in human beings. If, he argues, tuberculosis in cattle is not stamped out, the time may come when, with the diminution of the human type, the bovine type may take its place, increasing among human beings, even though it remained stationary among cattle. A year ago in our own columns,[4] A. S. Griffith and W. T. Munro reported a "startling" number of cases of pulmonary tubercle associated with the bovine bacillus in England and Scotland. They were very unequally distributed over the country.

STATESMAN, PRIEST, AND PHYSICIAN

THE name of Robert Laws, who died in a nursing-home in London at the age of 83 on Monday last, is probably familiar to many as a missionary and statesman, though the fact that the starting-point of his career was medical may have escaped notice. He received a full medical education, however, at the University of Aberdeen, and later studied at the Edinburgh Presbyterian Theological College. He obtained a doctorate in both faculties and was ordained a medical missionary in 1874. He continued in medical practice as a resident in the Glasgow small-pox hospital until the founding by the United Presbyterian Church of a mission in Nyasaland in memory of Livingstone. Laws formed one of the small party sent out to organise the starting of the mission, and his medical knowledge was of great value to his comrades; in the development of the work which followed it proved of the first importance. Two years later his wife joined him in Nyasaland, and for 50 years the Livingstonia Mission had Laws as its organising head. While he placed his work for the gospel in the forefront of his personal programme, his energy in the cause of education, his industry in acquiring native languages, and his organising power were the other qualities to which he owed his wide influence in the Protectorate. He translated the New Testament into Nyanja, and wrote an English-Nyanja dictionary and various school-books in Nyanja and Tonga. He was nearly 80 years of age when he left Nyasaland to pass the days of his retirement in Edinburgh.

ANOTHER KIND OF MILK

THE Milk Marketing Board are proceeding with their scheme for a register of "accredited" milk producers, and its operations are to begin next January. The new scheme establishes what is in effect yet another grade of milk. To become accredited, the producer must have his herds "clinically" examined once in six months by an approved veterinary surgeon, and must permanently remove all animals considered a danger to the milk-supply. The county agricultural organiser will certify that the methods of production and handling are satisfactory, and the county medical officer of health or county bacteriologist will examine three samples annually and declare that their bacterial count does not exceed 200,000 per c.cm., and that *Bacillus coli* is absent in 0·01 c.cm. These bacteriological standards are the same as for Grade A milk on delivery, but cows supplying Grade A must be inspected every three months. Under the new scheme the accredited producer will have an extra penny a gallon for his produce, this being raised by a small levy on all producers of milk. It is hoped that with this inducement a large proportion —even a majority—will seek to qualify and that the whole standard of milk production will thereby be raised. So far so good; and in commending the proposals the *Times* (August 6th) expresses surprise that "the authorities at the Ministry of Health have not been at all enthusiastic over the scheme, because it does not, in their opinion, go far enough." Readers of an article from a well-informed correspondent which we published on May 12th (p. 1028) will be less astonished. "Assuming efficient control," he said, "it is obvious that at the best it is Grade A milk over again but with rather relaxed standards. And Grade A milk is fairly universally accepted as failing to give a safe milk-supply. . . . Stated briefly, the scheme of the Milk Marketing Board will materially assist in the production of a clean milk-supply but will do comparatively little to give a safe milk-supply, and it is a *safe* milk-supply which is insistently demanded by the medical profession." While every step towards cleanliness is highly desirable and the Board is making a useful advance in the right direction the credentials offered by accredited milk are not sufficient to make it a suitable drink for children unless its dangers are removed by heating. A roll of accredited producers combined with pasteurisation of the milk-supply would, as our correspondent pointed out, be a very valuable combination; but where there are no adequate guarantees of safety the profession will never be able to join wholeheartedly in the cry of Drink More Milk.

STANLEY MELVILLE

A COMMUNICATION from Sir Humphry Rolleston, Lord Rutherford, and eight representative co-signatories, asks that the services rendered to radiology in all its aspects by the late Dr. Stanley Melville should be recognised by some such suitable memorial as a travelling fellowship in radiology connected with his name. The National Physical Laboratory, the Royal Society of Medicine, the Society of Radiographers, St. George's Hospital, and the Brompton Hospital—the two institutions with which Melville was connected, and the British Institute of Radiology, all endorse the appeal, as does the British X Ray and Radium Protection Committee. The connexion of this last body with the appeal is particularly significant, for Melville played a prominent part in bringing home vividly to the public and the medical world the dangers of X ray work as illustrated by the tragic deaths of so many of the pioneers. Melville was also active in establishing the Cambridge diploma in medical radiology and electrology; the incorporation of the British Institute of Radiology with the Röntgen Society was another of his successful activities, for he always displayed particular anxiety with regard to the welfare of the lay-workers. Melville was himself a long and sad sufferer from injuries incurred in his professional work; he never spared himself, and always thought of others. We commend the movement to keep alive his memory to our readers. Dr. J. Duncan White and Dr. A. E. Barclay, of the British Institute of Radiology (32, Welbeck-street, London, W.1), will receive now donations however small, and a meeting will be called later of those who subscribe to decide upon the exact form which the memorial shall take eventually.

THE medical superintendent of the new British Post-Graduate Medical School, Sir Thomas Carey Evans, has received from Mr. Arthur Evans a collection of pathological specimens illustrating diseases of the gall-bladder. The specimens are beautifully mounted, each with a clinical record of the case, and the collection will form the nucleus of the museum of the school. It is hoped that other collectors may be as generous.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XIV.—PROGNOSIS OF APPENDICITIS IN CHILDHOOD

THE prognosis of appendicitis in the case of a child is a matter of some difficulty, much more so than in that of an adult. It may be regarded as an axiom that the younger the subject the more dangerous is the outcome.

That this should be so is due to several circumstances. The appendix in a child differs from that of an adult in that the walls are relatively thin and contain relatively a larger amount of lymphoid tissue. As a consequence, should appendicitis occur the reaction is more acute, and the peritoneum is so rapidly involved by infective process s that protective adhesions between adjacent structures have had little or no time to form. The blood supply to the appendix in childhood is not so adequate as that in later life. This is another factor which accounts for the more rapid extension of inflammation in the former. The most common position of the appendix in a child is the retrocæcal. This is due to the fact that with the descent of the cæcum during development the appendix is liable to be carried behind this structure. As a rule the omentum is so poorly developed in a child that it can afford very little protective influence. As compared with an adult, the child has had but little time to acquire immunity, and consequently its intestine is much less resistant to bacterial infection. For some reason or another appendicitis tends to occur in an epidemic form in children while it does not do so in adults.

The actual prognosis of appendicitis in a child, although difficult, depends on certain factors which should be taken into consideration in every case.

Early Diagnosis.—Although this is of vital importance it is often neglected by the practitioner. It must be remembered that appendicitis is the most common and, in my opinion, the most important abdominal disease occurring in children. This is borne out by statistics from children's hospitals both at home and abroad. "Colicky" abdominal pains in children are too often, even in these enlightened days, thought to be natural phenomena both by parents and practitioners. Rupture of the appendix and peritonitis are not infrequently caused by the administration of a dose of castor oil given in order to relieve such pains. It cannot be stressed too forcibly that "colicky" abdominal pains in childhood demand most careful investigation, and the possibility of an inflammatory condition of the appendix should always be kept in mind.

The mortality varies greatly, and is dependent chiefly on the time which has elapsed between the onset of the acute attack and operative treatment. There is only one form of treatment, and that is operation, which should be carried out immediately the condition is diagnosed. If this were more widely realised by both the medical and lay public there would be far fewer tragedies in the world. In the treatment of acute appendicitis there is no reason whatsoever for delaying operative measures.

Age of the Patient.—Although uncommon in infancy appendicitis has been recorded in babies soon after birth. As a general rule the younger the infant the more serious is the prognosis. The mortality during the first three years of life is high; infants cannot tolerate septic infection. The mortality is higher among boys than girls. The younger the child the less likely is the infection to become limited, owing to the thin wall of the appendix, to its poor blood supply, and to the immature and short omentum, which does not nearly reach the right iliac fossa, and cannot exert its protective mechanism which is so often such a useful feature in adult cases. In the young child again, as has been said above, immunity has not yet been acquired against the various forms of bacteria present in the bowel.

The *position of the appendix* cannot always be ascertained prior to the operation but is of great importance in prognosis. It must be generally understood that a prognosis given before operation is subject to review thereafter. If this were done as a routine there would be fewer disappointments and a better understanding between the surgeon, the family doctor, and the parents of the patient.

The appendix may occupy various positions but some are of more moment than others. The retrocæcal appendix is very common, and as long as the infection is limited to the appendix the prognosis is good. If, however, the appendix has perforated and the cellular tissues on the posterior abdominal wall are infected the prognosis is grave. Another type of case in which the prognosis is not good is one in which the appendix is long and is actually retrocolic. Here it is difficult to prevent the absorption of septic material; moreover, the infection is very liable to spread upward towards the diaphragm. In this way pulmonary complications may be added to the list of sequelæ which in themselves are severe in an infant already toxic from absorption from the acute appendicitis. The pelvic appendix is quite common, as may be gathered from an analysis of a large series of cases of appendicitis occurring in children. The prognosis is good, even when the appendix has ruptured. The infection is limited to the pelvic cavity, and the pelvic peritoneum is better able to deal with it than the peritoneum elsewhere. These cases, however, are often diagnosed late, and the surgeon frequently has to operate when there are definite signs of peritonitis. The anterior position, or the so-called "splenic" position of the appendix, is fortunately rare, as the prognosis is anything but good. The appendix lies either in front of or behind the terminal part of the ileum, and as it is there in relation with the root of the mesentery, there is a grave possibility of acute intestinal obstruction. Furthermore, the veins in the root of the mesentery may become thrombosed and lead to gangrene of the gut, or portal pyæmia may ensue with fatal results. In cases of pain in the *left iliac* fossa left sided appendicitis must be considered. As a rule this form is diagnosed late, and the prognosis is therefore unfavourable. In cases of transposition of the viscera the appendix is found with the cæcum in the left iliac fossa, where it is also situated in cases where intestinal rotation has failed during development.

Type of Infection.—It is not always possible to be sure of the type of organism responsible for acute appendicitis, but quite commonly this can be ascertained. A streptococcal infection makes the prognosis unfavourable; children do not tolerate streptococcal infection at all well. In these cases postoperative abscesses are common. Streptococcal appendices may be hæmatogenous and may follow infection of the throat with the same organism, the appendicitis frequently developing before the child acquires immunity from the primary focus. The prognosis is good when infection is limited to the appendix itself. It is at this stage that the appendix should be removed, and an excellent result should be obtained in a hundred per cent. of cases. The appendix is swollen and turgid, but no infection has spread into the peritoneal cavity, although there may be some enlargement of the lymphatic glands in the ileocæcal angle. If the infection has been more severe, or the case is seen at a later stage of the disease, the appendix may be gangrenous and perforated. The perforation may be opposite a stercolith, or may occur quite commonly in the absence of one. The most frequent site of occurrence for a perforation of the appendix is at the junction of the proximal two-thirds, with the distal third ; the meso-appendix carrying the appendicular artery is mostly present only in the proximal two-thirds of the appendix, and perforation occurs at the junction of the good and poor blood-supply of the appendix. A guarded prognosis is necessary when the appendix has perforated in a child. The highest mortality-rate is found in the cases in which general peritonitis is present ; children cannot withstand such a general toxæmia.

Concomitant Diseases.—When the child is already suffering from some congenital or acquired disease or abnormality, such as a cardiac lesion, nephritis, bronchitis, diabetes, cyclic vomiting, or one of the exanthemata the prognosis is gravely affected.

Post-operative Treatment.—This is an important factor in prognosis. Anxious parents may try to insist on an operation performed at home, the patient sleeping in his own cot, and with his own nurse in attendance. The psychology of the child must be taken into account, but it is essential that a trained nurse should be in charge. Nurses trained at a children's hospital are, in my experience, far more competent to look after cases of acute appendicitis in children than those trained in a general hospital. It is also better for the patient to be admitted to a special nursing home for children. A trained nurse who is kind, sympathetic, and cheerful, and understands a child, is of more value in post-operative treatment than all the drugs in the pharmacopœia. A good nurse will frequently encourage sleep in cases where drugs have continually failed.

Complications.—Fortunately, it is only following perforation that complications such as secondary abscess formation, fæcal fistulæ, and acute intestinal obstruction arise. The possibility of the supervention of any one of these must be borne in mind when a prognosis is being offered.

Chronic Appendicitis.—It is wrong to imagine that chronic appendicitis is a disease limited to adult life. Cases occur in children and often show quite typical symptoms. Here, again, the correct treatment is appendicectomy and the prognosis is good.

The prognosis of appendicitis in children is thus not easy to determine by itself. The general condition of the child, its disposition and mentality are factors to be taken into consideration in every case.

CECIL P. G. WAKELEY, D.Sc., F.R.C.S., F.R.S.E.,
Surgeon, Belgrave Hospital for Children ; Senior Surgeon, King's College Hospital.

SCHOOL MEDICAL HISTORY OF PERSONS WHO DEVELOP PULMONARY TUBERCULOSIS IN YOUNG ADULT LIFE*

BY P. L. MCKINLAY, M.D., D.P.H. ; and
E. WATT, M.D., D.Sc., F.R.C.P.
MEDICAL OFFICERS, DEPARTMENT OF HEALTH FOR SCOTLAND

ROUTINE medical inspection has for some time been advocated as one of the hopeful methods of advance in modern preventive medicine. It is not our present purpose to discuss the place or merits of such a practice in the field of modern hygiene, but in the following investigation we desire mainly to illustrate the need for, and one of the practical applications of careful record keeping of the findings to be derived from such periodical medical overhauls. The primary objects of regular inspection appear to be: (1) the treatment of minor ailments which otherwise would perhaps be ignored and which occasionally are the precursors of disabling or even fatal sickness ; (2) the diagnosis of more serious disease in its incipiency when the exhibition of skilled treatment is most likely to be successful ; and (3) the recognition and, if possible, the rectification of deviations from some, often arbitrary, "normal" standard. With regard to the expediency of (1) and (2), little need be said—their value is self-evident. It is to the third point that we desire to devote special attention in this paper. It is well known how individuals, aparently perfectly healthy, differ widely from one another in respect both of physical and physiological attributes ; but we know too little about how such variations predispose to different diseases or influence the duration of life and manner of dying. What, for example, is the precise significance of discovering in early adult life deviations above or below a certain normal (usually an age-specific average) in the case of body-weight, blood pressure, exercise tolerance, vital capacity, &c.? We know as a result of certain inquiries that some of these—e.g., overweight—are of significance in predisposing to the onset, or perhaps being one of the early signs of certain diseases or in curtailing life. Similarly, too, it is suspected that such conditions as enlargement of the tonsils and focal sepsis, if untreated, predispose to or cause more serious disease later in life. In general, however, the significance of individual variations is insufficiently known to allow of accurate prognostication. It is from this standpoint of research particularly, therefore, that we would stress the present value of routine medical inspection and accurate and detailed record keeping. The correlation of variations of bodily attributes in individuals at a given period of life with subsequent life-history is, we submit, one of the principal tasks to which modern hygienists must apply themselves before the maximum return from routine examination will ever be forthcoming.

Origin and Nature of the Inquiry

A problem illustrative of the foregoing points confronted us recently with regard to pulmonary tuberculosis developing in young adults. The course of mortality from this cause at these ages (15–25 years) has, compared with that at other periods of life, become a matter of special concern ; and the question arose as to whether by routine clinical examination it would be possible to predict the type of child most likely to become tuberculous in later —i.e., in this particular case, young adult life. In other words, we are asking ourselves, can anything distinctive be discovered in the physical make-up or previous medical history of school-children who are destined to develop tuberculosis at ages 15–25 years which would suffice to indicate or even make us suspect the probable future appearance of the disease? Are they, in fact, different in any way from school-children who at the subsequent ages, 15–25 years, are, so far as is known, free from manifest disease of this kind? De novo inquiry to answer such a question would obviously involve time and money; but the idea occurred to us that material for exactly that type of experiment was already available through the official records kept regarding the state of children as found at school medical inspection. We accordingly approached the public health officials of the city of Dundee for the necessary records, and to them, Drs. W. L. Burgess, A. E. Kidd, and J. H. Hunter, we desire to record our indebtedness for the willing response to our request which has made this study possible.

---

* A paper read before the Tuberculosis Society of Scotland, April 20th, 1934.

The inquiry involved searching out the school medical inspection records of persons notified as having developed tuberculosis within the ages mentioned, and simultaneously a series of records for a control group, these being as far as practicable for persons of the same age and sex, from the same schools, examined by the same medical officer at the same time. (In practice, this ideal was not quite obtained, particularly with regard to the exact similarity in the dates of examination.) Comparisons of this nature eliminate to a great extent differences of social class and correlated factors between the two groups of children and, more important still, the examination by similar medical officers eliminates for all practical purposes differences of medical assessment. The latter is vital in comparisons involving the incidence-rates of such non-measurable factors as malnutrition, enlargement of the tonsils, adenoids and glands, rickets, unsatisfactory or dirty clothing—as will be fully realised by those who have attempted a study of the geographical variations of such conditions on the basis of the statistics contained in the annual reports of school medical officers throughout the country.

The Data and their Significance

In all, we have available the medical records of 97 children who were ultimately notified as tuberculous at ages 15–25 years, and a like number for persons of similar ages not known to be so suffering.

INCIDENCE OF INFECTIOUS DISEASES

In Table I. are set out the percentages of children with a previous history of the principal infectious diseases. (The standard errors of the differences in this and subsequent tables have not been tabulated, but the statistical significance of the differences is made evident in the text.)

TABLE I

Incidence of infectious diseases (per cent.)

	Control.	Ultimately tuberculous.
Measles	77·32	80·41
Scarlet fever	7·22	18·56
Diphtheria	3·09	4·12
Whooping-cough	58·76	60·82
Chicken-pox	24·74	31·96
Bronchitis and pneumonia	6·19	8·25

Apart from scarlet fever, there is no evidence of significant difference of prevalence of the specified diseases in the two groups of children. A past history of such infections, therefore, is as likely to be found among controls as among the ultimately tuberculous.

CONDITION AT EXAMINATION

With regard to the actual findings at medical inspection, for some children we have available the results of more than one routine overhaul, so that the subsequent statistics relate to the total number of examinations, *not* the total children. Actually, there were 292 inspections, of the ultimately tuberculous 151 (males 84, females 67) and of controls 141 (males 74, females 67). Although there is a slightly higher proportion of females in the control group, the subsequent figures are set out for the sexes combined because of the rather small numbers available.

(*a*) *External conditions.*—The percentage incidence-rates in each group of the conditions under this heading are shown in Table II.

TABLE II

External Conditions

	Control.	Ultimately tuberculous.
Insufficient clothing	0·71	1·99
Dirty clothing	1·42	5·30
Clean heads	82·98	73·51
Nits	12·77	21·19
Verminous heads	2·13	1·99
Clean bodies	85·11	86·75
Flea-bitten bodies	11·35	7·95
Verminous bodies	3·55	3·97

Although the scanty numerical basis precludes dogmatism, the suggestion would appear to be that dirty clothing, dirty heads, and nits are more prevalent among the ultimately tuberculous. In other features the differences found are unimportant.

(*b*) *Physical condition.*—The incidence-rates for the more important factors are collected in Table III.

TABLE III

Physical Condition

		Control.	Ultimately tuberculous.
Tonsils enlarged		26·44	18·54
Adenoids present or probably present		4·96	3·31
Enlarged submaxillary glands		21·28	17·22
Enlarged cervical glands		6·38	3·97
Teeth	Perfect	7·80	4·64
	Under 4 decayed	27·66	26·49
	4 decayed	41·84	47·68
	More than 4 decayed	22·70	21·19
Oral sepsis		4·26	3·97
Nutrition	Above average	47·52	45·70
	Average	48·23	51·65
	Below average	4·26	2·65
Anæmia		8·51	4·64
Bronchial catarrh		1·42	7·28
Rickets		0·71	2·65

It would appear from the nature of the differences and their statistical significance that, here again, no noteworthy differentiation of the two groups exists except in respect of bronchial catarrh, wherein the difference is more than twice the standard error. It is difficult, however, to assess the exact weight to be laid on this, since no indication is made as to the location or permanence of these adventitiæ and to other chest findings; but since in these 11 cases, 8 were noted at ages under 10 years, 2 at 11, and 1 at 13 years, and since none of these children was notified as tuberculous until at least the age of 15 years, it would be hazardous to attach much significance to this finding and especially unwise to regard these as examples of permanent lesions, the nature of which was missed at such an early age. In all probability the finding may denote no more than a transient bronchial catarrh.

(*c*) *Body-weight*.—The average weights, heights, and ages of the children separated as to sex are shown in Table IV.

TABLE IV

Average weights (pounds), heights (inches), and ages (years)

		Weight.	Height.	Age.
Males	Control	63·59	51·47	10·64
	Ult. tb.	61·42	50·75	10·65
Females	Control	60·14	50·52	10·35
	Ult. tb.	63·57	51·95	10·67

Ult. tb. = Ultimately tuberculous.

In males the weight of the ultimately tuberculous is lower, in females is higher than in the respective control series. It will, however, be noted that there are corresponding differences in the average heights and slight differences of average age. Since body-weight in school life is to such a large extent governed by height, obviously before accurate comparisons can be instituted, allowance for differences of height and age must be made. Since the total number of observations is small, it is impossible to attempt comparisons of body-weights for specified heights and age on the basis of the crude data. From the original observations we have derived the following regression equations relating weight to height and age:—

(1) Boys (control) .. W = 2·83H − 0·18A − 79·99
(2) ,, (T.B.) .. W = 2·66H − 0·19A − 71·51
(3) Girls (control) .. W = 2·62H − 0·08A − 71·56
(4) ,, (T.B) .. W = 2·80H − 0·53A − 76·14

W = weight; H = height; A = age.

From these the body-weights for certain ages and heights have been predicted for each group and are shown in Table V., wherein also the weights of the ultimately tuberculous are expressed as a percentage of the corresponding control figure.

TABLE V

Body-weights for specified age and height, with weights of ultimately tuberculous expressed as percentage of controls

Age.	Height.	Males.		Females.		T.B. per cent. of control.	
		Control.	T.B.*	Control.	T.B.	M.	F.
5	40	32·2	33·9	33·0	33·1	105·3	100·3
7	45	46·0	46·8	45 9	46·1	101·7	100·4
9	50	59·7	59·7	58·9	59·0	100·0	100·2
11	55	73·5	72·7	71·8	71·9	98·9	100·1
13	60	87·3	85·6	84·8	84·9	98·1	100·1

M. = males; F. = female; * Ultimately tuberculous group.

From these figures no gross differences of body-weight would appear to exist between the two groups. The ultimately tuberculous are, while of school ages, in no way inferior in this respect to controls of equal ages and heights.

A further problem arises as to whether these two selected groups of children differ from the general school population of the area. Since it is possible for the two selected groups not to differ one from the other and yet to differ grossly from the general population, we have compared (Table VI.) the actual average body-weights and coefficients of variation with the averages and coefficients of variation in a numerically equal sample of Dundee school-children of the same ages and heights. For each child in the two groups—that is, we have determined the weight for its height and age from a table published in the Dundee school medical officer's annual report for the year ending July, 1927, and compared the derived averages and coefficients of variation (columns headed "expected" in Table VI.) with those calculated from the actual body-weights.

The actual average in each case is lower than the expected figure. While the consistence of the deficit is obvious, there are two noteworthy points in connexion therewith. In the first place, the differences are very small indeed (at the outside 2 per cent.) and statistically quite insignificant. In addition, the general figures for Dundee relate to school-children examined in 1927 and the children in the two groups under investigation attended school long before that. Improvement in the physique of school-children over recent years might account for part of the observed differences. If these two points be considered, it is clear that in this respect there is no appreciable difference between the two series and the general school population of Dundee. With regard to variability, as expressed by the coefficients of variation, while in three out of the four cases the actual exceeds the expected, in no case has the difference any statistical significance.

TABLE VI

Comparison of actual and expected body-weights (averag and coefficient of variation)

		Average.		Act. per cent. of exp.	Coefficient of variation.	
		Act.	Exp.		Act.	Exp.
M.	Control	63·59	64·56	98·5	27·56	26·08
	T.B.	61·42	62·94	97·6	26·39	26·91
F.	Control	60·14	60·44	99·5	27·36	24·54
	T.B.	63·57	64·90	97·9	28·59	27·43

M. = males; F. = females; Act. = actual; Exp. = expected.

A more detailed study of body-weights can be obtained by comparing the weights of these two groups at specified ages and for given heights with the corresponding figures for Dundee. This has been done but, except at age 5 years, where the Dundee figures exceeds that for either group, no notable differences were found.

In a report of the proceedings for 1932–33 of the Joint Tuberculosis Council just issued, the following paragraph occurs (p. 7): "It is to be hoped that sooner or later the Council will initiate research to investigate the statement that it is not the delicate children in tuberculous households, but the more robust, who later develop tuberculosis." While the children in the group examined here do not necessarily come from tuberculous households, it is clear from the above findings that, in respect of those developing tuberculosis at young adult ages, the physique does not differ significantly from that of control or even average children of school ages. Neither under- or over-average physique would appear from our data to predispose to the onset of young adult phthisis.

Summary and Conclusions

In this investigation we have scrutinised the available school medical details regarding two sets of persons, one developing tuberculosis in young adult life, the other free from this disease at that age, the object being to elicit whether such tuberculous people show any prior stigmata by which they might be singled out for special supervision or specialist examination before the onset of manifest disease. It is obvious that if differences did emerge, it might be possible to concentrate specialist diagnostic services —e.g., radiography in this particular instance—on a much smaller number of persons and, correspondingly more economically than if such services had, in the absence of directional findings, to be applied wholesale.

In actual fact, only in two respects have significant differences been obtained. In the prior incidence of scarlet fever and in the presence of bronchial catarrh the excess frequency among the ultimately tuberculous ppears to be statistically significant. With regard to common infectious diseases other than scarlet fever, the observed differences might well have arisen by chance. In the conditions found at school examination, the more frequent occurrence among the ultimately tuberculous of dirty clothing, dirty heads, and nits (indicative to some extent of the quality of maternal care—an important factor in child life) is probably significant statistically.

The physical condition of the children in respect of other factors such as tonsils, adenoids, submaxillary and cervical glands, dental decay, nutrition, anæmia, and rickets does not differ substantially in the two groups, and the differences found, irrespective of statistical insignificance, are by no means consistently in favour of the controls. With regard to the accurately measurable factor of body-weight, our investigation shows no important difference between the controls and the ultimately tuberculous, nor between these two groups and the general school population of Dundee. We cannot, of course, be dogmatic on the basis of this limited experience, but perhaps our essentially negative findings will stimulate others to whom such records are available to try out such an inquiry on a larger scale. What should be emphasised, however, is that if, on more extensive inquiry, the differences found were only of the nature and numerical order found here (but because of the larger numerical basis were statistically significant) it is quite impossible from ordinary routine medical inspection to predict with any degree of accuracy the type of school-child likely to develop tuberculosis in young adult life. If, as is commonly believed, the infection is acquired in earlier life, it would appear from our findings that it does not reveal itself in any way detectable by ordinary clinical methods.

Finally, we would re-emphasise the fact that as this inquiry is of a kind which could be instituted in respect of other diseases if routine inspection were to be generally introduced, careful and accurate recording of medical details is an essential part of the framework of any such scheme. For instance, in an investigation of this nature, more details of physical condition—such as vital capacity readings, chest measurements, and blood-pressure readings—and some details of other features such as the results of intelligence tests and elaborate details as to intercurrent illnesses of all kinds would have added appreciably to the interest and importance of our essentially negative results.

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF MEDICINE

IN this section, Dr. J. A. RYLE (London) being in the chair, a discussion on the ætiology and treatment of

Bacillus Coli Infections

was opened by Prof. D. M. LYON (Edinburgh). He dealt first with the natural habitat of the organism in the large bowel, especially the cæcum and ascending colon, where conditions were most favourable to its growth, and the methods by which it spread. Contrary to former belief, several workers have shown the organism to be capable of penetrating the bowel wall even when in normal condition. The bacilli, it seems, are constantly entering the blood stream from the bowel, and being there destroyed. The urinary tract was commonly infected through the blood stream; it was not however yet explained why the right kidney was more often affected than the left, nor why women are more liable to pyelitis than men. Experiment has shown that the healthy animal has an enormous resistance to the colon bacillus when introduced into the blood stream, and it is difficult to infect the urinary system in this way. Spread of infection took place from lower to upper parts of the urinary tract via lymphatics, and not by urethra nor ureter. Some authors discarded the terms pyelitis and bacilluria in the belief that in all cases there was some invasion of the kidney substance. Important in the ætiology were urinary obstruction and inflammatory lesions of the bowel and the abuse of purgatives. It had been suggested that the non-appearance of organisms in the urine after a dose of cascara might be used as a test of cure. Persistent bacilluria could result from foci of infection in the gall-bladder or appendix. The gall-bladder might be infected either by blood-vessels, lymphatics, or bile-ducts. Hurst has shown that the colon bacillus could grow in the duodenum and stomach when HCl was not secreted and when stomach movement was inhibited; these conditions favoured retrograde infection. Any abnormality which interfered with drainage from the gall-bladder and any focus of infection elsewhere—e.g., in the appendix—assisted in the production of cholecystitis. While the bacillus readily entered the blood stream, its persistence and growth there was a rare occurrence. Many alleged cases of coli septicæmia were in reality simply the overflow of bacteria from some local focus, such as the appendix or gall-bladder.

Prophylactic measures consisted in the avoidance of debilitating conditions and ensuring free drainage in the urinary and biliary tracts. Constipation should be treated, though severe purging was likely to aggravate an infection. So-called intestinal antiseptics were probably of little value; the best in this class were calomel and sulphur. Liquid paraffin and agar and high colon lavage were helpful. Protein and fat should be restricted in the diet. Prof. Lyon believed treatment with vaccines to have been disappointing, probably because a large number of different organisms were covered by the term colon bacillus. For the same reason there were difficulties in getting good results from bacteriophage or antisera. In the treatment of acute urinary infections the essentials were rest, warmth, and copious drinks; flushing of the urinary tract was held by many to be the most effective measure. Alkalis were helpful in the early stages; several hundred grains of potassium citrate and sodium bicarbonate could be given in the 24 hours. The urine should be kept alkaline throughout the day, and for several days after the temperature had come down to normal; but not long enough to cause depression. In children the urine should be kept mildly alkaline for some weeks, and in pregnancy alkalis should be given till the end of term. If alkalis fail to relieve, acid might be tried or alternate courses of each for seven to ten days. Acid sodium phosphate would usually convert alkaline urine to acid. Ammonium and calcium chlorides produced stronger acidity but were liable to cause nausea and to irritate the urinary tract. Hexamine, which acted by liberating formaldehyde in an acid urine, probably did no more than inhibit the growth of the colon bacillus. To avoid interaction before reaching the urine acid and hexamine should be given at different times; in acute infections this combination was too irritant to the urinary passages and should be avoided.

Many other antiseptics had recently been introduced —e.g., the dyes of the pyridine and the flavine series; in chronic cases a succession might be tried. For the resistant resort should be had to the ketogenic diet; it had proved successful in 50 per cent. of one series which had resisted other methods. Treatment of chronic biliary infections where surgery was not advisable lay in measures likely to increase the flow of bile, such as copious drinks, magnesium sulphate direct into the duodenum or by mouth. Its action was enhanced by a preliminary *injection of pituitrin.* Olive oil and sodium salicylate could be used as cholagogues. Hexamine was given, but its mode of action in an alkaline medium was difficult to explain. In coli septicæmia the urgent necessity was to search for a focus of infection.

Dr. Cuthbert Dukes (London) discussed his observations on a large series of cases which had had extensive pelvic operations, chiefly for rectal carcinoma. Although the renal tract was normal before operation, in a large proportion it became infected afterwards by the colon bacillus. Retention of urine was the most important factor. Minor defects of function, leading to a reduction of urea clearance to 40–50 per cent. of normal, or an increase in blood-urea to 50–60 mg., did not predispose to infection. Urinary antiseptics had no effect on the *course* of the disease; infection occurred just as readily when they were given prophylactically. Alkalis were found to have a *slightly* beneficial effect.

Dr. C. M. Wilson (London) had found the ketogenic diet superior to other methods in the treatment of chronic urinary infection. Of 100 cases, 12 failed; the remaining 88 were cured, but 15 relapsed later. With such a high proportion of *initial* successes it was a moot point whether or not a preliminary surgical overhaul was advisable or not. For a success there were two essentials: an intense ketosis, and a reduction of the pH of the urine to about 5. He advised a diet containing 300 g. fat, 10 g. carbohydrate, and 50 oz. fluid. The patient should not be kept in bed. The diet was kept up for at least one week after the urine became sterile. If the urine failed to give a positive ferric chloride test by the fourth or fifth day of treatment success was unlikely. Tests should be made morning and evening, as ketones might be absent in the morning specimen. Relapse might occur after some months; if then a surgical lesion could be excluded the treatment should be repeated.

Dr. Hinds Howell (London) said that using this form of treatment he found it very difficult to devise a diet containing less than 25 g. carbohydrate; or to get a urinary ketosis giving a pH of less than 5·8 and a strongly positive ferric chloride test. Ammonium chloride up to grs. 125 daily in addition to other measures might bring the pH down to 5. Avoidance of alcohol and vigorous exercise were important in preventing relapses.

Dr. E. P. Poulton (London) said he found a more marked ketosis to occur if more protein was given in the diet. Recently he had used calcium chloride (grs. 7½ six times daily in pill form) as an alternative to dieting.

Dr. W. H. Oxley (Poplar) said he found it difficult to get patients to keep to the diet, and asked if β-oxybutyric acid was the antibactericidal principle produced by the treatment; if so, it might be possible to get results by giving this alone.

Dr. Dorothy Hare (London) mentioned the capillometer as a simple method of testing urinary acidity. As a preliminary to treatment she believed X ray examination of the kidney after intravenous uroselectan was advisable, but the trauma of a surgical investigation might be detrimental.

Dr. E. H. White (Bournemouth) stressed the importance of large quantities of fluids by mouth in the treatment of the acute case. The free drainage of the renal tract thus produced was important in preventing acute infection from becoming chronic.

The Chairman classified cases of urinary infection into four groups: the acute case with and without obstruction, and the chronic case with and without *obstruction. He believed that by thorough treatment* of the acute case, without obstruction with much fluid and much alkali, there would be fewer chronic cases. More than 400 grains of alkali could be given daily, since it was extremely difficult to produce an alkalosis in a patient *with coli pyelitis.* It was, he said, easy to overlook an early acute pyonephrosis and the *possibility should be considered where the symptoms* were predominantly unilateral.

Dr. S. C. Dyke (Wolverhampton) mentioned two cases of so-called pyelitis which he had examined post mortem; in one case the kidney contained a septic infarct, in the other there were multiple cortical abscesses. He found that 50 per cent. of women over 50 had pus and colon bacilli in the urine, without symptoms. Did such people, he asked, need treatment; *and need anything be done for those showing* a simple bacilluria?

Dr. G. W. Goodhart (London) thought that the available methods for detecting the bacillus in the blood might be defective, and that actually a persistent slight bacteræmia might exist, due perhaps to a constant leakage of organisms from the rectum into the blood stream.

Dr. Wilson in reply said that unless the urinary *pH was reduced to less than 5·8* the ketogenic treatment would be ineffective. A very low carbohydrate intake was rendered possible by giving fruit.

Prof. Lyon said that good results could often be obtained by simple methods of treatment. The use of β-oxybutyric acid without carbohydrate restriction would, he thought, be of no value.

SECTION OF PATHOLOGY

At a meeting of this section, with Prof. J. W. Bigger (Dublin) in the chair, a discussion on

Œstrus-producing Hormones

was opened by Prof. E. C. Dodds (London). It was perhaps unfortunate, he said, that considerations of laboratory convenience had caused all the work on these hormones to be done on rats and mice, so that any discussion on them automatically called up a mental picture of small rodents. Active material had at first been prepared from ovaries by extraction with volatile solvents. Later the placenta had been found a useful source, and finally it had been discovered in the urine of pregnant women, where it was relatively uncontaminated and could be studied. The material was known to contain carbon, hydrogen, and oxygen, and at a later date was proved to belong to the sterol group possessing in common with them a partial hydrogenated phenanthrene ring system. The two most important forms of the hormone occurring in the urine are ketohydroxy-œstrin and trihydroxy-œstrin. Further interesting chemical compounds may be obtained by a process of hydrogenation of ketohydroxy-œstrin. The first of these, dihydro-folliculin, is many times more potent then the original substances. Still further hydrogenation leads to a compound resembling the male sex hormone. Other œstrus-producing substances have been found from natural sources. *Plants contain a compound called* tokokinin which has the same type of structure as œstrin. It has also been found that coal and certain mineral fuel oils contain œstrus-producing substances. According to some this power is due to the tokokinin of prehistoric forests, but other explanations are possible. Whilst ketohydroxy-œstrin itself has not yet been synthesised a series of synthetic œstrus-producing agents has been manufactured in the laboratory (Cook, Dodds, Hewett, and Lawson, 1934, Proc. Roy. Soc. Sec. B., cxiv., p. 272) and these are in the main derivatives of phenanthrene and dibenzanthracene. Vitamin D in very large doses was also capable of producing œstrus. Thus the naturally occurring œstrus-producing hormones were linked on the one hand with carcinogenic substances and on the other with vitamins and plant sterols.

All female animals responded to these hormones if enough were given, the response varying directly with the body-weight. C. Kaufmann had shown that the administration of œstrin with corpus luteum hormone produced menstrual changes in the uterus even of ovariectomised women. The results of his work had made it possible to state definitely that this natural phenomenon could be produced at will in castrated women. Enormous doses were necessary in ovariectomised women, but in animals a series of regular cycles could be induced after castration and then the amount required was nothing like so great as the initial dose. Much smaller quantities were necessary if the ovaries were present, and the changes might be produced by œstrin alone. Kaufmann had also demonstrated the typical picture of cystic hyperplasia of the endometrium produced by very large doses spread over several weeks. The practical application of this work was that the menses might be produced in cases of primary and secondary amenorrhœa. Very good results from 50,000 mouse units twice weekly had been reported in menopausal cases, and chronic inflammations of the vulva associated with the menopause and senility also responded well. Corpus luteum hormone controlled certain types of menorrhagia, and patients subject to abortion had been brought to term by its aid. The biochemist and biologist had placed an entirely new set of weapons in the hands of the practitioner.

Mr. A. S. Parkes, D.Sc. (London), said that the sexual cycles of all mammals had the same essential features: a phase characterised by the growth and ovulation of the Graafian follicle, and a second phase characterised by the growth of the corpus luteum. Œstrus-producing hormones were essentially associated with the first phase, and the changes characteristic of it could be produced by the injection of the hormone into ovariectomised animals: for instance, in the baboon, the perivulval skin showed extreme swelling. Œstrus-producing hormones sensitised the uterus to the action of progestin, which could not produce its effect unless the womb had been brought into the condition of œstrus by œstrin. Ketohydroxy-œstrin was stronger, weight for weight, than the other forms, but it was very doubtful whether there was any real biological difference. It was possible to say definitely that the œstrus-producing hormones would produce in the ovariectomised or inactive animal all those changes normally associated with the growth of the follicle.

Dr. H. Gardiner-Hill (London) said he had been able to use Prof. Kaufmann's extracts clinically. Two methods had been adopted: a series had been treated exactly as Prof. Kaufmann suggested; œstrin during the first half of the cycle and luteal hormone in the second half. Another series had been treated with œstrin alone. Four cases of anorexia nervosa with amenorrhœa and six cases of amenorrhœa otherwise normal had had the full course. Only one of the normal group had failed to respond. All the cases of anorexia nervosa had menstruated after treatment. None, however, had menstruated a second time spontaneously. Of five cases treated with œstrin alone two had anorexia nervosa. Three responded but the reaction was delayed. One patient had three further spontaneous normal periods. Two patients with primary amenorrhœa, aged 19, had also been treated; one had failed to respond at first but had menstruated after the second and third courses. The other had had four courses; there had been no menstruation, but definite puberal phenomena were appearing. The extracts undoubtedly controlled climacteric symptoms. A woman of 62, treated successfully for migraine, had begun to menstruate again.

Dr. J. M. Robson (Edinburgh) spoke of the effects produced on the uterine muscle. There was maximum activity during menstruation. Response to oxytocin was at its highest then, and also showed a marked fall at the onset of pregnancy. In the later stages of gestation there was a gradual rise. The dose required to produce contraction was the same in the mouse, the rabbit, and the woman. The reactivity was controlled by various factors, including the luteal and œstrus hormones. Œstrin injected into the ovariectomised animal would raise reactivity to the parturition level. Similarly, a pregnant animal could be affected by œstrin. There was therefore hope that the œstrus hormone might have value in obstetrics. A fairly high concentration of œstrin must be maintained. In woman it was fairly rapidly destroyed, so that dosage must be large and given at intervals of a few hours.

Dr. P. M. Bishop (London) described two cases treated. One woman had suffered severely from flushes after artificial menopause and had been greatly relieved by œstrin. A case of secondary amenorrhœa, lasting 18 months, had had a period ten days after the first injections and her uterus had shown typical histological changes. He described a method of diagnosis of pregnancy by extracting œstrin from the woman's urine and injecting it into an animal which had had an endometrium graft into the anterior chamber of the eye; the graft could be seen to blush under the influence of œstrin. The diagnosis could be given within three or four hours, and the test seemed worth following up.

Mr. L. C. Rivett (London) classed primary amenorrhœa and intrinsic dysmenorrhœa together as indications of failure of development. There were two classes of intrinsic dysmenorrhœa: the first type of girl had malaise, headache, and sickness rather than much pain, from the very onset of menstruation. This must be a hormonal disturbance. The second type only began to develop severe colicky pain after three or four years of normal menstruation and might be accounted for by some developmental failure of the muscle. From the clinician's point of view the accepted idea of the time of ovulation—12–17 days after the period—did not correspond with experience. He suggested that this ovulation was the discharge of a spent ovum, and that the only ovum capable of being fertilised was one released by stimulus of intercourse, as was known to occur in the rabbit.

Dr. Marius Tausk (Holland) spoke of the action of œstrin in males. It was normally produced in the testis and excreted in male urine. It acted on the smooth muscle of the male genital tract; the seminal vesicles underwent marked increase in size when castrated animals were injected with œstrin. A normal male so injected suffered retardation of development of the testis, probably via the pituitary. This result marked the effect on the secondary sexual elements. In addition to muscular growth of the vesicles there were epithelial changes, and there might be some connexion with the prostatic enlargement of old age. The male hormone counteracted the effects. Unfortunately there was a confusion of units of measurement of these hormones. Dimenformon was about twice as strong as the international standard, but its benzoate was about the same, so that 200 units given by Prof. Kaufmann was about the same as 200 international units. Slight impurities in a hormone might materially alter the biological effects, and hence dosage by weight was still far from practicable.

Prof. D. Campbell (Aberdeen) said that treatment of hormone deficiency by œstrin could only be replacement therapy, comparable with insulin or thyroxine. Real treatment might be attained by means of the gonadotropic substance produced by the anterior pituitary. He showed a series of slides illustrating this action, and suggested that it would be worth while to try the effect of small doses of anterior pituitary for therapeutic purposes.

SECTION OF PÆDIATRICS

With Dr. Hazel Chodak Gregory in the chair this section held a discussion on

Osteomyelitis

Prof. John Fraser (Edinburgh) said that a statistical survey carried out by C. P. G. Wakeley in the decades 1900–1910 and 1920–1930 seemed to show that osteomyelitis was a disappearing disease. There had been, however, a curious increase in the last year, as shown by the figures of the Edinburgh Royal Infirmary, where the figures for the decade May, 1924, to May, 1934, were :—

3 .. 4 .. 2 .. 3 .. 3 .. 4 .. 5 .. 7 .. 5 .. 12 (48 cases).

This increase, he suggested tentatively, might be due to the unusually dry summer.

After emphasising the fact that osteomyelitis was only a local symptom in a general septicæmia, Prof. Fraser discussed the question why the infection should localise itself so constantly in the metaphyseal areas of long bones. This localisation had been attributed to a profuse but rather stagnant blood-supply, to the tissue activities of rapid growth, and to exposure to trauma. His own view was that an explanation lay in the large amount of reticulo-endothelial tissue present, which a growing body of evidence seemed to show was one of the most important defensive mechanisms of the body. Turning to treatment he said that he was becoming more and more conservative. The gutter operation had proved disappointing ; diaphysectomy appeared wholly wrong in principle and he preferred a modification of the Starr technique, perforating the cortex of the medulla with a series of holes one-eighth of an inch in diameter at intervals of a quarter of an inch and lightly packing with an emulsion of acriflavine 0·1 per cent. and potassium citrate 2 per cent. in liquid paraffin ; the limb then being put up in a light plaster for 14 days. General measures included immuno-transfusion, but he had not had much success with sera. His mortality in these cases had been 23·2 per cent.

Mr. H. Tyrrell-Gray (London) said he was convinced that attention should be concentrated on the septicæmia ; he had entirely abandoned operative treatment and had only had one death in five years. He exhibited X ray photographs and charts illustrating the resolution of the bone lesions under the treatment introduced by D. N. Nabarro by means of intravenous injections of mercuric perchloride gr. 1/40-1/16 and intramuscular injections of antistreptococcal serum. Unlike Prof. Fraser he had found blood cultures positive in many cases ; he had also been struck by the fact that the secondary abscesses were always staphylococcal even when the primary lesion was streptococcal.

Mr. H. W. S. Wright (London) said he believed that osteomyelitis, like rickets, could be abolished if only enough care were taken ; he drew attention to the remark made by Sir Cuthbert Wallace, when this subject was last discussed by the Association, that it was primarily a disease of dirt. Bone localisation was often a late symptom of the septicæmia ; he thought Prof. Fraser under-estimated the mechanical factor in causing this localisation ; the work of Hunter on the different blood-supply of the epiphysis and diaphysis had been completely vindicated and stagnation at the cartilage must occur. He advocated early, accurate, and limited interference by means of small drill holes with the minimum of interference with the marrow. He agreed that the gutter operation and diaphysectomy were bad, but thought that plasters were often left on too long, and preferred the Carrell-Dakin treatment in some cases.

Dr. Leslie Cole (Cambridge), speaking as a physician, laid stress on the importance of a minute examination of the bones in cases of unexplained pyrexia and on the value of a four-hourly temperature chart, blood counts and blood culture in the differential diagnosis. He had not noticed the increase in cases mentioned by previous speakers, but there had been a similar increase in tetanus which he attributed to the dry summer. Serum had not proved of value in his cases, but a recent report from Berlin claimed that convalescent serum was of great value. He was interested in Prof. Fraser's theory about the part played by the reticulo-endothelial system, but felt that splenic complications should be more common if this were involved.

Mr. S. A. S. Malkin (Nottingham), speaking as an orthopædic surgeon, referred especially to the importance of preserving function. Both the gutter operation and diaphysectomy were unsatisfactory in this respect. In his opinion radical sequestrectomy was not performed often enough and in ten cases where this was done long-standing sinuses had cleared up completely.

Mr. W. A. Mein (Bournemouth) discussed the original focus of infection and said he had been much struck by the number of cases of acute infections such as appendicitis and osteomyelitis, which came on a year or two after removal of the tonsils. He advocated surgery and described the technique he employed. He believed irrigation to be of great value.

Dr. E. L. Goffe (Kingston-on-Thames) asked for further details of Mr. Tyrrell-Gray's methods.

Mr. Robert Kennon (Liverpool) expressed astonishment that a treatment so contrary to surgical principles should have been effective ; surely if pus were present it was the surgeon's duty to let it out. He demonstrated where to feel for points of maximum tenderness, and said that a great danger of immobilisations in plaster was the difficulty of diagnosing secondary foci.

Dr. F. J. Poynton (London) commented on the anxiety of most physicians to hand these cases to the surgeon, while the latter he now understood was returning them to the physician. Acute lymphatic leukæmia had, in his experience, been mistaken for osteomyelitis with disastrous results.

Mr. W. J. Eastwood (Liverpool) said that he was in favour of the gutter operation ; drilling had been unsatisfactory in his cases because the involucrum round the holes made subsequent sequestrectomy harder and the number of secondary abscesses increased, while the drill holes became clogged with discharge. The gutter should not be along the whole length of bone where the periosteum was stripped up as a good deal of this was the result of œdema.

Prof. FRASER, replying, said that this discussion, like the previous one, revealed that there was still no unanimity of opinion. He stressed the sharp distinction between the streptococcal and staphylococcal infections; the former killed quickly or not at all, while the latter frequently killed after a long time. His experience with mercury had not been satisfactory and he had seen albuminuria following its use. He had never been convinced of the effect of trauma as a cause. Difficulties in diagnosis between scurvy and osteomyelitis had occurred in his experience. He had gradually become more and more conservative in his methods and felt that Mr. Tyrrell-Gray's work was on the right lines.

Mr. TYRRELL-GRAY, replying to questions, stated that the details of treatment could be found in the published work of Nabarro. In his experience the staphylococcal or streptococcal nature of the infection did not matter; in five years he had only had one death and no case of sequestrectomy. He preferred mercuric perchloride to mercurochrome and had seen no signs of poisoning except gingivitis. In some cases treatment had lasted as long as six weeks with intravenous injections given every other day; other cases required daily treatment. He was confident that the death-rate could be greatly diminished by conservatism.

SECTION OF OPHTHALMOLOGY

THE President, Mr. LESLIE PATON (London) being in the chair, Mr. A. D. GRIFFITH (London) opened a discussion on

Headaches

Speaking as an ophthalmologist, he said that 24 per cent. of his private patients came to him because of headache. The history of the headache helped him to determine whether it was of ocular origin. He first paid attention to the situation of the pain; ocular headache was generally (60 per cent.) frontal or orbital ("pain behind the eyes"), more rarely it was occipital or temporal, almost never vertical. The time of onset was also of importance. Ocular headache comes on at the end of a day's work, though it may be present as an early morning headache following the misuse of the eyes on the preceding day. The delay in the onset of headache is illustrated by the week-end headache—probably due to the fact that the patient makes every possible attempt to carry on during the week. The mechanism of headache was seen at its simplest in hypermetropia; tonic contraction of the ciliary muscle is a permanent condition in these cases and is exaggerated by close work. Muscular fatigue is thus induced. The hypermetrope with an unequal error in the two eyes has to exercise an unequal degree of accommodation. In astigmatism unequal contraction of the ciliary muscle is brought into action to neutralise the corneal astigmatism by inducing lental astigmatism in the opposite direction. This mechanism may be overdone, producing an artificial astigmatism in the contrary direction to the original error. The question of contraction of iris muscle as a cause of headache was, he thought, debatable. The earlier cinemas were more productive of headache than the modern ones. The abolition of flicker, the reduction in the size of the screen, the maintenance of a certain amount of general illumination, and the long corridors with gradually diminishing intensity of illumination, all tended to diminish excessive action of the pupil. In considering headaches due to abnormalities of the extrinsic muscles of the eye, he stressed the dangers of over-correction. Vertical imbalance is more productive of discomfort than horizontal. As a rule it was the poorer eye which tended to deviate upwards; when the two eyes were of equal refraction the hyperphoric eye was usually not the "master eye." In correcting heterophoria, he did not rely so much upon the Maddox rod as upon a simpler plan. The patient is made to gaze on a distant spot of light with a red glass before his right eye and a green before the left; if the red and green lights are mixed together his heterophoria does not need correction by prisms; if he sees the red and green separate the weakest prism which will enable him to mix them is to be taken as the maximum to be prescribed. In occipital headache the pain was referred from contraction of the frontales muscles caused by the attempt to screw up the eyes; the pull is transmitted along the epicranial fascia to the occipital muscles.

Dr. WILFRED HARRIS (London) contributed a paper on headaches in relation to ocular conditions. In the past, he said, it was usual to ascribe headaches to rise of intracranial pressure and to explain migraine as the result of influences, such as pressure acting upon the recurrent meningeal branches of the trigeminal nerve supplying the dura. Yet large areas of the dura were insensitive to surgical manipulations, whilst the sympathetic nerve supply was of doubtful significance in the conduction of pain. Clinically there was no doubt that a sudden rise of intracranial pressure does produce violent headache. This is seen in subarachnoid hæmorrhage, and in distension of the ventricles. General distension causes pressure which is transmitted through the cerebral substance, and it is an open question whether the pain thus produced is due to irritation of the meningeal nerves or of brain tissue itself, such as the thalamus. Speaking of migraine, there was, he said, little doubt that in the preliminary stage (aura) there was arterial constriction; narrowing of the central artery of the retina had been observed, followed later by throbbing and dilatation of the vessel. This fact suggested that a similar constriction of the cortical vessels, especially in the occipital region, might be concerned in the production of the hemianopia or of the scotoma scintillans, and the subsequent headache due to engorgement of the vessels and cerebral compression therefrom, the vomiting itself being suggestive of intracranial pressure. True migraine, he said, rarely had any direct connexion with ocular conditions. Migraine was a periodic headache, coming on at irregular intervals, of variable duration, generally associated with nausea and vomiting, together with sensory disturbances such as aura, scintillating scotoma, hemianopia, tingling along the lips and tongue, sometimes a temporary aphasia and weakness of an arm, rarely the leg. All these were obviously cerebral effects, totally different from the headache of refractive conditions. Often there was a family history of migraine, and other neuroses might be present in the family. Speaking of headaches of ocular origin, Dr. Harris pointed out that a difference in apparent size of the images perceived by the two eyes with a consequent difficulty in stereoscopic vision, has been recently advanced as a cause. He enumerated the conditions affecting the interior of the eye which caused pain and stressed the persistence of neuralgia in cases of herpes ophthalmicus. In particular he drew attention to the headache of cerebral arteriosclerosis, which the ophthalmologist can recognise by the changes in the retinal vessels. Such headaches were apt to be more severe at night. One pitfall, which was apt to send the patient from one specialist to another, was the pain in the condition he had described as maxillary neurosis. This was a chronic neuralgia of the jaw. In many cases the pain had started after severe dental extraction, and being unilateral was thought to be due to some piece of decayed stump or diseased bone. There often was complaint of flushing over the cheek, and though all the teeth might be removed, the antrum washed out, turbinal bones removed and glasses prescribed, the pain continued unabated. It was not paroxysmal or tic-like in character, but more or less persistent, though varying during the day. No operative treatment was of any value, and alcohol injection should be refused.

Dr. C. Worster-Drought (London) spoke of headaches in relation to ocular conditions from the standpoint of general medicine. Of 158 cases he had seen for persistent headache, no less than 78 were suffering from migraine, 16 had apparent cerebral arteriopathy or hyperpiesis without any evidence of nephritis, 4 had chronic nephritis. A group of 16 cases had no demonstrable organic condition, their general behaviour justifying the diagnosis of neurosis. Other groups were smaller: cerebral tumour, 8; occipito-cervical fibrositis, 6; gastrointestinal disorders, 4; effect of head injury, 4; error of refraction not adequately corrected, 3; high myopia with persistent headache in spite of constant use of glasses, 3; diabetes mellitus, 3; accessory sinus disease, 3; spontaneous subarachnoid hæmorrhage, 3; unsuspected chronic encephalitis, 2; pyorrhœa, 2; masked hyperthyroidism, gross deflection of nasal septum, and pelvic disease (tuberculous tubes found at operation), 1 each. In migraine he was satisfied that refractive errors played little or no part. Cerebral arteriopathy was apt to be overlooked, especially when the blood pressure was not unduly raised. In these cases the headache might be of an intermittent "bursting" character (a type usually associated with hyperpiesis); pain of a "numb" character might also be complained of, together with a lack of "clearness." Dizziness was a frequent symptom. A point to be stressed was the fact that the state of the palpable arteries and even the height of the blood pressure was no criterion of the condition of the arteries of the central nervous system. Hence the value of an ophthalmoscopic examination. In persistent headache associated with high myopia the provision of apparently suitable glasses generally failed to give relief; no other cause for the headache could be found and use of the eyes aggravated the pain. The headache was fronto-occipital in distribution, practically continuous, present on waking in the morning, and worse as the day advanced. Headache from accessory sinus disease, in the experience of the general physician, was not common. His cases of spontaneous subarachnoid hæmorrhage all complained of headache, usually occipital, but intense backache, pain in the neck, general pain or delirium was the predominant symptom. Apart from retinal arteriosclerosis in the elderly subjects, the most common ophthalmological finding in these cases was blurring of the margins of the discs, especially on the nasal side, and occasional small retinal hæmorrhages.

Mr. Maurice Sorsby (London) said that to the rhinologist headaches were a case of empty barrels making the loudest sound, for it was largely the air-filled sinuses which he had to incriminate. The anatomical basis was not the empti

forms of headaches was to be explained on the nuclear distribution of the Vth nerve. One form of headache which was puzzling to him was that seen after lumbar puncture. A grave form was that seen in patients under 40 suffering from hyperpiesis and showing soft retinal exudates. He agreed with Dr. Harris that there was no true migraine except with prodromal symptoms; migraine with vomiting seemed to constitute a distinct entity.

Mr. STENHOUSE STEWART (Hull) stressed the significance of muscle imbalance in headaches and discussed the methods to be employed in the prescribing of prisms.

Mr. A. J. BALLANTYNE (Glasgow) attached importance to imbalance, but pointed out that the nature of the patient's work was a deciding factor in precipitating the headache. He drew attention to the development of astigmatism against the rule with advancing years.

IRELAND

(FROM OUR OWN CORRESPONDENT)

CRIMINAL LAW AMENDMENT BILL

A FEW years ago the late Government of the Irish Free State appointed a small committee, containing representatives of the professions of the church, law, and medicine, and some social workers, to consider the existing laws governing the relations of the sexes, and make, if thought fit, recommendations for amendment. A report was submitted by the committee, but, for some reason which has never been stated, it has not been published. The Criminal Law Amendment Bill, which passed its third reading in the Dáil last week, is said to be based on this report, although in many points it is believed not to be as far-reaching as the committee desired. The most important changes proposed in the Bill concern the "age of consent," the suppression of prostitution, and the sale or importation of contraceptives.

By previous Acts it was a felony to have unlawful sexual knowledge of a girl under 13 years, and a misdemeanour to attempt to have such knowledge. In the present Bill it is proposed to make the age in each case 15 instead of 13. By previous Acts it was a misdemeanour to have or attempt to have unlawful sexual knowledge of a girl above the age of 13 years and under the age of 16 years. It is now proposed to make the ages 15 and 17. The "age of consent" will, therefore, be 17 if the Bill should become law. The period during which a prosecution for this offence may be commenced is to be prolonged from 3 months to 12 months. Section 16 of the Bill deals with solicitation, and Subsection 4 runs as follows:—

> "Every common prostitute who is found loitering in any street, thoroughfare, or other place and importuning or soliciting passers-by for purposes of prostitution or being otherwise offensive to passers-by shall be guilty of an offence under this section and shall on summary conviction thereof be liable, in the case of a first such offence, to a fine not exceeding £2, or, in the case of a second or any subsequent such offence, to imprisonment for any term not exceeding six months."

This clause is modelled on a local Dublin police law. An amendment to substitute "person" for "common prostitute" was rejected.

The section of the Bill which has given rise to most interest, and has indeed most importance to the ordinary citizen, is Section 17, which provides for the prohibition of the sale and importation of contraceptives. It declares that "it shall not be lawful for any person to sell, or expose, offer, advertise, or keep for sale or to import or attempt to import into Saorstát Eireann for sale, any contraceptive." An offence under this subsection will be punishable by a fine not exceeding £50 or to imprisonment for not more than six months or to both such fine and such imprisonment. Moreover, contraceptives are to be deemed to be included among the goods included in the Table of Prohibitions and Restrictions Inwards in Section 42 of the Customs Consolidation Act, 1876, and the provisions of that Act (as amended or extended by subsequent Acts) shall apply accordingly. The word "contraceptive" is defined as meaning "any appliance, instrument, drug, preparation or thing, designed, purposed, or intended to prevent pregnancy resulting from sexual intercourse between human beings."

These provisions of the Bill gave rise to some criticism in the correspondence columns of the daily press, but were criticised in the Dáil by only one member, a medical deputy. He pointed out that, rigorous as the section appeared to be, it was unlikely to stop the traffic in or use of contraceptives but might readily drive the trade underground. In so far as the provisions might be effective they would probably lead to an increase of such crimes as criminal abortion and infanticide. It was recognised that the moral judgment of the majority of the people of Ireland condemned as immoral the use of contraceptives as a measure of birth control, but there were many people who did not share that view. It was neither practicable nor just to impose the moral views of part of the population by statute on a minority In certain cases, by no means rare, a virtuous married woman was faced with the advice that a pregnancy might endanger her life or gravely prejudice her health. She had at present the alternatives of abstention from marital intercourse and of contraceptive precautions. Abstention might be almost impossible in some cases, and if it were attained might lead to grave nervous disturbances and unhappiness to both wife and husband. To deny the other alternative was unjust to those whose consciences allowed them to adopt it. Notwithstanding this protest the section was carried and remains part of the Bill.

It is not clear that the Bill makes any real advance in the protection of young girls, while, on the other hand, it appears to open a wider door to the practice of blackmailing. Indeed, the notion underlying the Bill seems to be that the male is always the aggressor. Many girls of 16 to 17 are, however, precocious, and it is probable that in most cases of licentious conduct between boys and girls of the same age it is the female who seduces the male. A young lad of 16 found guilty of carnal knowledge of a girl of the same age will be liable to a sentence of penal servitude, while the girl who may have been the tempter has committed no offence known to the law.

IRRADIATION IN UTERINE CANCER

Dr. Simon, reporting from the first gynæcological clinic of Vienna University, at a recent meeting of the Gesellschaft der Aerzte, reviewed the results of cases treated by irradiation at that clinic in the years 1926–28. Of 10 patients with cancer of the cervix, belonging to the group I. or II. of the usual classification, 4 are still alive and without symptoms, having had only primary irradiation. Of the inoperable cases (group III. or IV.) there were 110 under treatment, and only 14 of these are alive and without symptoms. Operations followed by irradiations were done in 115 cases, of which 49 per cent. can be deemed cured. The frequency of recurrences in irradiated cases is 12 per cent. in the second year of observation and 9 per cent. for the third year, whilst it is 6 per cent. in cases with post-operative irradiation. It is not feasible, however, to compare these two groups of patients, for they were chosen from different standpoints. Of 5 cases of cancer of the vulva treated by irradiation 1 only was cured; of 11 of cancer of the vagina 2 were cured; of 11 of cancer of the corpus uteri 3 were cured; of 23 cases irradiated after operation 19 were cured; and of 14 cases (not operated on) with cancer of the ovary 1 only was cured, 2 being improved. It appears that the second and third years show the highest figures of recurrence.

In a report from the radiotherapeutic institute of the city of Vienna, presented at the same time, Dr. Schloss gave the results of observations based on a two-year term; they had 96 women with malignant disease of the sexual organs, verified histologically. Primary irradiation resulted in 68 being alive after two years; only 46 are without symptoms, 6 are doubtful. At this institute also, groups I. and II. gave good results, group III. gave about 35 per cent. cures, and group IV. no cure at all (cancer of the cervix). With cancer of the corpus, the vagina, or the vulva the results were very much like those of Dr. Simon. Prof. Adler emphasised the excellent effects obtained by the combined method of operation followed at once (on the operating table) by X ray or radium therapy. Up to 36 per cent. five-year cures have thus been obtained, whilst operative mortality of the "extended vaginal radical operation" of Wertheim-Schanta is only 3 per cent.

A VENERABLE HOSPITAL

In August the well-known Allgemeines Krankenhaus, or general hospital, of Vienna, which for so many years—indeed, generations—was the Mecca of students of medicine from all parts of the world, will celebrate the 150th year of its existence. It was founded by the Emperor Joseph II., who was at that time (1784) considered the most advanced and liberal ruler, and was almost the originator of democratic ideas in Central Europe. The jubilee festivities, however, will not be held this year; on account of the difficulties now prevailing in Central Europe—of all sorts and kinds—it is intended that the August celebrations shall be purely domestic, and that the proposed meeting of former pupils of the hospital shall be postponed until next spring. Invitations for this meeting will be sent out to all the professors and students whose names are known, and the Government, as well as the medical faculty of Vienna, will do their best to make the affair a real success from every point of view. It is interesting to note that the building practically reached its present size 150 years ago, when it was first erected. Only a few additional extensions have been made in later years within its spacious *Hof* (garden-grounds), among them the famous tower-like building for the care and cure of the mentally afflicted, called *Narrenthurm* (fool's tower), an outstanding feature of the hospital. The old general hospital, with its 1800 ordinary beds and 600 reserve beds, is now in close connexion with the "new" hospital, where the splendid clinics for materia medica, rhino-laryngology, children's diseases, surgery and obstetrics, and neurology are located. Gradually the old hospital, which outwardly retains its antique appearance, has been inwardly transformed into a modern fully equipped institution.

POLAND

(FROM OUR OWN CORRESPONDENT)

THE FLOODS

THE recent floods have been worse than any for over a century. Whole villages have been destroyed, fields are lying covered with ruined crops, and there are people who have lost everything they possess. Financial assistance is being organised, but there is still another misfortune which threatens these unfortunate people—the outbreak of an epidemic. With this in view preventive measures have been carried out since the beginning of the floods by the department of health of the Ministry of Social Service.

The Minister and the head of the department of health paid personal visits to the flooded provinces in the early days of the disaster so that they might the better judge of the situation and decide on the steps to be taken. The department is in touch with the flooded areas by telephone and wireless, and has been able immediately to take steps to cope with new developments. All the chief officials of the department and their sanitary inspectors were sent to help in the work of rescue, and leave was cancelled for all members of the administration of the sanitary service who might help on the local rescue committees. Even the general practitioners of the districts were mobilised and sent to the flooded regions. The population were forbidden to drink water from rivers or wells which had been muddied or contaminated, and warnings were issued against drinking water or milk which had not been boiled. Good drinking water, which often had to be brought from a distance, was distributed among the people.

When the floods had subsided the purification and disinfection of the wells with chlorine or with lime was ordered. Houses which had been covered by the water were dried and whitewashed, and the carcasses of domestic animals were buried to prevent the people from eating the contaminated flesh. Propaganda for personal hygiene was carried on by medical hygienists, and parties armed with suitable apparatus were sent round to disinfect salvaged goods and chattels.

Inoculation against typhoid and dysentery was made compulsory and administered without fee, and in one week 8500 people were vaccinated for typhoid and 45,000 for dysentery. The State Institute of Hygiene had considerably to increase its output of vaccine. A service of ambulances which patrolled the districts was organised; the number of beds in the existing hospitals was increased, and new ones were improvised to accommodate all the sick. During the last few days a mild epidemic of common gastro-enteritis of short duration has been reported, principally among children, but so far there has not been a single case of dysentery or typhoid. It seems that the battle against epidemic diseases has been won.

ROYAL EAST SUSSEX HOSPITAL.—On July 14th Lady Willingdon opened a new nurses' home at this hospital. It was originally proposed to build a home near the hospital, but the large premises and grounds of a school nearby became vacant and the premises were acquired, reconditioned, and adapted at a cost of £25,000.

CORRESPONDENCE

CORONARY THROMBOSIS AND AFTER:

A PERSONAL STORY

To the Editor of THE LANCET

SIR,—This is not a scientific communication. erhaps for this reason an apology may be considered ecessary but much more must the writer ask pardon s it is an account of a personal experience in the rst person singular.

Five years ago at the age of 54 I was engaged a busy consulting practice. My work was exacting nd irregular. Long distances had to be covered by ar and I mostly drove myself and I was overweight and was putting on weight. I was smoking heavily—cigarettes, pipes, and cigars. At the week-ends I used to take violent exercise with the idea of keeping fit. One Sunday morning in June I turned a back somersault on the lawn. The best description of what happened afterwards is that I felt "queer" and I felt it necessary to lie still for some minutes. The same afternoon I played tennis and was conscious of an occasional tightness in the chest. The same night about 1 A.M. I was awakened by a severe pain across the lower ribs and epigastrium. As I gradually became more awake I thought I was starting an attack of gall-stone colic or pancreatitis, but in a short time the pain became more localised and was substernal about the level of the third and fourth interspace. It crossed my mind that the pain was cardiac, and I diagnosed a coronary thrombosis and waited for the next thing to happen. It is difficult to describe the pain as my sensibility was numbed after a time. But it was a gradually increasing pain, and I said to myself, "This can't go on much longer." All the time it was strictly localised. My mental attitude was strange. It seemed that it was happening to someone else. After a time I became restless and got out of bed. I was filled with curiosity and went to my dressing room and looked at myself in the glass. My face and brow were covered with sweat, the general colour was grey, and my lips blue. I said to myself: "This is shock, I need morphia." But as I had none I poured out some chlorodyne. I then thought that my last patient with this condition had been sick and I prepared myself to vomit but nothing happened. I then took the chlorodyne and went back to bed. For the first time I felt my pulse and it was very slow, but increased in rate as I became warmer.

Next morning I had almost forgotten about the attack and thought it was indigestion, but a return of the pain on attempting to do my exercises, and even with the effort of dressing, made me think differently. I then started the day's work and, as far as I can trace my actions, did it in much my usual way. I had a long country journey to a consultation, and I allowed my chauffeur to drive—which was unusual. The next few days passed in the same way, though two events are to be noted. I had been intending to have a doubtful molar out, and the extraction under local anæsthesia took 45 minutes' hard work; there was an abscess around two of the apices. I was none the worse for it—in fact, I felt better soon afterwards. The other event was an unpleasant committee meeting at the hospital. I had to speak, and said what I wished, but I brought my remarks to an early finish as I had pain. On sitting down my pulse was 140.

I asked a colleague about this time to take my blood pressure, and he found the systolic pressure was 96, the normal figure being 150 or more. At times I felt certain that the condition was cardiac but I would attempt to persuade myself that it was not so. I wrote to a friend who is a cardiologist and described to him as light-heartedly as I could what had happened. He wired "Go to bed." I compromised and gave up work and lay in a long chair in the garden. It was the time of Wimbledon, and I listened to the running description of the matches, but I found that the excitement brought on pain. I therefore collected a lot of books that I wished to read, but I hardly read a page as I promptly went to sleep. After ten days I was taken by road to see a cardiologist and an electrocardiogram was taken. I examined it and saw that the T wave was inverted in Leads II and III. I then consented to go to bed and stayed there a month. The time passed very pleasantly, as the weather was beautiful and from my bedroom I could see for many miles. With field glasses I could keep myself entertained, but reading was only possible for short periods. There was only one unpleasantness during my stay in bed. I was much bothered by premature beats and irregularities. I tried to repeat my own teaching about them. "They are of no importance except in so far as they are accompaniments of definite serious disease, they call attention to themselves and are fussy." But it did not work as it should. Another tiresome irregularity was a waning of the pulse. A wave of gradually lessening pulsation would set in and go on until the pulse was imperceptible. I was conscious of it without feeling my pulse. The sense of emptiness and of being nothing at all is indescribable. I used to wave my arms about to bring back the circulation. Finally I argued that I was too sensitive to my peculiarities, and in this I was right, for a mixture of chloral and bromide improved matters. The irregularities probably occurred but were not noticed.

The next event was the removal of the family to the seaside in August. I cannot say that I enjoyed it at first, chiefly because I missed my home comforts. But one afternoon I was alone on the beach with my younger child and she said, being in her bathing dress, "Daddy, do bathe, and then I can." The sea was inviting and the day warm, and the surf looked exhilarating. I went in under a breaker wondering what would come up. The change was miraculous. I came out feeling fit and strong and ready to run up the beach. After that a daily bathe improved my general and cardiac condition enormously. In September a second electrocardiogram was done, and the T wave in Lead II was the right way up. In Lead III it was inverted but I did not mind that.

After that I went back to work, cutting it down as much as possible. But it is only possible for a doctor to give up hospital work or similar work. If one refuses private work there is shortly none to refuse. For a year there was a constant endeavour to do as little as possible, but as private work went on increasing the only ways out of the difficulty were either to retire or start afresh elsewhere. The former meant being a bored invalid on a reduced income and therefore was not seriously considered, so 18 months after my cardiac accident I migrated. In my new surroundings I did nothing for three months, and enjoyed myself in simple pleasures such as sight-seeing and in doing things that are impossible in a busy professional life. Then becoming restive I took a consulting room and gradually collected practice once more. I now do all the work that comes my way, and I live an ordinary life, being now in my sixtieth year. I play a little tennis of the family kind, I punt at my own pace, I swim, occasionally I dance. Each winter I go to the Alps for winter sports, and can climb on skis as well as run down, though I must confess that each winter finds me more of a rabbit.

Of course, I have cardiac sternal pain on occasions, but I have learnt to avoid it to a great extent. It is not so much the product of effort as of mental disturbance and/or a full stomach. The conditions in which the sternal pain is likely to come on become recognised and thereby avoided. An ordinary breakfast for me is a mistake if I have to work soon afterwards. Fruit, toast, and marmalade are almost a guarantee of a comfortable morning. About 11 o'clock I can do anything. I can walk quickly and in comfort, and I can tackle anybody about anything. Lunch is a light one, and is not upsetting. Tea is given a miss and dinner is variable. At home I have a short and almost teetotal meal, but I have no fads if I am dining out or have friends to dinner.

Tablets of nitroglycerin, gr. 1/100, are a great help. If taken before exercise pain does not come on or is lessened. If the pain is on, a tablet slowly sucked will drive it away. Further the knowledge that there is a supply in my pocket helps to keep pain at a distance. How nitroglycerin acts may be known to pharmacologists. In my case the first event is a good belch, followed by relief of some of the pain, possibly attributable to relaxation of spasm of the cardiac sphincter. It is curious that I have a great desire to suck lozenges. Anything will do, but I prefer a mild eucalyptus lozenge of a popular make. It is certain that with me one attack of pain in the early part of the day makes it easier for other attacks to follow. Nitroglycerin is invaluable in preventing these unpleasant happenings. Also bromides are useful, especially when some tantalising exhausting patient or telephone operator has been a nuisance. After an attack of pain ten minutes sleep in a chair is the best preventive of another.

Effort by itself can bring on pain and it is very selective. For example, digging is easier than shovelling. Walking with someone whom I do not know well, and to whom I do not wish to explain my peculiarities, is more trying than walking alone. The fear of pain coming on is likely to bring it on. Struggling to my seat when late for a theatre is sure to bring it on. I have learnt to miss trains without trying to catch them. I only board stationary buses, and I take a taxi and do not walk anywhere if I am late. Being fussed is a more potent cause of pain than effort, and when fussed effort is impossible. The following incident is a good illustration. Being a casual backer of horses, one day I backed two by telephone and doubled them. At my club, to my surprise, I found that both had won and at long odds. I suddenly wondered if the telephone message had been correctly received, and started to walk the half mile, some of it uphill, to the bookmaker's office. I had to stop four times on the way and on arrival could not manage the stairs to the first floor office. However, when I opened his door his first words were: "Well, doctor, that was a very pretty double you had to-day." I walked home at four miles an hour and without pain. This trivial incident shows very conclusively how much bunkum there can be in effort pain—at any rate in my case. But bunkum or not, the pain is real and insists on being respected. The lesson to be learned is the importance of a calm and tranquil attitude of mind, which is of even greater importance than a comfortable stomach.

Sunshine and all that it brings make pain disappear. In Switzerland for winter sports I can ski and skate quite comfortably. My performances are not what they were but I do not need to avoid expeditions on account of my condition. The only time when I had a tiresome pain was when a party of us were doing an expedition on a dull day and had to be at a certain point at a certain time in order to get a lift back. This entailed going against the clock and I had to stop. I have not done any shooting in the last few years as keeping line and being at a particular stand at the right time might be awkward. But I have waded in a salmon river and used a 16-foot rod. Driving a car is easy, but when tucked away deep in a car park the heavy work of turning the wheel to and fro is likely to bring on pain. When pain brings me to a standstill it goes on and becomes more severe for 10 or 15 seconds and then gradually goes off. It would seem that slowing of the heart at first increases the pain. With nitroglycerin, however, this symptom is not noticeable.

If there is any value to any sufferers from minor degrees of cardiac pain in what I have written it will be very gratifying to me. My advice to any who have similar symptoms is as follows: do not be upset by it; do not test yourself to see what you can do; take everything calmly and in your stride and if the pain catches you rest and suck a nitroglycerin. Regulate your life as regards meals and movements after meals. Do not be strict about diet but be sensible; do not become a valetudinarian; keep your weight down and do not smoke much—better do not smoke at all. Follow your inclinations and you will learn how much is easy for you; adopt the philosophy of the "lower level of activity" and you will find with surprise how little there is that you cannot do; remember the three things to consider in the order of importance are mind, stomach, heart.

Lastly, it is of interest that the managing director of a well-known insurance company said to me recently: "We find we can safely take the load of such heart cases as yours, as their lives are as long or longer than those of so-called normal individuals, because these heart patients have learnt to regulate their lives."—I am, Sir, yours faithfully,

July 30th. LEARN AND LIVE.

GOLD SALTS IN ASTHMA

To the Editor of THE LANCET

SIR,—Some time ago, without knowledge of any previous attempts of the same kind, we started treating cases of bronchial asthma with Sanocrysin in small doses. We were surprised to find that in every case the asthmatic attacks ceased after the first, and sometimes after the second, injection. The bronchitis also improved; so much so, that all adventitious sounds disappeared and wheezing and tightness of the chest between the attacks were banished.

Our cases may be divided into two categories, according to whether they were treated in my section at Kasr-El-Ainy Hospital or in my private practice. During the last ten months I have treated in my private clinic 55 cases of asthma, of duration varying from a few months to 14 years. All but three of these cases ceased suffering, and even these showed slight improvement. Five of the cases were purely allergic and showed no chest signs between the attacks. The rest were all bronchial. About 20 were of the seasonal type, which made me choose to treat them during the period of illness; the rest had attacks all the year round.

At the hospital there have been 46 cases in all, f which did not come back after the first injection l could not be traced. A first series of 18 cases (11 them continuous, 4 seasonal) were treated as patients, with the result that 15 were cured and other 3 improved. The second series of 28 cases re treated as out-patients. Three of these, as eady stated, did not come back after the first jection; 10 cases of seasonal asthma were all red; 15 cases of continuous asthma showed 3 lures and 12 cures. In all the above cases tuberlosis was excluded by radiography of the lungs and peated sputum examinations.

The sanocrysin is given by intravenous injection ice a week, beginning with a small dose of 0·05 g. d gradually increasing it by 0·05 g. each time. sually not more than five injections are given. nprovement appears after the second injection; the bronchitis disappears at the end in most of the cases.

Certain precautions, however, should be taken in adopting this method of treatment. First, the kidneys and liver must be sound. Examination of urine before every injection is imperative, for even if the kidneys are healthy at the beginning the gold compound is capable of producing acute nephritis; though, happily, with the small doses we have used we have had no cases developing this very unwelcome complication. Sometimes fever appears from 6 to 24 hours after the injection; but it is of short duration, not exceeding two or three hours, and the temperature never rises beyond 38° C. (100·4° F.). A very few cases have developed dermatitis, but it was so slight it was not even remarked by the patient. After the first injection the bronchitis was usually accentuated. Three patients developed slight albuminuria, but this ceased in a few days and treatment was resumed. I found that by putting the patient on a salt-free diet for three days, including the day of the injection, all these complications were obviated.

In conclusion, I may say that I have gone through all the available international literature on the therapeutics of asthma and have not found that anyone has treated the uncomplicated non-tuberculous disease with our method. In 1932 Dr. A. Dudan reported on 20 cases of tuberculous asthma treated with gold injection of which 17 cases were cured and 3 improved (Schweiz. med. Woch., 1932, lxii., 96).

I am, Sir, yours faithfully,

G. P. G. SOBHY.

Cairo, Egypt, July 16th.

THE CAUSE AND PREVENTION OF MALIGNANT GROWTHS

To the Editor of THE LANCET

SIR,—Our knowledge of the ætiology of cancer is steadily advancing through the long efforts of earnest workers, and prophylactic measures are now being suggested, though some still hold that preventive ideals are as yet only dreams of no scientific value. All, however, recognise the important part played by long, grave irritation, while to me cytology seems to point to a poisoning germ being present and converting into actual cancer a tumour or other local disease previously non-malignant. This is a clinical view. Long experience has led me to the opinion that "cancer is a putrescence, which, having entered into an animal by being swallowed or inhaled, or more rarely having been formed within the patient, finds a weak place in the body, where the blood is unable to cope with it, and, modified by its organic involvement, continues its putrefying career, meeting with resistance, which it finally overcomes, the victim failing through slow putrescent poison." In many cases, however, cures are effected through promptness in diagnosis and wise choice of early treatment.

I had not been long engaged in practice—say 50 years ago—before I was forced to the conclusion that the truth about cancer was not what I had been taught. Our instructors used to teach us that tumours were innocent or malignant, and that they did not change from the former to the latter. Having doubts about this view, I was glad to note that others were forming similar opinions; and soon the name *pre-cancer* began to be given to a weak spot susceptible to infection—a wart, adenoma or other growth, hitherto benign, or a fissure, ulcer, or any site of chronic inflammation. It early suggested itself to me that, as the tendency of cancers was to ulcerate with offensive discharges, the infection in pre-cancer was itself a product of putrescence. If so, what is the other contributing element, locating the position and bringing about the beginning of a cancer? What is the genesis of the first malignant cell? The answer seems to be a previously non-malignant cell becoming unable to resist the putrescent poison, because the blood of the immediately local circulation has lost its power to adequately oxidise and by phagocytosis destroy the invader. The putrescence, having got into the patient, ramifies through the body, and, though beaten off by the vitality of the individual everywhere except in the pre-cancerous place, poisons the latter which is too weak to resist it, and thus is accomplished the beginning of malignancy.

Whether or not the germs of cancer are specific has yet to be proved; but I submit it is possible that one, or more than one, of the vicious germs, already known to us, may so poison a cell in a weak place as to forthwith make it malignant. The point is that lack of power to resist the entering toxin enables the infecting germ to start the change, thus altering the pre-cancer into a malignant growth. If the entering poisonous germ has in itself malignant properties they are not destroyed in the pre-cancer, as they are by the blood, wherever the tissues are healthy, and the same equally applies if the first malignant cell is an embryological freak created by the union of the infecting putrescent germ with one of the cells of the pre-cancer. There appears to me to be nothing unlikely in a putrescent invader causing gastro-enteritis in one person and possibly no complaint at all in another, yet in a third case so poisoning a pre-cancer as to change into a malignant cell one that had been hitherto innocent.

Nature physiologically provides the inhibition of cell growth beyond what is required for the maintenance of health or repair of wounds and injuries, but in a limited area, where this natural power of inhibition is pathologically lost, a cyst or other tumour may grow, often started by a very slight cause. This cell proliferation is primarily quite a separate thing from cancer. Pressure and lack of maintained nutrition may cause in certain tumours necrotic changes which, though fatal in their own way, are neither sarcoma nor carcinoma. The excessive activity of oxygen in the blood of young persons, even in inflammatory and weakened parts, is probably the explanation of their generally escaping malignant diseases.

Some authorities teach that heredity plays an important part in cancer. Striking instances have been recorded in occasional family histories, and further clinical investigation of this aspect of malignancy is much needed. It may be that in good health powers of capacity to fight enemy germs are normally passed down from parents to children, and that in lack of adequate health the absence of these desirable transmissions is the reason why diseases are, or so often appear to be, hereditary.

Some contend, while others are sceptical, that cancer is infectious. In the case of endangered persons, not immune by adequate youth or freedom from pre-malignancy, I consider that emanations from ulcerating cancers *are* infectious.

Carcinoma is often thought to be an increasing disease, but I do not agree with this view. These growths were rampant 50 years ago, and their great prevalence specially interested me in their nature. Statistics used not to be prepared with the care and accuracy that they now are. When consulted by patients suffering from certain forms of cancer, my experience has been the usual one—I have almost invariably found long neglected local growths, or the patients have been the victims of chronic irritations or slow inflammations which had never received serious treatment. They had also been accustomed to eat too much animal food or their daily consumption of alcoholic drinks had been beyond the limits of ordinary prudence. I have, however, long watched the advancing years of patients following rules of health which I had given them. Those still living are quite free from cancer, while the others, who have passed away, never suffered from malignant growths but died of other complaints or of old age. As soon as a pre-malignant place is suspected, the help of the radiologist and surgeon should be sought. When the truth about cancer comes fully to light, I feel that it will be the outcome of team-work, clinicians making their contribution alongside of the efforts of radiators, surgeons, and laboratory workers.

In conclusion, I am fully conscious that, whether we consider malignancy from the point of view of causation or prevention, it still presents a theme so baffling that none dare venture to dogmatise about it. Only in a spirit of disciplined humility, with slow and halting steps, can we submit opinions to our fellow practitioners for their consideration.

I am, Sir, yours faithfully,

Liverpool, August 1st. GLYNN WHITTLE.

MEDICINE AND DENTISTRY

To the Editor of THE LANCET

SIR,—It has been reported that there are too many newly qualified medical men. It has also been reported that there have been too few students entering the dental schools to ensure an adequate supply of dental practitioners for the near future. Therefore would it not be a good plan for some of the newly qualified medicals to join forces with established L.D.S.'s, and assist and learn from them with a view to practising permanently as dental surgeons, a designation to which they are entitled? These post-graduate students—for that is wha y would be—could carry on some medical prac start a medical practi e same time, and of it later to a nei other if their practice necessitated lieve this wh would benefit bot al and the professions and the

BUYING CENTRES

To the Editor of THE LANCET

SIR,—In terms of Mrs. Beaton the chief ingred of a "buying centre" is buyers, and plenty of th A pudding sparsely compounded of the ingredie from which its name is derived may just as wel called by any other name and at the best is li to be insipid. The idea of a buying centre is good: place where, under one roof, a person who wants buy a chair, for instance, could see, and sit down every kind of pew constructed by every chair-mak would be an ideal rendezvous for chair buyers. could you get chair buyers to come? Who is prevent one or two of them from sneaking round th corner to the nearest furniture shop and "doin deal" there and then, buying centre or no buyi centre? A week or two back a popular noblem opened a buying centre for hospital equipment and su plies which has been established at British Industr House, which is near the Marble Arch. The ceremo was attended by a large and distinguished compan indeed we are informed that more than two thous persons were present and this is not to be wonde at, since the invitation list was big and good and and cakes were served, presumably ad libitum. It was wise advice which Thomas Carlyle gave, that one should not judge of a building while the scaffolding i up, and, having this in mind, we decided to pay second visit; so a few days after we went ag Shades of Hans Breitmann! "Vhere ish dat ha now?" The caravan had passed on and save fo well-informed and very courteous guide we had ten thousand square feet hospital ward with modern beds, modern ventilation, modern locke modern lighting system and all its modern wonde fulness literally to ourselves. One recalled the st ness of the mortuary. The silence of the operati theatre was broken only by the questions and answ of the same two persons and the like can be said the clinical laboratories, the surgeons' rooms and the whole magnificent suite.

Well, one might say, it is too soon to expect throng of buyers; it is too soon to hear the babel the 23 languages which the interpreters can spe So stepping into the most magnificent lift we ha ever seen, walled with plate glass covering pleasing tapestry, so it seemed, we were taken to a higher storey, to the exhibits of medical supplies which hav been in situ for quite a little time. Still ourselv and our urbane guide wearing his old school tie, ve proper, were in sole possession. Then we went to th club rooms and sat in the buyers' chairs: wonder chairs reminding us of Egypt and Tottenham Cour road at the same time. But where were the buyers

An immense amount of thought has been expende on the general design and the selection of the exhib and it is a most wonderful exhibition of hospit requisites and of the goods used by medical pra titioners; it is in a magnificent setting. Obvious much wealth has been dispersed to get together su a comprehensive display in such pleasing surrounding Everybody concerned with hospital administratio should go to the British Industries House, and think it is the duty of the organisers of this uni uying centre to take pains to ensure that the n ngredient of buying centres, as prescribed by should be there in abundance.

I am, Sir, yours faithfully,

clear that our correspondent does ly permanent disappointment with edical section of the British Industries House, and perhaps unduly impressed by the difference in the mosphere and environment found on a gala day d an ordinary working day. It is not to be expected at any crowd of intending purchasers should resort ily to the Marble Arch, but it is to be hoped that a arket which appeals to so wide if defined a clientele ll establish itself as a regular place of resort. When is found that so many needs and so many questions e satisfactorily settled by visiting the medical ction there should be no want of prospective buyers. -Ed. L.

INDUSTRIAL DERMATITIS

To the Editor of The Lancet

Sir,—I feel sure you will allow me a little space o draw attention to what seem like two important missions from the article on Industrial Dermatitis by Dr. Sibyl Horner in your last issue, the more so s she writes in her official capacity in the Home Office. It will have been noticed that she makes no reference whatever to the fact that in many, f not most, of the industries associated with the production of industrial dermatitis the workers are exposed to small quantities of carbon monoxide gas in the atmosphere which they inhale. Small quantities of carbon monoxide gas inhaled over a prolonged period have a debilitating effect of an accumulated nature on the blood, and the tissues exposed to irritation being lowered in vitality as a consequence fail to recuperate after each exposure.

A person exposed to a combination of carbon monoxide gas and some other poison such as lead fumes becomes a ready victim to lead poisoning, and, as Dr. Horner knows, I have been able to show that by reducing the amount of carbon monoxide gas to which workers in spelter works are exposed it has been possible to eliminate lead poisoning from a large and important factory (Med. Press and Circ., Nov. 23rd, 1932). Dr. Horner makes no mention of the different responses made to these trade irritants by workers in the several health categories from A1 to C3 to which I have already drawn attention (Brit. Med. Jour., June 2nd, 1934, p. 1008). The C3 type falls a victim more readily than one belonging to the A1 category, and this surely is a point of very great importance in more ways than one.

The presence of CO gas is important because some of these cases of dermatitis are but the prelude to industrial cancer, which I have shown occurs only amongst workers who have been exposed to the inhalation of CO gas over prolonged periods of time (Med. Press and Circ., August 30th and Sept. 20th, 1933). I am, Sir, yours faithfully,

Swansea, August 7th. G. Arbour Stephens.

MEDICINE AND THE LAW

Claims by Infants

During the judicial sittings which ended last week an unusual point was taken on a claim for alleged negligence in respect of treatment in a L.C.C. hospital. In October, 1932, a number of infants entered the hospital. Through their parents they complained that at the hospital they contracted a disease during that month by reason, it was stated, of the negligence, unskilfulness, and breach of duty of the medical superintendent. On Jan. 31st, 1934, they took out a writ claiming damages from the L.C.C. as the responsible authority and from the medical superintendent personally. The lapse of time before the writ was issued is important. The Public Authorities' Protection Act of 1893 sets a six-months' time-limit on the bringing of actions against a public authority for any alleged negligence in the execution of a public duty or of an Act of Parliament. The L.C.C. is undoubtedly a public authority within this protection and has often defended itself by pleading the statute. The plaintiffs on this occasion sought to get round the statute by arguing that it did not apply to infants. They referred to the old Statute of Limitations (of 1623) which expressly reserves the rights of infants until they come of age. Thus a preliminary question of law was brought before Mr. Justice Roche for decision—was the Public Authorities' Protection Act of 1893 no protection against a claim by a person under age? The judge held that the infants' claim was barred; the 1893 Act made no exception in favour of infants and the 1623 Act was a different affair altogether. He did not, however, dismiss the action outright; he merely struck out the statement of claim and thus left the plaintiffs free to begin again. They can now raise any matter which has happened within six months of the writ. If, therefore, they are still uncured of the effects of the disease and have consequently suffered damage within the six-months period, they can shape their claim afresh accordingly. The L.C.C. will presumably rely upon the usual defence that it did not itself render the alleged unskilful treatment and that its duty to the plaintiffs was finished when it appointed a suitable medical officer.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

The following appointments are notified:—

Surg. Capts. J. P. Shorten to *Drake*, for Plymouth Hosp.; G. F. Syms to *Victory*, for Haslar Hosp.; and H. M. Whelan to *Pembroke*, for Chatham Hosp.

Surg. Comdrs. G. Kirker to *Drake*, for R.N.B.; W. A. Jolliffe to *Cairo*; T. N. D'Arcy to *Rodney*; L. W. Gemmell to *Pembroke*, for Chatham Hosp.; M. S. Moore to *Renown*; L. S. Goss to *Drake*, for R.N.B.; and M. B. Devane to *Victory*, for R.N.B., and to *Resource* on recommg.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. T. C. Larkworthy to be Surg. Lt.-Comdr.

Proby. Surg. Lt. (D) A. B. Bateman to be Surg. Lt. (D).

The following appointments are notified:—

Surg. Lt.-Comdrs. W. H. Butcher to *Vernon*; D. C. Wilson to *Victory*, for Haslar Hosp.; and S. B. Borthwick to *Victory*, for R.N.B.

ROYAL ARMY MEDICAL CORPS

Capt. A. E. Campbell to be Maj.

Lt. (on prob.) D. M. Ahern is restd. to the estabt.

ARMY DENTAL CORPS

Capt. A. H. Kay to be Maj. (prov.).

TERRITORIAL ARMY

Lt.-Col. D. S. Sutherland to be Bt. Col. and retires on completion of tenure of comd. and *retains his rank*, with permission to wear the prescribed uniform.

Maj. J. F. O'Grady to be Lt.-Col., and to comd. the 12th (2nd Western) Gen. Hosp.

Capts. W. Lumley and J. Cohen to be Majs.

INDIAN MEDICAL SERVICE

Col. G. D. Franklin retires.

Col. C. W. F. Melville, K.H.P., to be Maj.-Gen.

Capt. C. V. D. Rose to be Maj.

Capts. (on prob.) to be Majs. (on prob.): P. V. Karamchandani and R. K. Misra.

Lt. (on prob.) V. M. Albuquerque to be Capt. (on prob.).

Temp. Lt. Ilahi Bakhsh to be Temp. Capt.

The promotion of the undermentioned officers as Capts. is confirmed: B. D. Khurana, E. H. Lossing, R. J. Jarvie, M. Sendak, and G. W. Miller.

Ilahi Bakhsh to be Capt. (on prob.).

powers of capacity to fight enemy germs are normally passed down from parents to children, and that in lack of adequate health the absence of these desirable transmissions is the reason why diseases are, or so often appear to be, hereditary.

Some contend, while others are sceptical, that cancer is infectious. In the case of endangered persons, not immune by adequate youth or freedom from pre-malignancy, I consider that emanations from ulcerating cancers *are* infectious.

Carcinoma is often thought to be an increasing disease, but I do not agree with this view. These growths were rampant 50 years ago, and their great prevalence specially interested me in their nature. Statistics used not to be prepared with the care and accuracy that they now are. When consulted by patients suffering from certain forms of cancer, my experience has been the usual one—I have almost invariably found long neglected local growths, or the patients have been the victims of chronic irritations or slow inflammations which had never received serious treatment. They had also been accustomed to eat too much animal food or their daily consumption of alcoholic drinks had been beyond the limits of ordinary prudence. I have, however, long watched the advancing years of patients following rules of health which I had given them. Those still living are quite free from cancer, while the others, who have passed away, never suffered from malignant growths but died of other complaints or of old age. As soon as a pre-malignant place is suspected, the help of the radiologist and surgeon should be sought. When the truth about cancer comes fully to light, I feel that it will be the outcome of team-work, clinicians making their contribution alongside of the efforts of radiators, surgeons, and laboratory workers.

In conclusion, I am fully conscious that, whether we consider malignancy from the point of view of causation or prevention, it still presents a theme so baffling that none dare venture to dogmatise about it. Only in a spirit of disciplined humility, with slow and halting steps, can we submit opinions to our fellow practitioners for their consideration.

I am, Sir, yours faithfully,

Liverpool, August 1st. GLYNN WHITTLE.

MEDICINE AND DENTISTRY

To the Editor of THE LANCET

SIR,—It has been reported that there are too many newly qualified medical men. It has also been reported that there have been too few students entering the dental schools to ensure an adequate supply of dental practitioners for the near future. Therefore would it not be a good plan for some of the newly qualified medicals to join forces with established L.D.S.'s, and assist and learn from them with a view to practising permanently as dental surgeons, a designation to which they are entitled? These post-graduate students—for that is what they would be—could carry on some medical practice or start a medical practice at the same time, and dispose of it later to a neighbour or other if their dental practice necessitated this. I believe this whole plan would benefit both the dental and the medical professions and the public.

I am, Sir, yours faithfully,

R. MEYNELL PEARSON, L.D.S.

Gillingham, Kent, August 1st.

BUYING CENTRES

To the Editor of THE LANCET

SIR,—In terms of Mrs. Beaton the chief ingre of a "buying centre" is buyers, and plenty of t A pudding sparsely compounded of the ingredi from which its name is derived may just as we called by any other name and at the best is l to be insipid. The idea of a buying centre is good place where, under one roof, a person who wants buy a chair, for instance, could see, and sit down every kind of pew constructed by every chair-mak would be an ideal rendezvous for chair buyers. could you get chair buyers to come? Who is prevent one or two of them from sneaking round t corner to the nearest furniture shop and "doin deal" there and then, buying centre or no buy centre? A week or two back a popular noblem opened a buying centre for hospital equipment and s plies which has been established at British Industr House, which is near the Marble Arch. The cerem was attended by a large and distinguished comp indeed we are informed that more than two thous persons were present and this is not to be wonde at, since the invitation list was big and good and and cakes were served, presumably ad libitum. It was wise advice which Thomas Carlyle gave, that one should not judge of a building while the scaffolding up, and, having this in mind, we decided to pa second visit; so a few days after we went ag Shades of Hans Breitmann! "Vhere ish dat b now?" The caravan had passed on and save f well-informed and very courteous guide we ha ten thousand square feet hospital ward with modern beds, modern ventilation, modern lock modern lighting system and all its modern won fulness literally to ourselves. One recalled the s ness of the mortuary. The silence of the operat theatre was broken only by the questions and answ of the same two persons and the like can be sai the clinical laboratories, the surgeons' rooms and the whole magnificent suite.

Well, one might say, it is too soon to expe throng of buyers; it is too soon to hear the bab the 23 languages which the interpreters can sp So stepping into the most magnificent lift we h ever seen, walled with plate glass covering pleas tapestry, so it seemed, we were taken to a high storey, to the exhibits of medical supplies which ha been in situ for quite a little time. Still oursel and our urbane guide wearing his old school tie, w proper, were in sole possession. Then we went to t club rooms and sat in the buyers' chairs: wonde chairs reminding us of Egypt and Tottenham Co road at the same time. But where were the buyer

industrial disease or the conditions in the factories. Some pressure should, he thought, be brought by the Government on the General Medical Council to secure that the tendency of medical education should be more in this direction.

He felt that Mr. Rhys Davies had laid more stress on the deficient success that had resulted from the work of the factory surgeons, the medical officers, and the whole factory system in regard to the prevention of industrial disease. If risks were to be reduced to a minimum before any new process or industry was allowed to arise it would not be possible to get the fresh employment that was required. They must face risks. A large number of new industries and processes were being discovered as a result of research in industry and fresh industrial diseases would constantly arise which required vigilance on the three sides of industry.

UNDER-SECRETARY'S REPLY

Captain CROOKSHANK said that as soon as new symptoms of industrial disease were discovered all the skill that could be found was brought to bear to try and find remedies. At the end of it one was still left with the fact which struck one on practically every page of this report and that was the almost incredible number of avoidable accidents. He assured Mr. Davies that the strength of the inspectors' department was to be reviewed before the next estimates were presented. As to a medical inquiry into the more-looms-per-weaver system they had not yet sufficient medical data for scientific investigation. The Home Office had taken up the question of dust trouble in malt houses with a view to preventing the inhalation of dust. He did not think they could make the deduction that there was a tendency for skin cancer to increase. Because the figures went up it did not necessarily mean that there were more cases. It probably meant that cases were notified more quickly and earlier. The increase in the number of cases of anthrax from 2 to 10 had nothing to do with the Liverpool disinfecting station; they arose entirely from hides and skins. The Home Secretary had now completed his review of the proposals submitted to him for the amendment of the silicosis compensation scheme. Last week he sent to the Mining Association and the Miners' Federation of Great Britain a memorandum indicating his conclusions. Limitation to particular underground processes gave rise to serious difficulties and he proposed to expand the scheme so as to include underground employment generally in coal-mines. As regarded the increase in industrial accidents it must be the case that as employment increased, unless more attention was paid to safety devices there would be more accidents. By the law of averages before Parliament met again there would have been something approaching 30,000 accidents in industry and 150 people would have lost their lives. That fact put considerable responsibility on everyone concerned. These matters were largely matters of education. If only more would come to the Home Office Industrial Museum and see the kind of safety devices which up-to-date factories could employ to avoid accidents he thought they might get an improvement.

MEDICAL NEWS

English Conjoint Board

At the recent final examination of the Board the following candidates were approved in the subjects indicated, but are not yet eligible for the diplomas of the colleges :—

Pathology.—B. Agranat, Guy's; H. F. Anderson, Camb. and St. George's; T. G. Armstrong and R. A. J. Asher, Lond.; Minnie Atkin, King's Coll.; E. C. Atkinson and D. S. D. Barber, St. Bart.'s; A. J. E. Barlow, Leeds; A. H. Barwell, St. Georges; P. W. G. Baxter, Guy's; W. M. Beattie, Camb. and Liverp.; R. D. I. Beggs, Camb. and Middx.; A. L. W. Bell, Guy's; G. Blackburn, Camb., and St. Bart.'s; D. M. Blomfield and G. L. Bohn, St. Bart.'s; A. P. Booth, Lond.; B. B. Botha, St. Bart.'s; P. I. Boyd and Margaret Brodigan, Univ. Coll.; H. S. Brodribb, Oxon. and St. Bart.'s; E. A. Brown, St. Mary's; K. P. Brown, L. H. Buckland, and A. Z. Butt, St. Bart's; H. B. C. Carter-Locke, St. Thos.; T. D. Chablani, St. George's; J. Charnley, Manch.; L. J. Clapham, St. Mary's; J. V. Clark, Guy's; W. E. Clarke, Charing Cross; P. E. G. Clements, St. Bart.'s; G. H. Collier, Manch.; W. T. Cooke, Camb. and Birm.; M. Cohen, King's Coll.; E. C. Cordeaux, Middx.; J. O. Creighton, St. Thos.; T. Csato, Middx.; J. V. Dacie, King's Coll.; D. A. Davies, Guy's; Hilda S. F. de Peyer, King's Coll.; W. H. H. J. de Wytt, Dublin; J. F. Dow, Camb. and Middx.; A. J. Surgery.—J. Adler, Charing Cross ; C. Anderson, St. Bart.'s ; G. T. Balean, Guy's ; D. M. Blomfield and D. M. Bressler, St. Bart.'s ; Margaret Brodigan, Univ. Coll. ; R. Bruce, King's Coll. ; A. F. Bryson, Lond. ; A. S. Bullough, Manch. ; Margaret M. B. Carey, Roy. Free ; W. P. Cargill, Manch. ; R. S. Carpenter, Lond. ; A. H. Casson, St. Bart.'s ; R. F. Courtin and J. O. Creighton, St. Thos. ; T. Csato, Middx. ; S. M. Davidson, Camb. and St. Mary's ; D. W. Davies, Cardiff and Middx. ; T. F. Davies, Guy's ; E. W. Dunkley, Lond. ; R. S. Ellis-Brown, Guy's ; M. Epstein, St. Bart.'s ; I. A. Feldman, Leeds ; Joan I. Franklin-Adams, Roy. Free ; P. R. Gavin, St. Thos. ; Muriel C. Goodchild, Roy. Free ; W. E. Hadden, St. Thos. ; J. P. Harrison, Lond. ; R. B. Heisch, Camb. and Middx. ; H. F. G. Hensel, Lond. ; C. F. Heys and R. C. Hill, Guy's ; G. S. Hodge, Univ. Coll. ; D. A. B. Hopkin, St. Mary's ; C. Houghton Brown, St. George's ; G. O. Jelly, Oxon. and Guy's ; D. V. John and W. H. Jones, Camb. and Univ. Coll. ; M. D. Kiddon, St. Mary's ; F. H. Lamb, St. Thos. ; J. H. Lawrence, Leeds ; V. Lewis, St. Mary's ; P. T. Liem, St. Thos. ; G. M. Lloyd, St. Bart.'s ; O. Lloyd, Middx. ; I. B. McCrae, Charing Cross ; P. E. C. Manson-Bahr, Camb. and Lond. ; E. C. Marsh, Edin. ; F. H. Masina, Camb. and St. Bart.'s ; K. M. Mayall, Camb. and St. George's ; A. B. G. Mein, Westminster ; S. G. Mobler, St. Mary's ; R. L. Moody, St. Thos. ; Elizabeth C. Morris, Roy. Free ; J. H. Moseley and J. T. Murray-Aynsley, Camb. and St. Thos. ; Anisa Nagi, Roy. Free ; S. Paul, Cape and Guy's ; A. L. Peers, Camb. and Guy's ; Lillian M. Pickford, Univ. Coll. ; A. R. Pope, Camb. and St. Bart.'s ; Kathleen G. Priestman, Roy. Free ; A. W. Probert, Univ. Coll. ; J. J. C. Rainsbury, Sheff. ; J. Rapoport, St. Mary's ; M. S-M. Rayner, Camb. and St. Thos. ; J. W. Redgate, Middx. ; M. G. Robinson, Birm. ; J. S. Ross, Camb. and St. Thos. ; B. D. Sachdeva, West Lond. ; H. H. Samson, Lond. ; J. K. Samuel, St. Thos. ; B. J. Shaw, Birm. ; C. W. T. Shuttleworth, Guy's ; J. Simon, Lond. ; J. H. E. Summerhill, Camb. and Univ. Coll. ; C. Tetlow, Manch. ; Constance M. Vallange, Roy. Free ; H. A. Wallace, Camb. and Univ. Coll. ; J. D. S. Watling, Univ. Coll. ; F. H. Weston, Guy's ; D. O. Wharton, Manch. ; C. W. K. Willard, Univ. Coll. ; and J. G. Williams, Westminster.

Royal College of Physicians of London

Licences to practise (additional to those recorded in our last issue) were on August 2nd conferred on the following candidates :—

E. J. J. Borges, Bombay and West Lond. ; F. I. Evans, Camb. and Guy's ; J. R. Nassim, Oxford and St. George's ; H. N. Perkins, St. Mary's ; and F. F. Rundle, Sydney.

Royal College of Surgeons of England

A meeting of the council of the college was held on August 2nd, with Sir Holburt Waring, the president, in the chair. Mr. L. R. Broster, surgeon to Charing Cross Hospital, was elected a member of the court of examiners in the vacancy caused by the resignation of Mr. Claude Frankau. Dr. Ernest Bulmer, Dr. A. H. Douthwaite, Dr. R. A. Hickling, and Dr. R. A. Rowlands were elected examiners in medicine for the L.D.S.

Mr. Kennedy Cassels, M.A., F.C.I.S., was appointed secretary to the college in succession to Mr. S. Forrest Cowell, who retires at the end of September. Mr. T. W. P. Lawrence was reappointed acting pathological curator for a further period of six months, and Mr. F. H. Bentley was appointed Bernhard Baron scholar during the current quarter. Mr. Wilfred Trotter, F.R.S., was reappointed a member of the executive committee of the Imperial Cancer Research Fund.

Diplomas of membership were granted to the candidates whose names were given last week (p. 286) as recipients of the L.R.C.P., and to those who received the diploma of the Royal College of Physicians on August 2nd. Licences in dental surgery were granted to the following candidates successful in the recent examination :—

Naga M. A. Abul, A. P. Austin, K. C. Baker, A. L. H. Bakry, C. F. Ballard, R. O. Barber, Beatrice M. Bell, Shaker Botros, J. C. Carr, F. L. Ferris, W. R. Foreman, Marjorie G. Frost, Harry Gill, D. A. G. Greensted, Werner Grünthal, A. A. Hassan, A. G. Heberlein, Herman Kanter, J. H. Kendall, J. B. Knight, Mitchel Lang, W. B. Lewis, W. J. Littleton, R. W. Lovel, Benito Machado, J. C. Manchanda, L. C. Mandeville, R. S. Martin, C. E. A. Mason, A. E. W. Miles, H. E. Nathoo, D. D. Nogid, T. C. O'Flanagan, G. B. Oliver, E. J. Parks, M. F. Porterfield, L. P. Quenet, Martin Radford, E. E. H Sampson, Harold Stewart, Margaret E. Stewart, A. R. Thatcher, J. L. Thompson, D. P. Walther, D. U. Warburton, W. E. A. Watson, and R. A. E. Williams.

University of Cambridge

During June and July titles of degrees (B.Chir.) were conferred on C. M. Cavell, R. A. Kellgren, and D. J. Thompson.

University of London

At a meeting of the senate on July 18th it was resolved that university readerships in medicine, surgery, obstetrics and gynæcology, pathological chemistry, and bacteriology should be instituted at the British Postgraduate Medical School, Hammersmith. Particulars of these posts will be found in our advertisement columns.

Recipients of grants from the Thomas Smythe Hughes medical research fund and the Beaverbrook fund include Prof. C. A. Lovatt Evans, Dr. R. C. Lightwood, and Dr. T. W. Mimpriss. Applications are invited for the William Julius Mickle fellowship, which is awarded annually to the graduate of the university who has in the opinion of the senate done most to advance medical art or science within the preceding five years. Applications in proper form must be received by Oct. 1st, and particulars may be had from the academic registrar.

The Sharpey scholarship in physiology at University College has been awarded to Dr. D. H. Lee.

Dr. W. E. Roper Saunders, divisional medical officer for the London County Council, has obtained the diploma in public administration.

Fellowship of Medicine and Post-Graduate Medical Association

A lecture-demonstration on hysteria will be given by Dr. Clark-Kennedy at the Medical Society of London, 11, Chandos-street, Cavendish-square, W., at 2.30 P.M. on Tuesday, August 14th. On August 21st Dr. Clark-Kennedy will deal with asthma. Mr. Alan Gairdner will give a short course of demonstrations on the treatment of fractures at St. George-in-the-East Hospital, Raine-street, at 2.30 P.M., from August 13th to 17th. The course will include fractures of the upper extremity, fractures of the spine and pelvis, and fractures of the lower extremity. A course in infants' diseases which will deal principally with nutritional disorders and dietetics will be held at the Infants Hospital, Vincent-square, London, S.W., from Sept. 3rd–14th. Daily instruction in various branches of medicine and surgery is provided by the panel of teachers, and further particulars may be had from the secretary of the Fellowship, 1, Wimpole-street, London, W.1.

National Hospital, Queen-square

A course of lecture-demonstrations on neurology will be held at this hospital from Oct. 8th to Dec. 7th. It will include demonstrations of anatomy, physiology, and pathology, and demonstrations on post-mortem materia at 12 noon; lectures on the principles of neurology and on diseases of the nervous system at 3.30 P.M.; and demonstrations of clinical methods of examination at 5 P.M. A second course will be held from Jan. 28th to March 29th. Further particulars may be had from the secretary of the hospital, Queen-square, London, W.C.1.

Post-graduate Course in Newcastle

Under the auspices of the University of Durham College of Medicine, Newcastle-upon-Tyne, a post-graduate course will be held from Sept. 10th to 21st. There will be lectures and demonstrations daily from 9.30 A.M. to 4 P.M. from Mondays to Fridays, and they will all be given at the Royal Victoria Infirmary, except those on Monday, Tuesday, and Thursday afternoons, when visits will be paid to the *Babies* Hospital and *Princess Mary* Maternity Hospital. The programme of the course may be had from the registrar of the College.

Instruction for D.P.H.

The medical officer of health to the London County Council announces that a three months' course of lectures and demonstrations on clinical practice and in hospital administration will be given at the North-Western Hospital, Lawn-road, Hampstead, N.W., by Dr. A. Joe, the medical superintendent, on Mondays and Wednesdays at 9.30 A.M., and alternate Saturdays at a time to be arranged, beginning on Monday, Oct. 1st. A similar course will be given at the Brook Hospital, Shooter's Hill, Woolwich, S.E., by Dr. J. V. Armstrong, the medical superintendent, the dates and times being the same. Applications should be made to the medical officer of health, London County Council, Public Health Department (Special Hospitals), the County Hall, S.E.1.

Appointments

HENDERSON, ALEXANDER, M.B. St. And., D.P.H., has been appointed Assistant Medical Officer to the County of Aberdeen.

HERITAGE, KENNETH, M.S. Lond., F.R.C.S. Eng., Honorary Surgeon to the Saint John's Hospital, Lewisham.

MCCRAE, R. H. B., M.B. Glasg., Medical Referee under the Workmen's Compensation Act for Wick Sheriff Court District.

SHARPE, J., M.B. Glasg., D.P.H., Deputy Medical Officer of Health for Leeds.

WRIGHT, Prof. HEDLEY D., D.Sc., M.D., Bacteriologist for City of Liverpool.

Infants Hospital, London, S.W.—The following appointment are announced:—

FLETCHER, H. MORLEY, M.D. Camb., F.R.C.P. Lond., and STILL, G. F., M.D. Camb., F.R.C.P. Lond., Consulting Physicians;

ADDISON, O. L., M.B. Lond., F.R.C.S. Eng., and WAUGH, G. E., M.D. Lond., F.R.C.S. Eng., Consulting Surgeons.

Certifying Surgeons under the Factory and Workshop Acts: MCCLELLAND, T. A., M.B. Belf. (Warrington); MACFARLANE, E. P., M.B. Glasg. (East Kilbride, Lanark); MCLEAN, R., M.B. Glasg. (Carluke District, Lanark).

Vacancies

For further information refer to the advertisement columns

Altrincham General Hospital.—Sen. H.S. At rate of £150.

Birkenhead General Hospital.—Sen. H.S. At rate of £150. Also Second H.S., H.P., and Cas. O. Each at rate of £100.

Birkenhead Municipal Hospital.—Deputy Med. Su[illegible] Also Res. M.O. £300.

Birmingham, Ear and Throat H[illegible] d H.S. £150.

Birmingham Royal Cripples' [illegible] H.S. £200.

Bradford, Grassington Sanatoriu[illegible] 's.—[illegible]

Bradford Municipal General H[illegible] H.S.'s. Each at rate of £15[illegible]

Buxton, Derbyshire, Devonshire [illegible] —A[illegible] At rate of £150.

Cardiff, Glan Ely Tuberculosis H[illegible] Sc[illegible] £500. Two H.P.'s. Each at [illegible]

Cardiff, King Edward VII. Welsh N[illegible] Thr[illegible] O.'s. Each [illegible]

Carlisle, [illegible] *Infirmary.*—H[illegible]

[illegible] *Hospital.*—[illegible] [illegible], *S.W.*

Charing Cross Hospital, W.C.—H.P. to Radiological Dept. At rate of £50.

Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £150.

Connaught Hospital, Walthamstow, E.—Sen. Res. M.O. At rate of £150.

Dudley, Guest Hospital.—Second H.S. £170.

East Ham Memorial Hospital, Shrewsbury road, E.—H.P. At rate of £150. Also Res. M.O. At rate of £200.

Exeter, Royal Devon and Exeter Hospital.—H.S. to Ear, Nose, and Throat Dept. At rate of £150.

Finsbury Metropolitan Borough.—Asst. M.O.H. £600.

General Lying-in Hospital, York-road, Lambeth, S.E.—Jun. Res. M.O. and Anæsthetist. At rate of £100.

Great Yarmouth General Hospital.—H.S. £140.

Greenwich Metropolitan Borough.—Sen. Asst. M.O. for Maternity and Child Welfare Work. £600.

Guildford, Warren-road Hospital.—Res. Asst. M.O. At rate of £250.

Ilford, King George Hospital.—Pathologist. £500.

Institute of Ray Therapy, &c., 152 Camden-road, N.W.—Part-time M.O. At rate of £100.

Lincoln County Hospital.—H.S. At rate of £150.

Liverpool City.—Res. Asst. M.O. £200.

Liverpool, David Lewis Northern Hospital.—Cas. O. and H.S. At rate of £120 and £80 respectively.

Liverpool, Hahnemann Hospital, Hope-street.—Res. M.O. At rate of £125.

Liverpool, Royal Southern Hospital.—Res. Orthopædic H.S. M.O. to Spec. Dept., and Res. Anæsthetist. Each at rate of £60.

London Jewish Hospital, Stepney Green, E.—Hon. Clin. Assts.

London University.—University Readerships. Each £500. Also William Julius Mickle Fellowship. £200.

Maidstone, West Kent General Hospital.—H.P. £150.

Manchester, Ancoats Hospital.—H.S. At rate of £100. Also Surg. and Med. Reg. Each at rate of £50.

Manchester Babies Hospital, Burnage-lane, Levenshulme.—Sen. Res. Medical Officer. At rate of £125.

Manchester and Salford Hospital for Skin Diseases.—H.S. At rate of £100.

Manchester Centre, National Radium Commission Scheme.—Asst. Radium Reg. £400–£500.

Manchester, Christie Hospital and Holt Radium Institute, Withington.—Res. Surg. O. At rate of £150. Also Hon. Radiologist.

Manchester Royal Infirmary.—First Asst. for Clinical Laboratory. £350.

Manchester, St. Mary's Hospital.—Hon. Surgeon for Children's Dept.

Middlesbrough, North Riding Infirmary.—H.P. At rate of £125.

Middlesex Hospital, W.—Radiologist. £500. Also Asst. Radiologist (Diagnostic). £100.

Newcastle-upon-Tyne Eye Hospital.—Sen. Res. H.S. £300.

North Kensington Women's Welfare Centre, Telford-road, W.—Medical Officer.

Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £120. Also H.S. to Spec. Depts. £120.

Plymouth City Hospital.—Deputy Med. Supt. £450.

Plymouth City (General) Hospital.—Jun. Asst. M.O. £250.

Plymouth City and Port.—Asst. M.O.H. £500.

Poplar Hospital for Accidents, East India Dock-road, E.—Second Res. O. £175.

Preston County Borough.—Asst. School M.O. £500.

Preston, County Mental Hospital, Whittingham.—Res. Jun. Asst. M.O. £500.

Preston and County of Lancaster Royal Infirmary.—Res. Surg. O. £300. Also H.S. and Cas. O. Each at rate of £150.

Preston, High Carley Sanatorium, near Ulverston.—Asst. Tuber. M.O. £450.

Queen Mary's Hospital for the East End, Stratford.—H.S. Also Cas. O. £150.

Reading, Royal Berkshire Hospital.—Res. Anæsthetist. At rate of £150.

Royal College of Physicians, Pall Mall East, S.W.—Milroy Lecturer.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. and Asst. H.S. At rate of £150 and £100 respectively.

Royal Naval Medical Service.—Ten M.O.'s.

Sheffield Children's Hospital.—H.P. At rate of £100. H.S. £100.

Shrewsbury, Royal Salop Infirmary.—Cas. O. and Res. Anæsthetist. At rate of £160.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—Asst. H.P. £125.

Surrey County Council.—Asst. M.O. £600.

Swansea General and Eye Hospital.—Cas. O. At rate of £150.

Taunton and Somerset Hospital.—Hon. Physician.

Warwick, King Edward VII. Memorial Sanatorium, Hertford Hill.—Jun. Asst. M.O. £200.

Warwickshire and Coventry Joint Committee for Tuberculosis.—Asst. Tuber. O. £600.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £15[illegible]

Westminster Hospital, Broad Sanctuary, S.W.—Wander Scholarship in Diseases of Children. £250.

ADDRESSES AND ORIGINAL ARTICLES

PROBLEMS OF GALL-STONES

BY E. R. FLINT, M.B. Leeds, F.R.C.S. Eng.
SURGEON TO THE GENERAL INFIRMARY AT LEEDS

IN abdominal surgery apart from acute appendicitis the pathological condition most often found is cholelithiasis and its complications; yet, frequent as the lesion is and common as are the remedial operations performed, there are many problems relating to both which are not satisfactorily solved. For example, as regards the former, are gall-stones primarily due to some chemical disturbance, and, if so, what nature, or do they form secondarily to an infective cholecystitis? As regards the latter, what are the reasons for the appalling mortality of 14·65 per cent. following operations for stone in the common duct? (This is the death-rate arrived at from a collective investigation into the subject made on behalf of the Association of Surgeons of Great Britain and Ireland recently.) Again, why should infection play such a prominent part in causing those deaths which may follow any kind of operation on the biliary passages?

What do we know about the ætiology of gall-stones? There are two predominating views—the infective and the metabolic. According to the first the gall-bladder is infected by one or other of several routes—the hæmatogenous being that most generally favoured. Following the cholecystitis so induced gall-stones develop. Those who uphold the second theory say that owing to some chemical upset biliary constituents separate out to form stones, and subsequently may or may not give rise to cholecystitis. It is important to get the ætiology right, otherwise we cannot expect to progress with preventive treatment; in other words, which is the cart and which the horse?

It is generally conceded that the single cholesterin stone has a metabolic origin; I think it is beginning to be agreed that the pigment and mulberry stones do not owe their origin as a rule to cholecystitis, and the combination stone, which appears as the result of infection, is in the first place a solitary cholesterin stone and therefore metabolic. It is held, however, that if all the cases in which a metabolic origin is conceded are subtracted from the total number of cases in which stones are found, there is a fairly large credit balance in favour of the multiple-faceted stones; this is supposed to make it evident that the commonest occurrence is for cholecystitis to antedate stone-formation.

THE INFECTIVE THEORY

A great impetus was given to the infective theory by E. C. Rosenow and later by A. L. Wilkie, of Montreal, from the experimental side. Briefly the results are these: Cultures were made from the cystic gland obtained from the human subject in cases of cholecystitis; the organisms grown were streptococci in 86 per cent. of the cases. Suspensions of these organisms were made of 250 millions to the cubic centimetre. About 2 c.cm. of the suspension were repeatedly injected into the veins of rabbits with the result that a progressive chronic cholecystitis was caused in most cases; if the cystic duct had been previously ligatured small calcium and cholesterin stones formed, or cholesterin stones only if the duct was left patent

These experiments appear rather convincing, but so far as I am aware they have not been substantiated further; moreover, the animals used were rabbits, which seem to be rather peculiar in that gall-stones can be produced in them by prolonged feeding with cholesterol—which, I believe, has never been accomplished in any other animal. Also I find it hard to believe these repeated massive injections reproduce human ætiological conditions. It is quite easy to understand they can cause cholecystitis; it is also possible to cause cholecystitis chemically by intravenous injections of Dakin's solution; but it is quite another thing to suggest human cholecystitis has a like origin to either method.

I have again and again sent the human gall-bladder and cystic gland to be cultured after removal at operation, and only on the rarest occasions got a growth of streptococci; in a few cases, mostly acute, *Bacillus coli* have been grown, but for the most part the cultures have been negative, and this is the experience of many others who have interested themselves in this subject.

If it be granted for the moment that streptococcal infection occurs, where do the organisms come from? It is suggested they are set free from the teeth, tonsils, sinuses, appendix, and pelvic organs, to mention a few of the multiplicity of foci. If it is the pelvic organs we should expect married women to be relatively more often the victims of gall-stones than spinsters, and though this is generally believed to be the case, reliable statistics do not substantiate this belief, as D. M. B. Gross has shown. A. F. Hurst, too, has come to the conclusion that this is an incorrect statement.

As regards the other sites, the surgical and dental industry, which has been going on here for many years, has reduced the incidence of gall-stones not at all—which is rather odd if the premiss is correct.

CLINICAL EVIDENCE

Experimental work on animals may be suggestive, but it cannot be considered conclusive, at any rate so far, in its application to the human being, and as we are unable to repeat such experiments on the human subject we have to rely largely for our information on clinical (including operative) evidence. Unless notes are taken with the specific object of determining whether biliary colic or cholecystitis was the initial symptom they may not be very helpful, and, too, patients may be excused if they are rather hazy about events which happened maybe 20 years ago. Again, operative notes seldom give precise information as to the character of the stones found. But taking the notes for what they are worth in an analysis of 300 cases of operations on the gall-bladder and ducts, in which stones were present in 252, I found 106 began with violent pain and in 74 of these the attack appeared to be typical biliary colic. In 94 the patients complained first of indigestion and in the other 100 the first symptom was not definitely expressed. In the 94 cases we are on rather uncertain ground, because though cholecystitis probably accounted for the first symptoms yet it is possible for stones to lie quiet until by impaction or constant fretting of the gall-bladder they promote inflammation. In the 100 indeterminate cases the proportional incidence was probably much the same as in the others. It seems fair to say, therefore, that in about half the cases stone almost certainly antedated infection of the gall-bladder. This receives support from my cases done in the last 15 months, in which the special points in the history have had more particular attention; in this series of 100 cases colic was the initial symptom in 45 and indigestion in 40; in 15 there was uncertainty.

The metabolic origin of gall-stones is emphasised further by other considerations; for example, the commonest operative finding in acute cases is a single cholesterin stone impacted in the neck of an acutely inflamed gall-bladder; in these cases it seems certain the gall-stone is the primary condition, and it is in the younger patients one finds this lesion most frequently. Moreover, it is quite common to find gall-stones when there has been no complaint of any trouble suggesting their presence, especially when operating for ovarian cysts or uterine fibroids. Again, they are found not infrequently post mortem when the clinical notes have given no indication of their presence. In 2731 autopsies at the General Infirmary at Leeds there were 20 per cent. with either gall-stones or strawberry gall-bladders in cases over 40 years of age; of these 211 showed liposis. I do not know the significance of the strawberry gall-bladder, but I am sure of this from my own experience, that organisms virtually never grow on the ordinary media when culturing is attempted from the gall-bladder wall; that flatulent indigestion of the type one associates with cholecystitis is a part of the clinical history; and that the symptoms clear up after cholecystectomy. There were 28 cases of strawberry gall-bladder in my last 141 cases of cholecystectomy and in 9 stones were also present. Lastly, I can recall 2 cases in which a pure cholesterin stone has been removed from the ampulla of Vater in association with faceted stones in a chronically inflamed gall-bladder; this suggests the possibility of a metabolic stone passing into the intestine leaving behind all the appearances of infection for which it was primarily responsible, and thus swelling fallaciously the statistics of the infective theory.

As to the nature of the metabolic disturbance, I have not the knowledge to discuss this properly; it is probably related to cholesterol and bile-salts in some way, that is to say a liver rather than a gall-bladder matter. Any theory, however, must explain at least two clinical facts—namely, the association of gall-stones with obesity and femininity. It is not easy to see how infection can do this.

THE HIGH MORTALITY

The question of the mortality, to which I have referred above, is a surgical affair, but not only, and in my opinion not chiefly, one of operative technique. No doubt technical skill in operations on the biliary tract has more to do with keeping down the mortality-rate than in most other parts of the body, but even so I believe getting the patient ready for operation is more important still. I should say that probably more than half of the 14·65 per cent. mortality quoted at the Association of Surgeons' meeting is due to inadequate preparation. My particular interest in this aspect of the subject covers a period in which I have done 150 gall-stone operations—114 cholecystectomies with 3 deaths (2·6 per cent.), 34 choledochotomies with 2 deaths (5·8 per cent.), and 2 cholecystotomies with 1 death; these figures are rather more than half what they were before this period. The essential points to observe are: first, to allow ample time for acute symptoms to subside whether these are inflammatory as in cases of cholecystitis or obstructive as indicated by jaundice—this may mean postponing operation for weeks; secondly, to employ the waiting time in repairing liver damage, kidney function, and less tangible injury for which dehydration is largely responsible. It is very seldom indeed that immediate operation is necessary in gall-stone surgery.

Anatomical abnormalities of the ducts and blood-vessels are very common in the biliary tract region; this, together with the embarrassingly difficult access at times, and the importance of the structures being dealt with, make gall-stone surgery the most technically difficult of all abdominal work, especially when pathological distortions are superimposed. Often as it has been said, it cannot be too frequently repeated that nothing should be divided until it has been identified; neglect of this fundamental rule is responsible for most of the operative catastrophes. There is another point which I think needs emphasising—it is in my experience impossible in something like 10 per cent. of cases to be sure by palpation alone whether or not there is a stone in the common duct. This is especially so where the head of the pancreas is hard and nodular as it not infrequently is in association with gall-stones. In 3 of my last 30 cases of choledochotomy I found a stone or stones in the common duct only after opening it; in each case I could feel no stone, but my suspicions were aroused by the size and texture of the duct and the nodularity of the pancreas. This opinion is supported by post-mortem records; during 6 years there were 33 autopsies at the Leeds General Infirmary on cases which had died after cholecystectomy, no operation having been done on the common duct, and in 6 there were stones found in the common duct presumably undiscovered and certainly left at operation. Again, in 7 of the 34 choledochotomy cases referred to above the gall-bladder had been removed at a previous operation, and this almost certainly means that the stone found on the second occasion had been overlooked at the first.

The relationship between infection-and mortality-rate is a very obvious one; in 75 post-mortem examinations of patients dying in the Leeds General Infirmary after operations on the biliary passages 27 showed generalising or gross local peritonitis and 17 broncho-pneumonia, which is more often than not a terminal manifestation of infection elsewhere. Most of these deaths, I think, are preventable by delaying operation until the acute stage is well over. The low resistance of fatty tissue to even minimal infection, combined with the large wound which has to be made and the amount of necessary manipulation, are sufficient reason in my opinion for inciting peritonitis and wound infection in gall-stone cases in the acute period, where a stone in the neck of the gall-bladder and acute inflammation of the organ are commonly found.

So far as the common duct cases are concerned there were in the same series 10 deaths due to infective cholangitis and hepatic damage. It is only seldom one is obliged to interfere surgically in the acute period of cholangitis, and it is fortunate that this is so, for many of these patients, from the surgical point of view, are the worst possible risks; if immediate operation should be deemed imperative it should be limited to drainage of the common duct (leaving the *obstruction to be dealt with later*) combined with blood transfusion and continuous intravenous saline and glucose.

So far as the administration of fluid is concerned I want to emphasise particularly the value of the intravenous method. I have had a considerable experience of this, and for those cases which really require fluid I am certain it has very great advantages over any other parenteral method; 50 pints can be given without trouble in 4 or 5 days and is for the most part retained, since there is no obvious sweating or *proportionate increase in urinary excretion*. Moreover, we know it is being added to the body fluids in the same quantities as given; this is by no means the case when the other methods are employed.

THE TOXÆMIAS OF PREGNANCY*

BY DAME LOUISE McILROY, D.B.E., M.D.,
D.Sc. Glasg., D.Sc. Lond., F.C.O.G., M.R.C.P.

DIRECTOR OF THE OBSTETRICAL AND GYNÆCOLOGICAL UNIT, ROYAL FREE HOSPITAL, LONDON; PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF LONDON

II.—THE SIGNIFICANCE OF SYMPTOMS AND THEIR TREATMENT

General Outline of Treatment

No hard-and-fast rules for the treatment of toxæmia can be laid down, as its manifestations are varied in the case of each individual patient. In obstetrics, as in every other branch of medicine, experience teaches us that the patient is to be treated and not the disease. Prevention of toxæmia is obviously what we should more especially aim at now that the majority of cases of pregnancy are coming under early medical observation. With careful investigation and a knowledge of the normal, the slightest deviation from health will be taken as a danger signal and preventive measures employed in order to avoid complications. It is just this attention to detail and the supervision of the hygiene of pregnancy that is going to lower the maternal mortality of the country. Even now we can see the difference between the mortality in "booked" or supervised patients and those "emergency" patients who have had no antenatal care.

Careful attention in every patient to the condition of the teeth and skin, to the diet, and to the absence or presence of vomiting, hypertension, headache, and ocular symptoms, will go far in mitigating or eliminating the serious types of toxæmia such as acidosis and eclampsia. Sudden or fulminating attacks of toxæmia may occur especially in the later months of pregnancy. These cannot always be foreseen or prevented, but they are rare and in most cases when investigated will be found to be due to some gross error in diet. One must remember that pregnant women are not necessarily immune from any intercurrent pathological condition because of their pregnancy, although critics of our methods of antenatal care seem to demand from us a state of complete immunity for these women. Errors of diet have their consequences at any age and in either sex, but such errors have much more serious consequences if indulged in during pregnancy. The general treatment of toxæmia resolves itself into: (1) the careful avoidance by dieting of excessive or unsuitable food intake and the adoption of a diet which will make up for deficiences resulting from fœtal demands upon the maternal tissues; (2) the elimination of harmful substances by physiological rest and the suitable stimulation of those organs which are concerned with excretion. Right through the management of pregnancy and the treatment of toxæmia at any period these two principles must be our guide. We all differ as to details and put forth arguments in favour of some particular line of treatment which we fancy for the moment. Perhaps in no branch of medicine has fashion played such a part as in the treatment of the toxæmia of pregnancy. Drugs are excellent and in many cases necessary, but we shall do more by proper dieting and elimination than by any other means. Sedatives may be necessary but their employment is an indication of our ineptitude in stimulating physiological function. The less dependence we have on drugs and on interference with natural laws the more information will we be induced to seek in order to bring about a normal condition of affairs.

Diet

Much attention of late has been devoted to the importance of diet in the prevention and treatment of toxæmia, and we now find that our results are much improved as compared with those which we associated with the more or less indiscriminate administration of drugs. During pregnancy the diet should be as far as expedient that to which the patient has been accustomed. It ought to be of a plain mixed variety and should include a supply of green vegetables and fresh fruit. Preserved foods are deficient in vitamins, and are therefore less nourishing. Cereals contain a considerable quantity of calcium and other minerals. E. Mellanby, however, advises that their consumption should be "protected" by the addition of milk. In the case of well-nourished patients, butcher's meat and eggs should be taken sparingly, if at all, in the last three months of pregnancy, in order to relieve the strain of protein excretion; fish, chicken, and cheese are good substitutes. In addition it is found as a matter of experience that there is less rigidity of the fœtal head on a reduced protein diet and as a consequence labour is rendered easier. There is a popular fallacy that the pregnant woman must "eat for two." This creed has been the means in some cases of over-eating and toxæmia. Smaller meals at frequent intervals are advisable in cases of digestive embarrassment; fluids are necessary but should be restricted if there is a tendency to œdema of the tissues. A mixed carbohydrate diet with a supply of sugar will prevent the onset of acidosis. E. Mellanby makes the following suggestion for a diet in pregnancy: Milk 1–2 pints, green vegetables once or twice daily, 1 to 2 eggs daily, sea fish (for iodine content) twice weekly or more frequently. Calf's liver can be given once a week; the rest of the diet is to be within reason as the patient wishes. If deficient it should be supplemented with cod-liver oil ʒ ii. daily. If on the other hand it is found necessary to limit food intake, the advice is often not welcomed by the patient as it means an irksome daily restriction. Bingham[1] advises ordinary light diet with a very moderate diet on alternate days only. This should consist of a cracker and glass of milk at three-hourly intervals, and I suggest the addition of two oranges. If attention is paid to limitation of quantity in the diet of mothers who are overweight or gaining excessive weight in pregnancy it will be found that in addition to the improvement in maternal welfare the fœtus derives a marked benefit. The child may be born below the average weight but it will have had an easier passage through the parturient canal and its postnatal loss in weight will be found to be less. Part of such loss in weight, which we find more marked in large infants, is now said to be due to reduction of excess of fluid in the tissues. Smaller and better babies are, therefore, to be desired, but we must exercise due care in this direction. Reduction in the expectant mother's weight can be brought about not only by dieting but by open-air exercise—two to three miles should be walked daily.

We are inclined to forget how dull and restricted the life of a woman is in the later weeks of pregnancy. She is cut off from most of her interests and is frequently very bored with life, whilst at the same time she has plenty of leisure to contemplate what the immediate future has in store for her. She is filled with fears about herself and anxieties about her baby. If we give her some interest in her food and make her take walking exercise up till almost the onset of labour we occupy her time and thoughts and accomplish much more than if we had only given her a prescription for the chemist. If her diet has been deficient and there is not time to make it up we may have to supplement with calcium, iodine, iron, and vitamins in the form of marmite, cod-liver oil, radiostoleum, and other preparations. My favourite prescription is 10 drops of concentrated radiostoleum in the juice of an orange once daily. If the patient is restless or sleepless or the fœtus is disturbing in its movements, she is probably deficient in calcium and this must be given. Calcium will also relieve the muscular cramp of pregnancy. One-grain doses of thyroid extract are beneficial in some of the skin affections of pregnancy, at the same time attention being given to dieting and the avoidance of excessive protein intake. Excessive purgation is a mistaken means of assisting elimination. Constipation is associated with vitamin and endocrine deficiency and should be treated on rational lines. One of the mild forms of purgation for pregnant women is a glass of warm water mixed with an infusion of senna pods to be taken early in the morning before breakfast.

---

*Second Ingleby lecture delivered in the University of Birmingham on May 3rd, 1934. The first lecture appeared in THE LANCET last week.

One cannot leave the subject of diet without reference to the care of the teeth. Pyorrhœa is a sign of vitamin deficiency. Caries is predisposed to by vitamin and calcium drain. Mrs. Mellanby's[25] work on this subject is well known. Every pregnant patient should be treated by a dentist if there is evidence of caries at all, even if only in one tooth. Oral sepsis is a predisposing cause of throat affections, toxæmia, and puerperal sepsis, and also of inability to suckling. Extractions do not produce abortions by any means, and in antenatal care dental treatment is one of the most valuable aids we possess. A condition of admission to the wards in the Royal Free Hospital for confinement is that consent should be given for dental treatment during pregnancy.

Significance and Treatment of the Symptoms and Signs of Toxæmia

Vomiting is perhaps one of the most frequent and important symptoms of toxæmia. It may occur at any period of pregnancy. It also occurs during labour in some cases, but is rarely observed in the puerperium. It may vary in intensity from the mild vomiting or morning sickness of pregnancy to the profound vomiting which is the result of toxæmia of both hepatic and renal origin. It is of more frequent occurrence in the first three months of pregnancy than in the latter months.

MORNING SICKNESS

In the examination of 100 consecutive antenatal cases in the Royal Free Hospital which were more or less normal, morning sickness had occurred in 50 per cent. In 14 out of 30 cases of eclampsia morning sickness was absent. In eight cases (four of which died) it was slight. I need not dwell upon the theories in regard to the causation of morning sickness. It is quite possible that acidosis may be closely associated with the symptom. The treatment, therefore, is to have a supply of barley sugar at the bedside and for the patient to eat the sugar in the early morning and also drink a glass of warm water. Attention to the functions of the intestine is desirable, but the indiscriminate administration of purgatives is to be condemned. The diet should be regulated in order to supply the vitamins which are necessary for normal metabolic function.

VOMITING IN EARLY PREGNANCY

This when frequent or prolonged usually denotes a condition of carbohydrate deficiency associated with an anxiety neurosis. Hyperemesis gravidarum should not be classified as a disease; it is a symptom of severe toxæmia, occurring early in pregnancy and is a very rare condition. Persistent vomiting when present in earlier pregnancy is proved by treatment to be due, in the majority of cases, to an anxiety neurosis. When patients suffering from worry and domestic anxieties are admitted to hospital or a nursing-home the vomiting soon ceases. It is a true "home sickness." Treatment carried out in hospital to some extent results in failure if the patient is kept in her home surroundings. I have not infrequently seen examples of a patient reacting quickly to treatment in hospital who, when sent home, had a recurrence of the symptoms, which again vanished on readmission to hospital. Investigation of all cases of vomiting should be thorough in order to ascertain if hepatic or renal damage is present. The persistent vomiting of pregnancy in a multipara not infrequently suggests renal damage. In a primigravida it is more likely to be early and hepatic in origin. The routine treatment is rest in bed, absolute freedom from worry, and adverse physical sensory and mental stimuli. For the first 24 or 48 hours the patient is kept on water with glucose and fruit juice. If the vomiting persists, washing out of the stomach combined with the administration of glucose solution per rectum is helpful in some cases. As soon as possible small carbohydrate meals should be given, beginning with dry biscuits, fresh butter, and barley sugar. This is to be followed by light mixed diet with limited protein. Sedatives may be necessary if the patient is worn out and sleepless. Calcium should be given either intramuscularly as calcium gluconate, or as calcium sodium lactate. The combination of calcium, potassium citrate, and bicarbonate of soda in a tumbler of water, as advised by Cameron,[26] is effective if the vomiting is not severe. In more severe cases no food or fluid should be given by the mouth. Fluids administered per rectum containing glucose and bicarbonate of soda are essential in order to avoid the dehydration which is likely to take place. Vomiting may start as a neurosis and cause acidosis from starvation. This in its turn keeps up the vomiting. The urine should be examined for albumin and the ocular fundi for retinal changes and the blood pressure taken for hypertension. If there is a positive result and the signs of toxæmia are present in a marked degree it will be necessary to empty the uterus, a procedure, however, which is rarely required.

HYPEREMESIS GRAVIDARUM

In this type of vomiting the toxæmia is profound and progressive. There is rapid dehydration of the tissues and not infrequently emaciation and jaundice are present. The blood pressure may be low, in which case the ovum should be removed without delay. No laboratory tests are required to inform us that such a patient is very seriously ill. Munro Kerr[3] points out that when vomiting ceases in severe cases the possibility of paralysis of the cerebral centre has to be considered, a fatal ending being not far distant. I have not seen one case of this type of severe vomiting in the last ten years, although a very large number of cases of vomiting are admitted to the wards for treatment. A considerable degree of success in carrying out treatment depends upon the assurance given to the patient that she has nothing to fear and that she will get well. Theobald[23] is opposed to the fact that vomiting is due in most cases to an anxiety neurosis, but there is no doubt that isolation and freedom from worry has a remarkable effect in bringing about a cure in the majority of cases; without this psychic adjunct dieting alone would be ineffectual. Fyfe Anderson[27] points out that vomiting is sometimes an evidence of pyelitis, and that the colon bacillus should be sought for in the urine.

In some cases vomiting in pregnancy may be due to gastro-intestinal conditions unconnected with pregnancy. Treatment on the usual lines for digestive trouble—viz., by bismuth subnitrate, lactopeptone combined with bicarbonate of soda—is of benefit and may cure the condition. Colon lavage is always useful in the treatment of vomiting.

HEARTBURN

This is sometimes a sign of grave impending toxæmia. I have found good results from advising small dry meals with low fat content. Fluids should be given between meals. This gives the gastric juices an opportunity to act. Dilute hydrochloric acid in 15-30 drop doses during meals gives relief in cases where hypo-acidity is present. Fyfe Anderson and Brian Rayner[28] have written on this subject.

HEADACHE

This if persistent may be due to anxiety, hypertension, eyestrain, or intracranial tension, and should never be overlooked. It is sometimes the first danger signal of the onset of eclamptic convulsions. Rest in bed is necessary in some cases and careful dieting of the carbohydrate type. If it is very severe lumbar puncture may give relief. Calcium lactate or calcium gluconate have also been given with good result. Pain on the whole is a rare symptom in pregnancy. It is present in severe forms of toxæmia in the region of the epigastrium and is due to tension under the liver capsule owing to small hæmorrhages. General treatment brings relief.

HYPERTENSION

This is frequently present and in toxæmia of the renal type may be persistent in spite of treatment. It may or may not be present in hepatic toxæmia, but in some of these cases the blood-pressure readings are found to be abnormally high. As a rule it reacts quickly to treatment. In persistent hypertension cardiovascular complications are present and cerebral hæmorrhage may occur. Hypertension if it does not yield to treatment is an indication for termination of the pregnancy; it is associated frequently with albumin and other signs of toxæmia, and in severe cases the blood pressure may fall rapidly. I have seen this occur before death in eclampsia as the result of heart failure. I have always been rather afraid of the rapid reduction of blood pressure by drugs such as veratrone, as there is danger of heart failure. Hypertension must have some protective function although we look upon it as an indication that the patient's condition is serious. In cases of toxæmia with high blood pressure I have been against excessive fluid administration intravenously or otherwise. I feel sure that blood volume increased in this way tends to aggravate the condition. Venesection, therefore, has an important place in the treatment of these cases.

Osman[17] points out the significance of essential hypertension in the follow-up of cases of toxæmia of pregnancy, and thinks that it might be a symptom in itself, and that it does not always indicate kidney damage. He refers to Cushing's statement that hypertension in eclampsia and also essential hypertension suggests an increase in the function of the posterior lobe of the pituitary.

Œdema is usually accepted as a sign of renal damage, but we have already seen in the previous lecture that in its association with increase of weight it is due in some instances to excessive food and fluid intake, in particular of sodium chloride. Rest in bed, regulation of the diet, and general treatment especially with small doses of magnesium sulphate will have a beneficial effect. Restriction of fluids also has a marked effect when balanced equally with the urine output. In œdema due to cardiovascular changes the treatment should be on ordinary medical lines.

OCULAR DISTURBANCES

In cases of severe or prolonged toxæmia, especially of the renal type, the ocular fundus should be examined by a specialist. The presence of hæmorrhages, separation of the retina, or of retinitis is a valuable indication for the termination of pregnancy. Ocular changes are much more frequent in nephritis toxæmia, although blindness may be more frequent in the hepatic type. As a rule the ocular symptoms disappear after the termination of the pregnancy in hepatic toxæmia but not to the same extent in kidney lesions. In 30 cases of eclampsia in the Royal Free Hospital only 3 had ocular symptoms. Only one patient was found to be affected out of 65 cases of severe toxæmia without convulsions. In the renal type ophthalmoscopic examination may reveal a very serious condition of affairs which may shorten life within some few months or years of the pregnancy.

ANÆMIA

In hospital practice one is frequently struck with the large number of anæmic women who attend the clinics or come into the wards. Although in this country we have not the profound anæmias which are described by Lucy Wills[21] and also by Green-Armytage[22] as occurring in India, there is a considerable amount of fairly serious anæmia in association with pregnancy. This anæmia is mainly due to vitamin and iron deficiency. Sunlight, fresh air, and a generous mixed diet is essential in the prevention and treatment. Green vegetables such as spinach contain iron. As already mentioned, the fœtal drain on the maternal iron is considerable.

In the antenatal clinics of the hospital we give yeast and massive doses of ammoniated citrate of iron in powder form to a large number of the patients. In the wards each patient receives once a day a routine dose of iron and cod-liver oil. Marmite and cooked liver or liver extract are given to some of our anæmic patients. Our biochemists, Dr. Pillman Williams[24] and Dr. Lucy Wills, investigate and superintend the treatment of this condition. I sometimes question how much absorption takes place in those cases in which massive doses such as 90 grains of Blaud's pills are given daily. Transfusion of blood, as most obstetricians know, is of great benefit in the treatment of severe anæmia, toxæmia, shock, and sepsis.

ANTEPARTUM HÆMORRHAGE

In hæmorrhage occurring most especially in the later weeks of pregnancy and apart from that due to placenta prævia the chief cause is toxæmia, which results in placental changes and separation from the uterine wall. Fœtal death is inevitable if the hæmorrhage is extensive. In my experience this condition has decreased very much of late—a fact which is a testimonial to antenatal supervision. If the placenta has not entirely separated the effect of the toxæmia on the mother is much more marked than when the placenta is free in the uterus. This points to the fœtal and placental origin of the toxæmia, but this condition may be secondary to the deficiency disease of the mother.

In the treatment of antepartum hæmorrhage all depends upon the conditions which determine whether simple rupture of the membranes or Cæsarean hysterectomy is indicated. The more severe the condition the less should be the surgical interference, as the hæmorrhage may be a symptom of a very profound toxæmia involving the liver and kidneys. It must also be remembered that version of the fœtus in breech positions may be followed by hæmorrhage in a toxic patient. I cannot too strongly stress the fact that in my opinion version is a serious operation and should not be undertaken lightly in cases of toxæmia. It not infrequently leads to fœtal death and sometimes to partial separation of the placenta.

In the investigation of 40 consecutive cases of toxic antepartum hæmorrhage in the Royal Free Hospital we found that it occurred more frequently in multiparæ, thus pointing to a renal origin of the condition. The fœtal mortality was high—25 per cent. No maternal deaths occurred, and Cæsarean section was not performed in any of the cases. Only 12 of the cases were near or at term; the earliest case was at the 30th week.

Postpartum hæmorrhage is due in the majority of cases to toxæmia and fatigue and can often be avoided by feeding the patient with light meals during labour and encouraging her to eat barley sugar. Abstaining from touching the uterus during the third stage of labour except when expelling the placenta prevents postpartum hæmorrhage in many cases.

INVESTIGATIONS OF BLOOD AND URINE

In mentioning the assistance we obtain for purposes of diagnosis in the investigation of the blood and urine of a case of toxæmia, I have not the courage to enter into any discussion in regard to the respective merits of the tests which the various biochemists put forward. I agree with Dr. Bethel Solomons [29] that a test is of little value to our limited intelligence as clinicians unless it can be put to some use at the bedside. What does it all narrow down to in the end?

The examination of the blood indicates not only the number of blood corpuscles and percentage of hæmoglobin, but in addition gives us some insight into the function of the kidneys by furnishing a report upon the urea content. This content is normally lowered in pregnancy, especially in the latter half. If the urea content soars to 30 or 40 mg. per cent. we feel there is some cause for watchfulness at least.

In a normal pregnancy a urea content of 22, or slightly over, reassures us that renal function need not be a source of anxiety. If the urea content indicates renal complications we try treatment by rest in bed and dieting, but if this fails the pregnancy may have to be terminated. Uric acid is, however, a finer test of nitrogen retention than urea. The sugar curve of the blood is an indication of the aberrations which take place in carbohydrate metabolism. In cases in which the blood-sugar content is high, insulin may be given with discretion.

Examination of the urine.—Albumin is the danger flag throughout pregnancy. When it persists and is considerable in quantity it indicates renal damage and should never be overlooked. Hence the routine examination of the urine in all cases of pregnancy is a necessity. A considerable amount of albumin in the urine should not be allowed to persist for more than two to three weeks as there is the danger of permanent kidney damage. It is an indication for the termination of the pregnancy (Gibberd [11]).

In regard to the feeding of patients suffering from considerable loss of albumin due to chronic nephritis, there is some diversity of opinion. If the protein loss is excessive the tissues will be drained. In the case of a pregnant patient suffering from this condition there is the added drain from her fœtus. She will, therefore, suffer from protein starvation unless her intake is supplemented by protein. Physicians not infrequently find that patients suffering from nephritis show signs of rapid improvement when a protein diet is provided. The whole question is admirably discussed by Cruickshank.[8] I have found for years that it is desirable to get a patient, suffering from toxæmia, on to a mixed diet as soon as possible. I have had much better results than when I adhered to the rigid rules which practically meant starvation.

The urea-concentration test is useful in determining renal function. The presence of casts is also of value. Bacteriological examination for the colon bacillus by culture of the urine at the bedside as advised by Colebrook [30] I find gives many more positive results than those obtained when the urine, after standing, is sent to the laboratory for culture. An important indication of renal damage is the low specific gravity of the urine. The quantity of urine passed is very important, especially in serious cases of toxæmia. The intake and output of fluid should be carefully measured and compared. Scanty or suppressed urine is a grave sign of toxæmia and may indicate immediate efforts for the termination of the pregnancy. In renal cases suppression is even more serious as it indicates a greater degree of concentration than toxæmia. I have no experience of decapsulation of the kidneys or other similar operations. I see little indication for them but rather the danger from surgical interference in these cases. Hot packs, electric light baths, and diuretics such as citrate of potash are of benefit. Urea may be used with care. Cruickshank advises guaiacum baths—painting the axilla with tincture of guaiacum 10 per cent. in glycerin and applying warm blankets for 20 minutes. Pyelitis rarely requires treatment other than rest in bed, dieting, warmth, and urinary sedatives and antiseptics. A very large number of these cases are sent into our wards for treatment, and in no case has surgical interference been necessary; as a rule, these patients clear up very satisfactorily, and a ketogenic diet is giving good results in some cases. In the study of the blood and urine changes the biochemists give us many tests and deductions which may persist or may change with the fashions. We go on our way thankful for any help in making a diagnosis, but we rely to a great extent upon our own clinical observations and our knowledge of the particular patient concerned.

ECLAMPSIA

This is the most serious form of all toxæmias. It would take a volume to contain the information we are given on the subject. We all treat it by methods of elimination and by sedatives in all their permutations and combinations, but we must remember that the prevention is our aim. Prof. Stroganoff came to London from Russia some years ago to show us how to treat eclampsia and asked us all to give him cases for demonstration. When he visited the Royal Free Hospital I told him we had none at the time and that our practical experience of these cases was getting less and less. He said to me: "I have ome to London to teach you all the treatment of clampsia, but I am returning to Russia having earned how to prevent it.”

Indications for Surgical Treatment

Statistics everywhere seem to be in agreement that the less we interfere with these cases of toxæmia the better, and that the lowest mortality is obtained by conservative methods, but when obstetrical indications require the application of forceps there is, of course, no ban upon their use. Pregnancy in some cases has to be terminated early in order to save the life of the mother or guard her from permanent ill-health. Termination in late pregnancy may be necessary for the same reasons and also perhaps to save the life of the infant.

A list of cases where the induction of therapeutic abortion has taken place in the Obstetrical Unit at the Royal Free Hospital shows the total number in 10 years (1921–31) to have been 52, classified as follows: pulmonary tuberculosis, 25; heart disease, 14; renal disease, 8; miscellaneous, 5. In no case was the uterus emptied because of uncontrollable vomiting.

The best method of terminating an early pregnancy is by hysterotomy which can be combined with sterilisation. The rapid evacuation of the uterus by the cervical canal is dangerous, except in very early pregnancy owing to hæmorrhage and shock. The slow method by tents or a small rubber bag gives better results. Premature labour can be induced by digital stretching of the cervix and by separation of the membranes at the internal os. Rupture of the membranes, or the introduction of a rubber tube or bag, are also to be advised.

There are no rules to be followed except those which are gained by our own experience. A case of nephritis may require induction of abortion or, preferably, abdominal hysterotomy and sterilisation. In some cases we allow the pregnancy to continue, and urge that it must be the last; this is a risky proceeding and requires great supervision, but the results in the chosen cases have been very satisfactory. If the patient has symptoms which do not react to efficient treatment, or the condition is grave and yet not grave enough for the risk of interference, then we confess that we have failed as physicians and must perforce recommend surgical interference. But my rule as in all cases of operations in obstetrics is “when in doubt do nothing.” We must remember that many women’s lives are just saved because we manage to avoid the strain and perhaps trauma of labour until the condition of toxæmia has been improved with treatment.

Cæsarean section has its place for consideration. It is advocated by Miss Basden,[31] who has obtained good results. I have found few indications for its use and avoid it in the treatment of acute toxæmia except in cases where there is a definite obstetrical indication. For example, in our treatment of 65 consecutive cases of grave toxæmia Cæsarean section was not performed in a single case, and there was not a maternal death.

ANÆSTHETICS

These require careful consideration in cases of toxæmia. Gas-and-oxygen is safe; chloroform is a hepatic poison; ether may cause pulmonary complications. If spinal anæsthesia is employed due attention must be given to the state of the blood pressure. If low, spinal anæsthesia is contra-indicated. I would like to give a warning as to the use of pituitrin injections in cases of toxæmia, especially those of renal origin. I have had a case of death from sudden shock and uræmia just after an easy spontaneous delivery in a multipara with renal damage. This occurred after the administration of pituitrin. In several other cases I have noticed the presence of varying degrees of shock after pituitrin injections. It is a method of treatment which cannot be used without considerable discrimination.

Postnatal and Antenatal Care

It is obvious from a study of toxæmia and its effect upon maternal morbidity that a thorough examination should be carried out in every case a few weeks after childbirth and the puerperium. If any complication is found to be present, further supervision and treatment are indicated. The investigations upon renal function show how necessary it is that this function should be tested. For this reason postnatal care is essential for every individual patient no matter how normal her confinement may have been. Every case attended by a midwife should be seen later by a doctor at least once; gynæcological complications would be reduced to a great extent by this means. In some cases it is necessary to forbid any future pregnancy or one before a given date, and for this reason contraceptive advice should be available at the postnatal clinic just as part of the general medical supervision. Separate clinics would not be necessary if every practitioner had a knowledge of contraceptive treatment.

The chief aim of antenatal care is to prevent the development of toxæmia or if it has developed to prevent the onset of serious symptoms such as acidosis or eclamptic convulsions. Most of the toxæmias of pregnancy can be prevented by a suitable mixed diet. Treatment of the condition becomes most effective when diet deficiencies are supplemented. Drugs may have to be given to replace more rapidly the tissue drain.

The Standard of Obstetric Work

In conclusion I would urge that the standard of obstetric work and teaching must be raised throughout the country. Clinics must be staffed by medical practitioners who have had special training in the work but who are not necessarily specialists. These should preferably be responsible for the supervision of the whole management of pregnancy, labour, and the postnatal maternal welfare. The Diploma of the College of Obstetricians and Gynæcologists or that of the Society of Apothecaries or other equivalents should be insisted upon by public health authorities as a qualification for undertaking the duties of an antenatal clinic. Antenatal work should be in the hands of qualified practitioners. Midwives should carry out the instructions of the doctor and should have facilities for immediate help when it is required in childbirth. A panel of practitioners should be available for this purpose and consultants referred to when necessary.

Much criticism is levelled against antenatal supervision, but in reply one has only to compare the midwifery of the present day with that before antenatal examinations came into practice. Craniotomy operations upon the living fœtus are now almost unknown and yet the Cæsarean section-rate has not increased in those clinics where antenatal care has been made a special feature. Accidental hæmorrhage and difficulties with malpresentations are rarely encountered now in the labour ward. In time also we shall gain much more knowledge of the prevention of eclampsia.

The physician who by research and practice lowers the incidence of general diseases such as rickets, scarlet fever, and rheumatism, will do much to aid us in the reduction in the maternal mortality of future generations.

ASSOCIATION BETWEEN NEUROSYPHILIS AND CARDIOVASCULAR SYPHILIS *

BY FREDERICK H. HEALEY, M.D., B.Sc. Birm., D.P.M.
MEDICAL SUPERINTENDENT, BRIDGE HOME, WITHAM; LATE SENIOR ASSISTANT MEDICAL OFFICER, COUNTY MENTAL HOSPITAL, CHESTER

WHEN I first entered mental hospital work I had expected to find cases of general paralysis of the insane exhibiting no cardiovascular lesions. I was thinking along the old lines that cardiovascular lesions were but tertiary manifestations and due to renewed activity of the spirochæte; whereas general paralytic changes were to be regarded as something entirely different, not due to direct spirochætal activity, and in fact parasyphilitic.

Collier, in arguing against the theory of two varieties of spirochæte, neurotropic and dermotropic, points out that it can no longer be held that tabetics and paretics are free from tertiary lesions. The clinical work to be reviewed brings all the different syphilitic manifestations into line with each other, and demonstrates the absurdity of the theory of two varieties of spirochæte. From a study of the work of Warthin, it seems only rational to expect to find cardiovascular changes in a large proportion of cases showing neurosyphilis. There are people who have weak cardiovascular systems, and who show arterio-sclerotic brain changes in association with heart lesions. When they get syphilitic infection (which we now know to be a widespread infection) they will be the people to show markedly this association between neurosyphilis and cardio-aortitis.

CLINICAL EVIDENCE

In 1930 Bach and Worster-Drought examined 25 clinical cases of neurosyphilis for cardiovascular changes, and 25 clinical cases of cardiovascular syphilis for neurosyphilis. Of 25 cases of neurosyphilis, 7 (28 per cent.) showed cardiovascular changes. Of 25 cases of cardio-aortitis, 4 (16 per cent.) showed some neurosyphilitic changes. Carey Coombs in the same year found that of 103 cases of cardiovascular disease due to syphilis, 26 (25 per cent.) gave evidence of neurosyphilis.

In 1907 Rogge and Müller of Breslau in 22 consecutive cases of tabes dorsalis found 8 (36 per cent.) with definite clinical evidence of syphilitic cardiovascular disease. In 1913 Denke reported on 153 cases of syphilitic aortitis, of which 63 (41 per cent.) showed physical signs of neurosyphilis. In 1923 Frisch published a series of 115 cases of neurosyphilis, of which 9 only (7 per cent.) showed clinical evidence of aneurysm or syphilitic aortitis.

Thus clinically one in seven of neurosyphilitics give evidence of cardiosyphilis. Viewing the relationship from the other standpoint, there is in cardiosyphilis a great variation in the percentage showing neurosyphilis :—

Bach and Worster-Drought	..	16 per cent.
Coombs	..	25 „
Denke	..	41 „
Average percentage ..	..	33 „

Thus, clinically, one in three of cardiosyphilitics give evidence of neurosyphilis.

PATHOLOGICAL EVIDENCE

Frisch, in 1923, in 115 cases of neurosyphilis found pathological evidence of syphilitic aortitis in 45 cases (39 per cent.), Kessler, in 1924, in 59 cases of tabes dorsalis found 39 cases with syphilitic mesaortitis (66 per cent.), Lowenberg in 341 cases of general paralysis found 114 cases with evidence of aortitis at autopsy (33 per cent.). This gives an average percentage of 38 and thus from the pathological evidence more than one in three of neurosyphilitics give evidence of vascular changes.

The difference between the clinical and pathological figures is accounted for in several ways. First, it is difficult to detect the cardiac lesions in life with ordinary methods of examination. These patients do not complain of any cardiac symptoms, and only recently have the newer methods of radiography and electrocardiography been applied to this work. Secondly, the neurosyphilitics are the class with the nervous system more vulnerable than the vascular system. Thirdly, when cases come to autopsy, both nervous and cardiac lesions will be well advanced.

AN INVESTIGATION

I will now give the results of an inquiry into 169 cases (seen at the County Mental Hospital, Chester) which were analysed for the correlations between neurosyphilis and cardiovascular syphilis. These cases, like those given above, have been divided into two groups, the clinical and the pathological.

Clinical evidence.—There are 114 cases in this group, subdivided into the following sections :—

(a) Cases discharged after malarial treatment ..	40
(b) Cases remaining in hospital at end of 1931 ..	33
(c) Cases dying *in the years 1925 to 1931,* but where no post-mortem examination was held..	41

The clinical evidence in these cases is derived from auscultatory findings, blood-pressure records, and radiographic examination. In each case by inspection and palpation an estimate is made of the size of the heart, particularly for left ventricle hypertrophy or dilatation. The aortic sounds are carefully examined. A systolic aortic murmur, loudest at the aortic area and propagated up into the vessels of the neck, is taken as evidence of aortic stenosis. The murmur is usually loud and rough, and often accompanied by an aortic systolic thrill. A diastolic murmur, soft and blowing, transmitted down the left of the sternum, especially if associated with left ventricle enlargement and Corrigan's pulse, is taken as evidence of aortic incompetence. The most common finding is a basal aortic systolic murmur, and an accentuated aortic second sound. Many cases gave the characteristic basal to-and-fro systolic-diastolic murmur.

The blood pressure has been taken in all cases with a baumanometer, in the lying-down position, between 11 A.M. and 12 noon. Both pulses are examined, and in many cases a marked difference has been found between the readings on the two sides. A raised blood pressure with an accentuated aortic second sound in a young man with a positive blood Wassermann is taken as evidence of early syphilitic aortitis.

---

* Part of a thesis for the M.D. degree of the University of Birmingham.

The chest has been screened in most of the cases, nd the more interesting cases have been plated. The gns looked for are: slight enlargement of the heart o the left, increase of the aortic shadow to the right, ilatation of the aorta, enlargement of the aortic nuckle, and in some cases obvious aneurysmal ilatation. In assessing each case the findings of the hree special methods of examination are carefully onsidered, and so an accurate picture is obtained of he cardio-aortic state.

Of the cases discharged after malarial treatment, 32 are Chester cases, the other 8 are cases sent from Denbigh Mental Hospital for malarial treatment.

TABLE I.—*Incidence of Cardiovascular Syphilis in cases treated by Malaria*

	G.P.I. cases.	Cardiosyphilis present.
1925	8	4
1926	2	1
1927	4	1
1928	1	0
1929	4	1
1930	3	3
1931	10	6
Denbigh	8	4
	40	20

In this series 50 per cent. of the cases of general paralysis give evidence of cardiovascular syphilis.

TABLE II.—*Cases remaining in the Hospital at the End of 1931*

Admitted.	G.P.I. cases.	Cardiosyphilis present.
1919	1	1
1925	1	0
1926	1	1
1927	6	5
1928	4	3
1929	6	4
1930	2	1
1931	12	6
	33	21

In this series 64 per cent. of the cases of general paralysis give evidence of cardiovascular syphilis.

TABLE III.—*Cases Dying 1925 to 1931, no Post-mortem Examination being Held*

	G.P.I. cases.	Cardiosyphilis present.	
1925	8	6	
1926	9	2	
1927	8	8	
1928	8	4	
1929	3	3	1 case of aneurysm
1930	1	1	
1931	4	3	
	41	27	

In this series 66 per cent. of the cases of general paralysis give evidence of cardiovascular syphilis.

From three groups of cases set out in Tables I.–III. it is seen that 59 per cent. of the general paralytics at Chester give clinical evidence of cardiovascular syphilis. This figure is much higher than any figures yet published. It shows that it is the rule, rather than the exception, for a well-marked case of general paralysis to show evidence of cardiovascular damage.

Pathological evidence.—There are 54 cases in this group of general paralytics, dying in the years 1925 to 1931. In each case a post-mortem examination was held, the heart and great vessels were carefully examined for evidence of syphilitic valvular disease and syphilitic mesaortitis respectively. Sections of the diseased aorta have been examined microscopically in doubtful cases, and in many the spirochæte has been demonstrated. In some cases it has been difficult to decide between senile atheroma and syphilitic aortitis. These doubtful cases have been rejected. Coombs, in his Lumleian lectures in 1930, discussed this difficulty, and his criterions have been adopted.

TABLE IV.—*Autopsies showing Cardiovascular Syphilis*

	G.P.I. cases.	Cases showing cardiosyphilis.	
1925	3	2	
1926	10	4	
1927	8	7	
1928	6	5	
1929	7	7	2 cases of aneurysm
1930	14	10	
1931	6	5	
	54	40	

In this series 74 per cent. of the cases of general paralysis give evidence of cardiovascular syphilis.

The 40 cases showing cardiovascular syphilis were distributed in age-groups as follows:—

Ages—								
28	*30–34*	*35–40*	*41–44*	*45–50*	*51–54*	*56*	*62*	*68*
1	3	4	13	10	6	1	1	1

Thus the biggest proportion of these cases fall into the 40–50 group, that is the fifth decade. It is to be noted that 8 cases occur in men under 40, this being contrary to Kessler's findings. Five cases showed a partial Babinski syndrome, being cases of tabes dorsalis with aortic valvular disease and aortitis.

PREVIOUS TREATMENT

I have made inquiries into the previous treatment, the date of infection, and the latent period. There were three cases where no history was obtainable. Two cases had received no treatment at all, but the latent period was estimated as 5 years and 20 years respectively. Seven cases gave a history of previous mercurial treatment only, and in these cases the latent periods were 12, 14, two at 18, 19, 20, and 30 years respectively. Twenty-eight cases had received early treatment with arsenobenzols. Most of these had acquired their infection during war service and had received one or two courses of "606" but did not persist in treatment. This group of cases is extremely important in connexion with the question of the efficacy of arsenobenzol treatment and the questionnaire sent round by the Medical Society for the Study of Venereal Diseases in 1925 (see Brit. Jour. Ven. Dis., 1925, i., 133). The latent periods of this group of 28 cases are as follows:—

Years—											
4	*6*	*7*	*8*	*9*	*10*	*11*	*12*	*13*	*14*	*15*	*20*
1	1	1	1	3	6	7	3	2	1	1	1

It is to be noted in this group that more than half of the cases have a latent period of 9 to 12 years, whereas in the group having had mercurial treatment the shortest latent period is 12 years. It thus seems that a short course of "606" predisposes to early and intense nervous and cardiac lesions. The two cases with 20-year and 15-year latent periods had received prolonged "606" treatment in America. Apparently the most dangerous treatment of early syphilis is a short course of "606," giving as it does great security at that time but intense morbidity in the space of 9 to 12 years.

DISCUSSION

The figures obtained in the series of cases examined at the Chester Mental Hospital show a much higher percentage of cardiovascular syphilis in cases of neurosyphilis than any yet published. They are higher even than those of the German clinics. It must be remembered that the cases of general paralysis sent to a mental hospital are very advanced in their disease, and hence such a close correlation between neurosyphilis and cardiosyphilis is to be expected. The general conclusion to be drawn is that syphilis affects the whole body more commonly than is supposed; it supports the contention of Warthin that spirochætes will be found in every organ of the body in a syphilitic. It also supports the view that general paralysis is an active syphilitic infection, and not a parasyphilitic process.

The incidence of cardiovascular syphilis in association with neurosyphilis and mental disease is of immense importance from the point of view of treatment by induced malaria. In the early years of this treatment many cases died suddenly during or just after their pyrexial course, and no clinical evidence of aortic disease had been found. I have seen such cases at the Chester Mental Hospital, and similar findings have been noted by Bach and Worster-Drought, Gerstmann, Rudolf, and Lowenberg. The correlation between the two kinds of syphilitic disease, cardiac and nervous, is really closer than had been thought. It was taught that the clinical diagnosis of the nervous lesions was predominantly in the fourth decade and that of the cardiac lesions in the fifth decade, but in mental hospital work the two kinds of disease occur together in the fourth and fifth decades. Which lesion will be noted first depends partly on the severity of the separate lesions and also on the relative sensitivity of the two systems in the one individual. Thus the make-up of the patient from both the physical and mental angles determines this issue. Ernest Jones has demonstrated that certain people have undue sensitivity of their internal organs, and if this state is very well marked, hypochondriacal symptoms will result. These psychasthenic people, when infected with syphilis, complain of the lesions according to the more sensitive system, and thus the diagnosis is determined to a cardiac or a nervous state. In general one would expect an earlier outcry on the part of the nervous system, as it shows a more sensitive reaction to disease.

With reference to the age of incidence of the two types of disease, and the period after initial infection, there are some differences of opinion. Kessler said in 1924 that cases of neurosyphilis under 40 years of age did not show aortic disease. I have referred to eight cases showing well-marked aortic disease with neurosyphilis under the age of 40 years. Stokes stated that it was rare to find the cardiovascular system affected by syphilis in the first decade after initial infection, that only 45 per cent. were diagnosed in the second decade, and that 55 per cent. occur in the third decade or later. In my series I have found cases of fulminating general paralysis with pronounced cardiovascular changes within a decade of the initial infection. This is an important point when discussing the early treatment of syphilis, as it is certain that the service men who had short courses of arsenobenzol treatment relapsed sooner than men infected in the early years of this century and treated with long courses of mercury. Coombs found the latent period in his series of cardiac cases to be 22·7 years, and Bruce found it to be 25 years. In my series I have differentiated between the cases having arsenobenzol and mercurial treatment, showing that the latent period averages about ten years with the former and twenty years with the latter. It is surely no accident that there is so close an association between the two sets of syphilitic phenomena, the cardiac and the nervous. The disease must have evolved in the same way in the two areas, and the only differences noted will be differences of function, depending on the relative weaknesses of the two systems in the individual concerned. Males predominate in all the series of cases published either of nervous or cardiac disease, Coombs showing that 90 per cent. of his cases were males. Again, even in congenital syphilitic disease the heart and the brain lesions fall into the same epoch, but the latent period is a little shorter.

It now remains to inquire if there is any fundamental explanation of this very close association between the cardiac and the nervous lesions. Warthin's paper on the lesions of latent syphilis shows that, once a person is infected with the spirochæte, foci of latent infection remain in all the organs for the rest of the patient's life. Thus it is not really surprising that, when activity is renewed, disease arises in both heart and brain; the wonder is that many other organs are not acutely affected in addition. There is, however, evidence that other organs do show active disease at a late stage, and in association with nervous and cardiac lesions. Bruce found diabetes mellitus, presumably of syphilitic origin, to be a frequent accompaniment of syphilitic disease of the circulatory organs. Marañon saw it 23 times in 140 cases of aortic syphilis. On the other hand, Coombs had not seen one such case. Bostock described a case in 1926, and I have in my series a very interesting case beginning as diabetes, then suffering from aneurysm, and finally dying of specific meningo-encephalitis, the spirochæte being found in all three lesions.

Now the infection must linger in some parts of the body and, after lying latent for a number of years, come into action again and acutely affect various areas. It has been suggested by Coombs that the lymph glands of the body are the sites of latency. Martland contributes to the view that the mediastinal lymph glands harbour the spirochætes in the latent period. Stern has proved a lymphogenous origin for tabes dorsalis, and it is very probable that both the aortic lesions and tabes dorsalis come from the same reservoir of infection, that is, the mediastinal lymph glands. This explains the occurrence of the Babinski syndrome, either in the complete form of tabes dorsalis with aneurysm or the less complete form of tabo-paresis with aortic incompetence. Lymphadenitis is a prominent feature of secondary syphilis and appears to mark the end of the bacteræmic stage. Presumably this is as true of the internal glands which are hidden from examination as it is of the external glands which are obvious and palpable. Experimental work has demonstrated the persistence of living spirochætes in the lymphatic glands for months or years after an animal has been inoculated with the disease. Moreover, Engmann and Eberson have demonstrated in three cases out of fourteen of general paralysis that the lymph glands contain spirochætes. It is thus very likely that the spirochætal infection lies latent in the main lymph glands, and at the end of the incubation period for the cardiac and nervous lesions, for some reason at present unknown, the infection flares up again and attacks the vital organs. We know that the posterior cervical glands are markedly affected in secondary syphilis, and I suggest that the spirochætes, lying latent in these glands, ascend into the spinal canal and cranial cavity and so cause syphilis of the spinal cord and brain. There is thus much scope for further research on this interesting problem of the late infection of the central nervous system in syphilis.

CONCLUSIONS

1. Cardiovascular syphilitic lesions are the rule rather than the exception in cases of so-called general paralysis. It is found that clinically 50 to 60 per cent. of so-called paralytics give evidence of cardio-aortic lesions, and that 74 per cent. of the autopsies of paralytics give the same evidence.

2. The latent period after short courses of "606" averages 9–12 years, whereas the latent period after mercury treatment averages 12–20 years. It is certain that early treatment of syphilis with inadequate doses of salvarsan is dangerous.

3. Many of the cases of general paralysis referred to in this paper acquired their infection while on war service and received short courses of "606." Within ten years these cases relapsed badly with cardiac and nervous syphilis. This evidence forms an alarming answer to the questionnaire formulated by the Medical Society for the Study of Venereal Diseases in 1925.

I thank the medical superintendent, Dr. G. H. Grills, for permission to publish the figures and cases referred to in this paper.

THE PENTNUCLEOTIDE TREATMENT OF AGRANULOCYTIC ANGINA *

BY JOHN F. WILKINSON, M.D., M.Sc., Ph.D. Manch., M.R.C.P. Lond., F.I.C.
HON. PHYSICIAN IN CHARGE AND DIRECTOR OF THE DEPARTMENT OF CLINICAL INVESTIGATIONS AND RESEARCH, ROYAL INFIRMARY AND UNIVERSITY OF MANCHESTER; AND

M. C. G. ISRAËLS, M.B., M.Sc. Manch.
ASSISTANT DIRECTOR IN THE DEPARTMENT OF CLINICAL INVESTIGATIONS AND RESEARCH, ROYAL INFIRMARY, MANCHESTER; LADY TATA RESEARCH SCHOLAR

IN her studies on living human blood-cells, Sabin [1] suggested that the stimulus for the production of non-motile polymorphonuclear cells might be products liberated from disintegrating homologous cells.

This led to a study of the leucocyte-stimulating properties of nucleic acid and nucleinates. Doan, Zerfas, Warren, and Ames [2] injected relatively large doses of sodium nucleinate intravenously into rabbits. They found that, after a preliminary decrease of leucocytes, a considerable leucocytosis followed. Their experiments pointed to the spleen as being responsible for the preliminary leucopenia, as after splenectomy this did not occur. Jackson [3] had meanwhile demonstrated the presence of pentose nucleotides in normal human blood. Doan [4] gave intravenous injections of pentose nucleotides into rabbits. He found not only a peripheral leucocytosis, but also a marked myeloid hyperplasia of the tibial bone-marrow. Repeated injections caused neither exhaustion nor malignant change in the myelopoietic elements, and after cessation of the injections the blood gradually returned to its former state.

C. Reich and E. Reich [5] have reported experiments on the Pentnucleotide treatment of rats, either young rats which are normally leucopenic, or those rendered leucopenic by previous treatment with benzol. Their results were uniformly negative, but they admit that benzol poisoning may not provide conditions comparable with human agranulocytosis. R. F. Phillips (unpublished) has recently tested for the Therapeutic Trials Committee the effect of pentnucleotide in rats made leucopenic by irradiation. No significant change was produced in the leucocyte counts of these animals, and the treated rats survived no longer than the corresponding controls.

In the human subject the syndrome of agranulocytic angina described by Schultz [6] presents a very constant picture. It commences with rapid onset of vague symptoms of lassitude. Then follows a general prostration accompanied by a rapidly spreading lesion in the mouth, both being characterised by a severity out of all proportion to the pathogenicity of the organisms found in the lesions. Examination of the blood reveals a complete, or almost complete, absence of polymorphonuclear leucocytes.

This is undoubtedly a rare condition, but since the original description several cases have been described and their treatment with pentnucleotide recorded. Jackson, Parker, and Taylor [7] reported a series of 69 cases collected from various sources, of which 74 per cent. recovered after pentnucleotide treatment. Cases treated with pentnucleotide have also been reported in this country by Bulmer,[8] Fairley and Scott,[9] and Marriott [10]; of these, two recovered, the case of Fairley and Scott being fatal.

In man the response takes the form of a steady increase of granulocytes. Jackson noted that this began as a rule on the fifth day after the commencement of treatment; but Doan's cases showed an immediate rise. Doan [4] also drew attention to the fact that the myelocytes showed a marked increase at the beginning of treatment, falling off again as the polymorphonuclear cells returned towards normal levels. This myelocytic response somewhat resembles the reticulocyte response in pernicious anæmia. The preliminary leucopenia noted by Doan in his experiments on rabbits has not been observed in the human cases so far recorded.

Last year the Therapeutic Trials Committee of the Medical Research Council accepted an application for clinical trials of pentnucleotide, and one of us (J. F. W.) was asked to coöperate in the tests of this product on the committee's behalf. The application to the committee was made by Messrs. Menley and James Ltd., agents in this country for the Smith, Kline and French Laboratories of Philadelphia, who manufacture pentnucleotide. In view of the rarity of cases of true agranulocytic angina (for which condition pentnucleotide is specially recommended), it has been felt justifiable to publish this single case as a preliminary report to the Committee.

CASE RECORD

A housewife, aged 34, was admitted to hospital on March 13th, 1934. Fifteen months previously she had had a severe attack of diphtheria. After her return home

---

* A Report to the Therapeutic Trials Committee of the Medical Research Council.

occurred pari passu with the fall in the leucocyte count.

A daily reticulocyte count provided significant information concerning the functional activity of the erythroblastic marrow. From an initial percentage of 3·8 the reticulocytes steadily diminished in numbers and, as indicated in Table II., the percentage on the day of death had fallen to 0·6. From those figures it may be concluded that immediately prior to death a condition of almost complete marrow aplasia existed. The depressed state of the marrow in the last week of the illness was such that no response was obtained either from blood transfusion or from intramuscular injections of nuclein. Although only two such injections were given, there is no reason to suppose that a granulocytic recovery could have occurred at this stage of the disease.

On reviewing the case as a whole it appears that the leucopenic state induced by the *B. typhosus* infection was associated with a markedly inadequate response on the part of the patient's immunity mechanism, if one may take the agglutinating titre of the serum as a criterion of the magnitude of the immunity response. The titre of the serum was estimated on several occasions and, as already indicated, never rose higher than 1 in 250. With the immunity mechanism depressed the septic anginal condition readily developed and the superadded toxæmia induced not only an agranulocytic state but a generalised inhibition of marrow function.

It is now recognised that in addition to idiopathic agranulocytosis first described by Schultz [2] in 1922 secondary agranulocytosis is met with in a variety of conditions. Thus Fried and Dameshek [3] claim to have produced leucopenia with granulopenia in experimental animals with strains of *B. suipestifer* isolated from human beings, and in rare instances an agranulocytic state has developed after injections of *B. typhosus* vaccine. The present case may be interpreted therefore as a secondary agranulocytosis complicating typhoid fever.

I wish to express my thanks to Dr. A. P. Martin, medical superintendent of the Salisbury Hospital, for kindly allowing me to investigate this case.

THE FATE OF FOLLICULAR HORMONE IN THE LIVING BODY

FORMERLY PROFESSOR OF GYNÆCOLOGY AND OBSTETRICS IN THE UNIVERSITY OF BERLIN

By Bernhard Zondek, M.D.

(From the Biochemical Institute of the University of Stockholm)

The following is a brief report of experiments dealing with the fate of œstrogenic hormone (folliculin œstrin) in the living body. A comprehensive paper in the *Skand. Arch. f. Physiologie* will deal with the literature and experimental technique.

After the oral or subcutaneous administration of folliculin only very small quantities are excreted in human or animal urine in an active state. In the case of a woman of 49 who had received during a period of 15 days 54 mg. = 540,000 mouse units of folliculin (α-hormone), I was able to discover only 1·6 mg. = 16,000 m.u. (i.e., 3 per cent.) in the urine. A sexually mature man who received a single subcutaneous dose of 40,000 m.u. excreted less than 5 per cent. during a period of ten days. The excretion in the case of rats is still less. Even after the injection of 20,000 m.u., which is a very big dose for a rat, no folliculin is excreted in the urine. What becomes of the hormone inside the body? Does it get stored up in the organs, or is it inactivated or destroyed? For the investigation of these questions infantile rats which had been given folliculin subcutaneously were analysed *in toto*. The animals were well minced and for this purpose the hide as well as any excreta (urine and fæces) that had been passed in the meantime were included. The resulting tissue pulp was subjected to exhaustive extraction by means of organic solvents. This produced the astonishing result that already three hours after the injection of folliculin (α-hormone) only very small quantities thereof could be demonstrated in the animal. On the introduction of 40,000 m.u., which is a very large dose for an infantile rat, only about 1 per cent. of the hormone was rediscovered in the total animal 72 hours after injection. So that 24 hours after the introduction of folliculin only traces can be rediscovered in the animal and this at a period when the biological effect of the hormone on the uterus and vagina is not yet visible.

From this it appears that α-hormone does not become stored up in the body, at all events not in an active state. Further experiments showed that α-hormone gets inactivated in the body. It was possible by hydrolysis to reactivate a part of the inactivated folliculin, the yield being, after 24 hours, 20 per cent. instead of 1 per cent. and, after 48 hours, 6 per cent. instead of 1 per cent. The fact that reactivation is possible in larger quantities at the end of 24 hours than at the end of 48 hours suggests that during the period that inactivation is taking place various bodies are produced which are capable of reactivation by hydrolysis in differing degrees. Reactivation is, however, only partially possible (maximum 20 per cent.). Whether the remaining 80 per cent. are so transformed by the body that they cannot be regenerated by our chemical methods (hydrolysis) or whether the body destroys any excess of hormone introduced cannot be said. Inactivation of α-hormone occurs apparently in the liver by means of enzymes. It does not take place in other organs nor in the blood. The experiments showed that folliculin becomes fixed by adsorption to the cell-wall in varying degrees, the adsorption being most intensive in the case of striped muscle.

In contradistinction to α-hormone, hormone benzoate is not inactivated in the body. From this there follows the supposition that the inactivating process attacks that part of the hormone molecule which in the case of hormone benzoate becomes saturated as a result of esterification with benzoic acid.

Folliculin is inactivated not only by warm-blooded animals, but also by cold-blooded animals and plants. Inactivation in cold-blooded animals (frog) is less than in warm-blooded animals (rat), being only 80 per cent. in the former and over 95 per cent. in the latter. In the hyacinth inactivation occurs in the root, as H. v. Euler and I have recently shown. Folliculin does not become inactivated by means of yeast.

I am indebted to Dr. Bernard Homa for the translation of this paper.

THORACOSCOPY BY SINGLE PUNCTURE

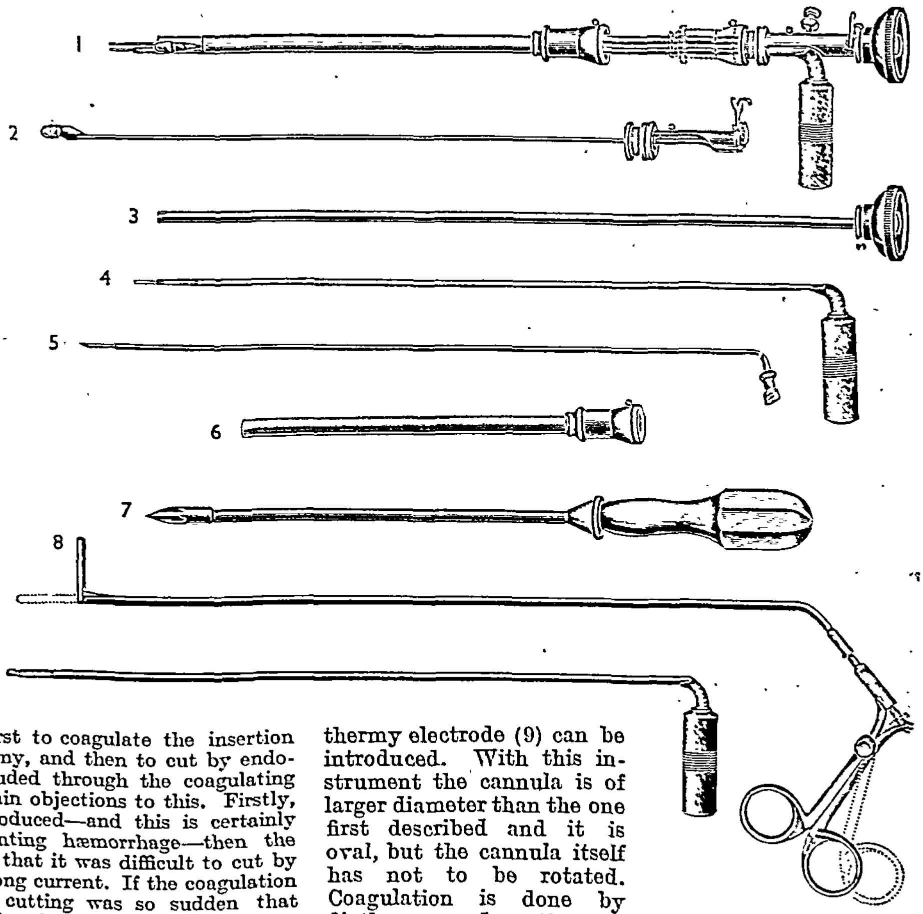
By F. G. Chandler, M.D. Camb., F.R.C.P. Lond.
PHYSICIAN WITH CHARGE OF OUT-PATIENTS, ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK, E.

Experience has shown that a large proportion of pleural adhesions, perhaps the majority, can be severed by the single-puncture method of thoracoscopy. If it can be done safely there is every advantage in avoiding the extra trauma involved in the two-cannula method—the risk of surgical emphysema is lessened and by a nervous patient the avoidance of the extra pricks of the local anæsthetic needle will be appreciated. I am not maintaining that this technique is always better than the two-cannula method—in fact, with the latter there is more mobility; if a small artery should spurt it is easier to get the lamp and the end of the telescope out of the way of the blood and so keep the bleeding point in view. Interchange of telescope and electrode is possible, thus more adhesions may become accessible at the one operation. In some cases I am sure that to have separate entry for light and operating instruments is essential, and with this method the technique of G. Maurer, of Davos, is probably the best and safest. With the right-angle telescope a much larger area of the pleural cavity can be brought successively into view, and it is possible to see round the edges of the adhesion. But whatever instrument or method is employed a right-angle telescope is an essential adjunct, and I invariably use it for a preliminary survey and not infrequently during the course of the operation.

The first instrument I described[1] employed a 30° telescope and was designed first to coagulate the insertion of the adhesion by diathermy, and then to cut by endothermy with a wire protruded through the coagulating electrode. There were certain objections to this. Firstly, if over-coagulation was produced—and this is certainly the safest way of preventing hæmorrhage—then the resistance became so great that it was difficult to cut by diathermy, even with a strong current. If the coagulation was not so complete the cutting was so sudden that hæmorrhage might be produced, and also the cut might be so fine that the adhesion failed to gape, and consequently coagulation of the deeper parts was rendered difficult and uncertain. The illumination was not very good. Moreover, to anæsthetise the pleural attachment of the adhesion or its neighbourhood it was necessary first to pass a direct vision telescope alongside which was passed the anæsthetising needle. This meant more instruments and the passing and withdrawing of various instruments. To obviate this Mr. R. Schranz, of the Genito-Urinary Manufacturing Company, made for me two very fine insulated rods which could be inserted alongside the telescope, one for diathermy coagulation and cutting, the other for electrocautery. These acted well, but the electrodes were naturally flimsy and bendable. I felt there was not sufficient control of bleeding, and the different instruments had to be passed in one at a time, which meant frequent changing and manipulation.

THE IMPROVED PATTERN

The instrument I now use has developed from the experience gained over the last five or six years. With it I have divided without hæmorrhage, without special difficulty, and without serious reaction, not only easy cord and band adhesions but wide adhesions 2½ inches in width and more, and of a thickness in parts up to ½ inch, and also series of adhesions. It has proved itself highly efficient. It is strong, the field of vision is wide, the illumination brilliant. The electrode carrier (4) is rigid, the electrode itself strong and not easily bent, and is of sufficient size to prevent and control bleeding. Should this occur, however, or if the adhesion is very vascular, or large vessels are encountered, a larger ball-shaped diathermy electrode (9) can be introduced. With this instrument the cannula is of larger diameter than the one first described and it is oval, but the cannula itself has not to be rotated. Coagulation is done by diathermy and cutting by electrocautery. Cutting can be done by endothermy if desired. The two currents are carried by the same electrode, which is a platinum-iridium loop. The currents are controlled by a bi-pedal footswitch. All the instruments required are ready for use in the cannula—needle, telescope, and electrode. Therefore, local anæsthetisation in the pleural cavity and cutting can be done without moving any of the instruments. The electrode can



---

[1] The Lancet, 1930, i., 232.

be removed and replaced by a Maurer's hook (8). The advantages of the instrument are the complete control allowed over the operative procedure, the steadiness and rigidity, the assemblage of practically all essential instruments together so that everything required is to hand at the one spot, and lastly ease of handling. There is no doubt that the single-puncture method is much easier than the two-cannula method, and to those who have only occasional use for thoracoscopy this must be a great advantage. For one thing the considerable difficulty of orientation is eliminated. It is true that after sufficient practice orientation and the "picking up" of instruments and objects becomes almost automatic, nevertheless it is obvious that some find the difficulty quite appreciable, and others may not be able to get sufficient practice.

At the moment the 30° purely diathermy instrument has been abandoned. To cut by endothermy is undoubtedly the quickest method, but after considerable experience I have come to the conclusion that it is safer to pursue the slower method of coagulating by diathermy and cutting by the electrocautery. Of course, endothermy cutting can be done with a coarser electrode, but the danger of hæmorrhage is not entirely eliminated.

With a single-puncture instrument accurate localisation is absolutely essential. After comparing stereoscopic pictures and the original method of rotating the patient described in your columns [2] I have come to the conclusion that the rotating method is by far the best. Dr. J. V. Sparks has given me the greatest assistance in this respect, and it is very rarely that the localisation beforehand and the selection of the optimum point of entry by trial on a skeleton have proved misleading. It is the usual experience to come straight upon the adhesion from the desired direction. If, for any reason, this is not so, then a second cannula can be inserted, either for the telescope or the operating instrument.

As in the one previously described, every part of this present instrument can be sterilised by boiling.

The new thoracoscope for single puncture (as may be seen from the illustration) can aptly be described as a bundle of rods (1) held together by an oval tube—the cannula (6). The nucleus is the lamp carrier, a metal cylinder with a central hole, and two lateral longitudinal grooves, to which a thin but firm metal tube is soldered carrying the lamp at the distal end (2). At the junction of the tube and metal cylinder is the cable connexion, which encircles the whole. Grouped round this lamp carrier, and engaging at the proximal end in the grooves cut for the purpose, are the telescope (3), the diathermy galvanocautery (4), and the hypodermic needle (5). The telescope only can be fixed to the lamp carrier, so that the relative position of the objective and the lamp remains constant. The cautery and the needle, on the other hand, can be advanced $1\frac{1}{2}$ inches beyond the objective.

The simultaneous introduction of all these instruments is obviously impossible, the calibre of the cannula would be much too large to be practical. In order to overcome this difficulty the telescope, cautery, and hypodermic needle are assembled round the lamp carrier in such a way that their distal end reaches only half-way between the lamp a
proximal end, and are held together in this
by a clip. The lamp, which occupies nea
whole lumen of the cannul introduc
and after emergence at th the rem
components are advanced. l is ov
cross-section and just large d the rod
components in close proxim p, wh
the pleural cavity, lies reall bundle
rods.

As already mentioned the telescope is locked to the lamp carrier when in position. The cautery and needle, when not required, hold by friction on the metal cylinder of the lamp carrier, and are out of view in this position. The instruments are of sufficient length to provide ample movement in the pleural cavity without moving the cannula. The drawback of having to rotate an oval cannula in the limited intercostal space is obviated by the direct vision telescope. The angular aperture of the telescope has been pushed to its furthest limits. The visual field is such that a good survey of the pleural cavity can be carried out.

The illumination is entirely novel. It is provided by a lamp which concentrates all the available light over an area roughly equal to the field of vision. The corresponding gain in clarity and definition is very noticeable. The combined galvanocautery and diathermy electrode is a rigid rod, the core of which is composed of two conductors insulated one from the other, carrying the low-tension current which brings the cautery point to a red heat.

In addition to the relatively thin insulation required for the low voltage, an insulating sheath of sufficient thickness to withstand high-frequency currents surrounds the two conductors. The instrument can therefore serve the triple purpose of bipolar galvanocautery, and monopolar diathermy electrode, or endothermy cutting electrode. The hypodermic needle is fitted with a record mount and bayonet catch to which a suitable syringe (5 c.cm.) is attached.

In practice it soon became apparent that this method of cutting adhesions complicated the wiring problem—i.e., the various connexions from the transformer and diathermy apparatus. To eliminate this drawback the endo-diathermy apparatus formerly described has been fitted into a slightly larger cabinet, and separate cautery and light transformers built in. The apparatus was thereby transformed into a distributing centre of the three circuits required for operation with one main cable feeding all three. All controls and terminals are situated in the panel on the apparatus. The cautery and endo-diathermy circuits are interconnected and controlled by a selector footswitch. As one or other pedal is pressed, so the cautery will function as galvanocautery (red heat) or diathermy electrode. The light circuit is independent of these two and permanently connected to the main via a separate earth-free transformer.

The apparatus can be wheeled into a convenient position near the operating table, and the two bipolar cables for light and diathermy galvanocautery attached to the towels with a clip, and do not drag or hamper the operator.

LIVERPOOL ROYAL INFIRMARY: ANNUAL REPORT. The report for 1933 records that it is many years since this hospital has been able to show both a reduction of expenditure and a credit balance. Since, however, the

THE LYSIS OF PNEUMOCOCCI BY SODIUM DESOXYCHOLATE

EFFECT OF VARYING CONCENTRATIONS OF SODIUM CHLORIDE

By A. B. Anderson, Ph.D., M.R.C.S. Eng.
ATTACHED TO THE MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL, LONDON; AND
P. D'Arcy Hart, M.D. Camb., M.R.C.P. Lond.
ASSISTANT PHYSICIAN TO THE HOSPITAL

The experiments reported here were suggested by the observation that high concentrations of potassium phosphate added to broth cultures of pneumococci facilitated the lysis of the organisms by sodium desoxycholate.

The favourable effect of magnesium sulphate on the lysis of pneumococci by bile-salts has been reported by Nicolle and Adil-Bey (1907). According to Falk and Yang (1926) the chlorides of monovalent cations (Na, K, NH_4, Li) in relatively low concentrations (0·004–1·0 per cent.) inhibit dissolution of washed pneumococci by bile, but in higher concentrations (2·0 and 4·0 per cent.) these chlorides may accelerate the dissolution of the bacteria. In Falk and Yang's experiments the chlorides of divalent cations Ca and Ba inhibited the lysis of pneumococci by bile more effectively in high than in low concentrations. Their experiments were limited in that they used only one concentration of bile with varying concentrations of electrolyte.

In the present communication the effect of varying amounts of sodium chloride and sodium desoxycholate on the lysis of washed pneumococci is described.

EXPERIMENTAL

The organism, a strain of pneumococcus Type I., was grown in veal broth prepared according to the method described in a previous paper (Hart and Anderson, 1933). The well-grown but not autolysed culture was centrifuged and the cells washed twice with M/20 phosphate buffer pH 7·0 and suspended in this buffer solution. The deposit obtained from 200 c.cm. of culture was suspended in 40 c.cm. of buffer. The bacterial suspension was measured into test-tubes (6×⅝ in.) in amounts of 1 c.cm., and water and solutions of sodium chloride and sodium desoxycholate (B.D.H.) were added in that order, the final volume being 2·4 c.cm. The tubes were shaken and immediately placed in a water-bath at 35° C. for 60 minutes. The final concentration of sodium chloride varied from 0 to 15 per cent., and of sodium desoxycholate from 1 in 800 to 1 in 60,000. After an hour in the water-bath the tubes were observed and the minimum concentration of sodium desoxycholate that gave a water-clear solution was noted for each concentration of sodium chloride.

When the minimum concentration of sodium desoxycholate in milligrammes per 100 c.cm. is plotted against the concentration of sodium chloride in grammes per 100 c.cm. a curve such as that shown in the Figure is obtained. The curve given, which represents the combined results of two experiments, is in the form of a rectangular hyperbola. It will be seen that there is a reciprocal relationship between the concentration of sodium chloride and the concentration of sodium desoxycholate required to produce lysis. When the amount of sodium chloride is small an increase of one or two grammes per 100 c.cm. in its final concentration produces a relatively large increase in the sensitivity of the system to desoxycholate. When the final concentration of sodium chloride is above 5 per cent. any further increase produces very little increase in sensitivity, and even in the highest concentrations of salt some desoxycholate was required to produce lysis. It should be noted that the solutions that contained no chloride contained other electrolytes, in the shape of sodium and potassium phosphates, provided by the buffer solution. These electrolytes produced some increase in sensitivity, as was shown by other experiments in which distilled water was used for washing and suspending the bacterial cells. It was found that the desoxycholate would still lyse the cells in the absence of sodium chloride, but that higher concentrations were required than when the cells were suspended in buffer.

In the method described above the readings were made at 60 minutes. In another experiment, in which readings were also made at 30 minutes, comparison of tubes containing the same amount of desoxycholate showed that the rate of lysis was increased by raising the final concentration of sodium chloride. For example, in a tube containing sodium desoxycholate in a concentration of 33 mg. per 100 c.cm. and sodium chloride 0·4 per cent. lysis was only partial at 30 minutes but complete at 60 minutes, while in another tube, containing the same amount of desoxycholate and 1·0 per cent. sodium chloride, lysis was complete in 30 minutes.

These results are not in agreement with the conclusions of Falk and Yang that sodium chloride in low concentrations inhibits the lysis of washed pneumococci by bile. But this difference is possibly due to the use, in our experiments, of pure sodium desoxycholate, instead of bile, as the lytic agent.

The effect of sodium chloride on the lysis of pneumococci by sodium desoxycholate may be compared with the work of Yeager (1929) on hæmolysis. He found that the resistance of red cells to lysis by sodium taurocholate was inversely proportional to the concentration of sodium chloride when the latter varied from 0·85 per cent. downwards, the isotonicity of the solutions being maintained by appropriate additions of sucrose.

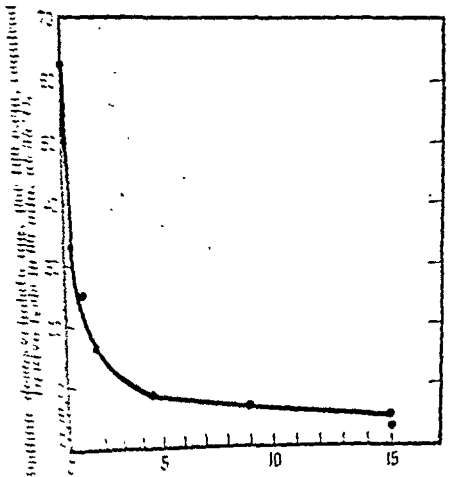
TREATMENT OF EMPYEMA WITH BILE-SALTS

A number of papers have appeared recently on the treatment of pneumococcal empyema by the injection of bile-salts into the abscess cavity after aspiration of the pus. Cocchi (1931), Schwartz (1932), and Thomson (1933) used sodium taurocholate, whilst Sworn and Cooper (1934) used sodium desoxycholate. The results described above suggest that this treatment might be more efficacious if the pneumococci in the empyema cavity were exposed to a relatively high concentration of sodium chloride at the time of introduction of the lytic agent. It would seem best in practice to aspirate the pus, wash out with hypertonic saline, leaving a hundred or more cubic centimetres in the cavity, and then immediately to inject the sodium desoxycholate dissolved in a small volume of water.

Apart from the question of their toxic effects, the quantities of sodium desoxycholate and sodium chloride that can be used are limited by the solubility of the bile-salt in solutions of the chloride. For example, whereas 100 c.cm. of 5 per cent. sodium chloride will dissolve 5·0 g. or more of sodium desoxycholate, the same volume of 7·5 per cent. sodium chloride will only dissolve 0·1–0·15 g. of the desoxycholate. If, therefore, the final concentration of sodium chloride, after washing out the empyema cavity, were greater than 5 per cent., the quantity of sodium desoxycholate that could be injected for each hundred cubic centimetres of fluid remaining would be necessarily restricted. With a concentration of 5 per cent. or less the limit of solubility would not be reached.

The total dose of sodium desoxycholate used by Sworn and Cooper for each injection was 0·25–1·0 g., but our in-vitro experiments suggest that a considerably smaller dose would be effective even if the contents of the cavity at the time of the injection amounted to several hundred cubic centimetres, provided that the concentration of sodium chloride were at least 1·5 per cent. (see Figure).

It should be made clear that the method outlined here has not so far been applied by us in treating cases of pneumococcal empyema. While therefore suggestions are made as to the range of final concentrations of sodium chloride to be aimed at in the chest cavity, the actual figure must at first be chosen [illegible] particularly if the pleura is considered [illegible] thickened, in order to avoid any [illegible] or other irritative effect due to the [illegible] electrolytic content of the saline [illegible].



[illegible] sodium chloride on the lysis of washed pneumococci by sodium desoxycholate.

SUMMARY

[illegible] was found to increase the [illegible] washed pneumococci to lysis by [illegible], there being a reciprocal [illegible] the concentrations of these two [illegible] to produce dissolution of the [illegible] suggested that the augmentation [illegible] sodium desoxycholate by sodium [illegible] in the treatment of pneumo- [illegible] results.

[illegible] Prof. C. C. Okell, in whose [illegible] carried out, and to Dr. F. C. [illegible] The work was carried out [illegible] (A. R. A.) of a part- [illegible] Research Council.

it have been recorded. Prosser White,[1] in his exhaustive book on the occupational diseases of the skin mentions several observers who have recorded linseed dermatitis. One of them, Vokoun, investigated the subject in the United States, and indicates that linseed dermatitis is not uncommon in factories where the oil is expressed.[2] In one series quoted by Vokoun it would seem that it was not the linseed but the burlap bags in which it was packed which caused the dermatitis. Kooperman, quoted by Vokoun, thinks that it is not the oil but the dust from the seed, both ground and seed, which causes the dermatitis, and in a footnote Prosser White states that from the description given by Vokoun in one of his publications it might be due to the dust and not the oil. The following instance which recently came under my observation may be of interest.

The patient, aged 28, is regularly employed in discharging cargo from ships, usually unloading grain but occasionally handling other cargoes. He has been so employed for about 12 years and has not had any previous skin trouble as the result of his work. On Feb. 15th and 16th he discharged barley, on the 17th and 19th linseed, and on the 20th maize. The linseed is already packed in bags and he carries these ashore, but has to fill the other substances into bags before taking them ashore. On the evening of Feb. 19th he noticed slight itching on the back of the neck. The following day the whole of the neck was inflamed, and on the 21st the eyes became swollen and redness appeared in front of both elbows. He attended the Royal Infirmary on this day. The eyes were swollen, there was redness over both ears, while over an area sharply demarcated under the jaw and chin and extending laterally out towards the acromion process on each side and downwards both in front and behind like an old-fashioned lace collar, there was a marked dermatitis venenata. In front of each elbow there was a diamond-shaped area of redness but no vesiculation. A few days later the dermatitis reached from the shoulder to the wrist on each side though the original areas in the antecubital fossæ were much better, as was also the dermatitis on the face and neck.

On March 7th, when the acute stage had entirely passed off, he was tested with maize and linseed to discover which was responsible. Some uncrushed maize seeds were applied dry as a patch test while others were moistened before being applied. Patch tests were made with linseed in the same way. Nothing was seen on March 8th, but on the 9th there was a marked positive reaction where the wet linseed had been applied. Coincident with the appearance of the reaction there was a definite focal reaction, the dermatitis at the original sites on the neck and in front of the elbows showing a marked exacerbation. This gradually subsided as the original condition had done.

This case would suggest that the dust from the seeds and not the oil was responsible for the dermatitis. According to Vokoun, the Indian seed is more irritating than the other varieties. A member of the ~urance company dealing with the man's claim inquiries and elicited the information which was being unloaded

REVIEWS AND NOTICES OF BOOKS

Green's Manual of Pathology

Fifteenth edition. Revised by H. W. C. VINES, M.A., M.D., Pathologist to Charing Cross Hospital, London. London: Baillière, Tindall and Cox. 1934. Pp. 928. 25s.

BROUGHT out first more than sixty years ago, and with a new edition on the average every four years, "Green's Pathology" has enabled countless medical students to meet the needs of the qualifying examiner. It was not, and is not, intended for research workers or for post-graduate study in pathology; the aim of successive editors has been to give the student some insight into the processes of disease. The present edition has been largely rewritten by Dr. Vines, who has added many new illustrations and replaced many of the old ones by photographs. Additional chapters have been introduced dealing with avitaminosis, diseases of the ductless glands, the generative tract, and the breast. The original arrangement of the work into two parts, one dealing with general principles, the other with the special pathology of organs, has been retained, but in other respects the order has been considerably altered by the present editor. For the most part these will help the student, but we have a misgiving about dealing with inflammation before the degenerations. It seems to us more rational to dispose of the purely retrogressive changes in pathology before attacking the progressive ones; teachers are aware that retrogressive cell changes are on the whole more easily demonstrated histologically to the beginner than the somewhat complicated cytology of inflammation.

There may be just a doubt whether the book has not now reached, or indeed somewhat overpassed, the limits of the medical student's capacity. There is perhaps a tendency in this edition to strive unduly after comprehensiveness and to lose balance by so doing. Hitherto the student has been guided in the direction of the fundamentally important sections by finding these dealt with at greater length than the others. Teachers may well differ on the relative importance of subjects, but silicosis, which is described incidentally in various parts of the book and briefly under lung diseases, might have been given a section to itself. Chronic nephritis, the importance of which to medicine cannot be denied, has hardly been given due weight, and Russell's classification, however valuable as a contribution to pathology, is not the clearest way of imparting to the student an idea of the sequence of events in the nephritic process. In dealing with pulmonary embolism no mention is made of the possible origin of emboli in the leg veins, which is regrettable when so much depends on drawing the student's attention to the dangers of post-operative swelling of the leg.

In its present form the manual will find, and deserve to find many new friends.

Morality and Reality

By E. GRAHAM HOWE, M.B., B.S., D.P.M., Associate Physician, Institute of Medical Psychology. London: Gerald Howe. 1934. Pp. 136. 6s.

THIS little book, which the author puts forward as "An Essay on the Law of Life," is made up of five lectures delivered for the Home and School Council; consequently the style is familiar, though not always easy. The book presents conclusions about the widest relations of human beings to the world, reached by the author in the course of his work as a psychotherapist. Morality and the nature of things have engaged the lifelong attention of the greatest thinkers, and some may hold that the production of an essay with such an ambitious title is an over-bold excursion into the realms of philosophy. But the polished systems of trained moralists are for many readers less likely to be of interest than the struggles towards a *Weltanschauung* of an individual whose training is that of a doctor and whose daily work is the treatment of neurotics. His contact with the problems of what is right and what is real in the world almost demands that he should form a working system for *himself*. Dr. Howe's system is now somewhat remote from its beginnings and basis; it has religious and mystical features and is presented here in a form in which its derivation from medical practice is no longer evident. This doubtless accounts for the difficulty and the occasional obscurity of his language, which is, however, lightened by a vigorous use of odd illustrations and original words—e.g., "oughty" and "escapologist," and by some diverting symbolical diagrams. In the first lecture the Good and the True are considered in relation to the Law, in the second Law and the Child, in the third Law and the Family; Law and the Social Group, and the Fulfilment of the Law are the titles of the concluding lectures. The book as a whole shows in an illuminating way the tendencies inherent in the theory that underlies much present-day analytical psychotherapy.

Early Forerunners of Man

A Morphological Study of the Evolutionary Origin of the Primates. By W. E. LE GROS CLARK, D.Sc., F.R.C.S., Professor Elect of Anatomy, University of Oxford; Professor in the University of London. London: Baillière, Tindall and Cox. 1934. Pp. 296. 15s.

IN this book Dr. Le Gros Clark brings together the anatomical evidence bearing on the vexed questions of anthropoid ancestry, for the justification of the main title lies in the inclusion of man in this group of the order of primates and not in any consideration of him as a species. It is a well-written work of very great interest, in which the author considers the relative positions of the groups with which he is dealing from the combined points of view obtained by reference to several anatomical systems. Skull, teeth, limbs, brain, special senses, digestive and reproductive systems are all examined with this idea in mind. His researches lead him definitely to certain conclusions, which appear to be reasonably based on the available evidence. The positions of the tarsioid and lemuroid groups are important questions; Prof. Le Gros Clark is decidedly of the opinion that the protolemuroids must have branched off from the less specialised line at a very early stage, so that it is probably not legitimate to speak of a "lemuroid" phase in the development history of the anthropoidea. He seems also very certain that the tarsioids did not linger much longer in the generalised line, since their structural specialisation appeared very early. He comes, in fact, to agreement with Hans Gadow's proposal to place tarsius in a central sub-order of the primates, with no connexion beyond a remote ancestral one with the anthropoids. There is a most interesting chapter on the tree-shrews, which the author would seem disposed to place among the primates—a sort of remnant from the time when protolemuroids and prototarsioids were separating from each other. The book is full of interesting detail, put simply and clearly. It brings out very well the parallelisms which obtain in the evolutionary history of the primates, as in other orders, characters which are referred for explanation to the principles of orthogenesis; this, however, is not pushed to its logical conclusion. Driven by the nature of his material, Prof. Le Gros Clark deals largely in assumptions, but these are kept in accordance with facts.

Each reader, doubtless, will have his own views on the many questions of evolution, but whatever these are he will derive both pleasure and profit from a study of this volume.

Applied Physiology

Fifth edition. By SAMSON WRIGHT, M.D., F.R.C.P., John Astor Professor of Physiology, University of London, Middlesex Hospital Medical School. London: Humphrey Milford, Oxford University Press. 1934. Pp. 604. 18s.

THE teaching of physiology has lately suffered from the criticism, applied also to other subjects in the medical curriculum, that the student is made to learn a great deal which is of "no use" to him in his future work. This arises from a false sense of values which Prof. Wright's book should go some way to correct. Here numerous facts of physiology are presented, reference being continually made to their application in medicine and surgery; anyone engaged in clinical study or teaching might be pardoned for regarding it as the perfect text-book of physiology. It is up to date, and contains many facts difficult to find elsewhere; if the student knew everything in these 600 pages he would know more than sufficient from the point of view of immediate utility. Yet this is emphatically not the book for the student reading for his second professional examination. It is too often forgotten that he comes from his pre-medical courses knowing virtually nothing about the body; in the short period of 18 months or so he has to learn a completely new language so thoroughly that in his subsequent work he thinks in terms of nothing else. This volume assumes a working knowledge of the language which it is the primary task of the physiologist and anatomist to teach, and the time when it should be added to the bookshelf is just before or just after the second examination. The student is now possessed of the necessary fundamental knowledge, and his critical faculties have been awakened; he requires orientation. Strictly speaking, "applied physiology" is medicine or surgery or midwifery, but Prof. Wright has gone far to create a new transitional subject, and his book is alike valuable in introducing a new point of view and in serving later for reference.

Its unsuitability for the uncritical reader is indicated on the fly-leaf where there is a quotation from the Book of Proverbs: "The simple believeth every word; but the prudent man looketh well to his going." The long list in the preface of subjects which have been revised indicates not only that the matter has been conscientiously brought up to date, but that nothing in the text must be taken as the final word. The book is written—no doubt in the interests of clarity—in a rather dogmatic fashion, the matter being presented where possible in tabular form. There is no harm in this for the reader so long as he does not mistake crisp style for certain knowledge. Controversial subjects are avoided or provisionally prejudged, and there is little discussion of the pros and cons of experimental evidence; this is compensated by introducing in successive editions the most recent work in all parts of the subject, and by the gain in continuity. The treatment of the nervous system is excellent; the anatomical tradition is broken, and the approach made physiological. This might well serve as a pattern for all text-books of physiology.

The fact that this book has run into five editions in a comparatively short time is in itself eloquent testimony to the place it has taken in medical education. Its general appearance is attractive, the illustrations are numerous and often original, the index is full and supplemented by cross-references in the text.

Coccidia and Coccidiosis

Of Domesticated Game and Laboratory Animals and of Man.

By ELERY R. BECKER, D.Sc., Associate Professor of Protozoology, Iowa State College. Iowa: Collegiate Press, Inc. 1934. Pp. 147.

COCCIDIOSIS has, during recent years, attracted considerable attention, chiefly on account of its bearing on the successful rearing of domestic animals. As a result there has accumulated much valuable information, which is, however, difficult of access since it is scattered in innumerable journals. Intensive study has revealed an unexpected multiplicity of species in some animals—for instance, in the fowl the two species previously recognised have now been extended to six. Similar results have been obtained with other animals such as cattle, sheep, and pigs, and it is becoming clear that each host has its own group of coccidia, which are highly specific in that they are unable to infect any other kind of animal. Each species is not only morphologically, but also immunologically and pathologically distinct, so that a fowl, for instance, would have to suffer from six separate infections if it were to become entirely immune to coccidiosis. Attempts have been made without success to discover drugs which will overcome coccidial infections or prevent them, while efforts have been made by careful hygienic measures to rear animals entirely free from contamination. It has been found, however, that as a rule the best results from the practical point of view of breeding are obtained by allowing a mild infection in the very young animals, a procedure which produces an immunity to what might be a more serious infection later in life. It is fortunate that coccidiosis in man is relatively rare, while the parasites of many animals are merely of zoological interest. This book is very complete, describing all the known species, lists of which, together with their hosts, are given in appendices. Each parasite is considered, so far as existing knowledge permits, from the various points of view noted above, special stress being laid on the effect on the hosts and the lesions produced. There is a sufficiency of good illustrations and a very useful list of references to literature.

The book should be in the hands of all those who are interested in the subject of coccidiosis, whether from the purely zoological point of view or that of the intelligent animal breeder.

THE LANCET

LONDON: SATURDAY, AUGUST 18, 1934

THE DEATH PENALTY AND THE PUBLIC

THE issue of a new journal, the *Penal Reformer*,[1] is fresh evidence of the feeling of many citizens that hanging is an obsolete and unjustifiable punishment. Its abandonment, they hold, should not be postponed till the advent of some general revision of criminal justice and prison administration; and in this they can point to the recommendation of the Select Committee on Capital Punishment which in 1930 advocated abolition of the death penalty for an experimental period of five years. It was unfortunate that, owing to dissensions and abstentions, the Select Committee's report was to some extent discounted as a one-sided statement, since apart from its conclusions it was valuable for its considered summary of the case for and against. Whether the true theory of punishment be the vindictive doctrine of the *lex talionis*, or the principle of atonement, or the security of society, or simply the reformation of the offender, well-known arguments against the gallows can be based on the sanctity of human life, the non-deterrent effect of hanging, the fallibility of human decisions, and the failure to offer reformative opportunity to murderers who are not necessarily hardened criminals. The abolitionists, however, are not all agreed on a practical policy. Dr. MAURICE HAMBLIN SMITH, whose long experience as a prison medical officer entitled him to speak with special authority, told the Select Committee that he deprecated treating the question as separate from other changes in the penal system. His broad view of the administration of justice led him towards the position that all crime was a disease and that offenders should be dealt with by boards containing psychological experts, though not exclusively medical in their membership. Mr. ALEXANDER PATERSON, one of the Prison Commissioners, a witness whose humane outlook no one would venture to attack, suggested that there should be a reduction in the number of executions—a sort of de-facto abolition which would prepare a conservatively minded public for legal abolition. Obviously, however, he was dissatisfied with the alternatives to hanging. Indeed, he declared that he regarded a sentence of imprisonment for more than ten years as less humane than the death-penalty.

It may well be said that we are moving towards some such system of de-facto abolition as Mr. PATERSON advised; and on the long-term view there are notable stages of progress. It has been estimated that 2000 people were executed annually for criminal offences in the reign of Henry VIII. and 400 in that of Elizabeth. In the ten years from 1920, on the other hand, the average number of capital sentences carried out was 14, and the latest available return (for 1932) shows that of 10 persons convicted of murder, 4 were executed and 6 had their sentence commuted to penal servitude for life. The prerogative of mercy, in fact, mitigates the severity and finality of the criminal law. The *Penal Reformer* is able, nevertheless, to print a depressing list of persons hanged since last November, while its summaries of the defences proffered might even suggest that there was room for doubt about the guilt of some of the executed. As to the risk of such a miscarriage of justice, Dr. HAMBLIN SMITH told the Select Committee that he did not see how, regard being paid to human fallibility, more care could be taken than the law takes at present. He would not entirely exclude the possibility; yet he added the hard saying that, if capital punishment is deemed desirable for other reasons, he would not allow the prospect of judicial error to weigh against it: "if you really thought it was the best form of deterrent, then I would not allow the possibility of the occasional execution of an innocent man to stand in the way." He thought, as others think, that it is the certainty rather than the gravity of the punishment which deters. The reformers, however, are not prepared to concede that, in the case of murder, the hand of the intending criminal is stayed by any deliberate study of the penal clauses of our criminal code. In their view the experience of other countries shows that the death penalty can be abolished without danger.

Death, we shall all agree, is the simplest solution of the problem of the criminal and from his own point of view is sometimes no doubt the happiest. But there are many other people whose advantage and disadvantage must also be borne in mind. Apart altogether from friends and relatives, or prospective criminals, there is the public at large. The form of execution which is used is calculated to inspire horror; and this horror is nowadays so fully exploited by the press that half the population has its emotions roused by dwelling on the murderer's ordeal. If, as we are assured, little more than 30 people have been executed since the Select Committee reported in 1930 one can only say that the newspapers have made these few executions go a very long way. There seems to be an almost continuous performance of the familiar sequence: the scene in court at the sentence; the protestations of innocence: the collapse of wives and children; the pathetic letters; the petition; the refusal of a reprieve; the last reported emotions; the hanging (at breakfast time); the unpleasantly excited crowd waiting for the notice at the prison gates; and the posters ("So-and-so Executed") in every street. Times have changed, it is true, since a hundred years ago when the first railway excursion was run in England—to see a double hanging. Indeed to most of our own generation such an outing would seem indecent, just as it would seem indecent to open slaughter-houses as places of public amusement. But the fact remains that the sufferings of murderers and their families are still used for public entertainment, and the sadistic element which is to be found in everyone, normal or abnormal, is regularly exploited in this way, in the name of the State and for the sake of large circulations.

ECLAMPSIA AND ANTENATAL CARE

ROUTINE antenatal care was first advocated by J. W. BALLANTYNE of Edinburgh. It is more than 40 years since his "Attempts towards a System of Antenatal Pathology" began to appear, and on this his scheme of care was to be based. Discussion (reported on p. 379) at the recent annual meeting of the British Medical Association indicates that the system of antenatal pathology is still far from complete, and that many of the good results which BALLANTYNE anticipated from his system of care have not been achieved. He looked for a fall in the maternal death-rate from sepsis, hæmorrhage, and embolism, and expected earlier treatment of toxæmia, syphilis, and heart disease. But though some of these hopes have been fulfilled, the maternal death-rate has remained stationary. There are limits, of course, to what antenatal care can do; as Prof. F. J. BROWNE has pointed out in our columns,[1] it cannot be expected to influence the death-rate from post-partum hæmorrhage or from shock after easy uncomplicated labour. The number of deaths from obstructed labour due to disproportion might fairly be expected to diminish, and indeed they are becoming rarer, but he thinks that in many cases the diagnosis of disproportion has led to unwarrantable interference: "It does not help a woman very much if she is rescued from the hypothetical consequences of an abnormality, and is killed in effecting the rescue." In these cases, he thinks, antenatal supervision has simply transferred the mortality from one column to another. A serious criticism of the present system of antenatal care is to be found in our failure to reduce the death-rate from toxæmia. True the rate has decreased in the past two years from 0·69 to 0·58 per 1000, but, as Prof. BROWNE remarked at the B.M.A. discussion, considering that eclampsia is almost entirely a preventable disease, the incidence and death-rate are still far too high. Dr. ETHEL CASSIE presented the findings at a Birmingham maternity home where the standard of antenatal care is exceptional; out of a series of 1000 consecutive cases, 26 per cent. were admitted for the antenatal treatment of conditions such as heart disease, pyelitis, and toxæmia, yet the mortality-rate was only 1 per 1000. In New Zealand the figures are still more remarkable. It is well known how high has been the maternal mortality of childbirth in that Dominion of recent years, and yet among the first 1000 deliveries since the establishment at Otago of a whole-time chair of obstetrics (with antenatal clinic) not a single mother died.[2] This indicates, Dr. CASSIE considers, that where the standard of antenatal care is satisfactory maternal mortality is reduced. To detect toxæmia in its early stages supervision must be close and continuous. Dr. CASSIE contrasted the findings at this maternity home with the results of an inquiry into the maternal deaths in the whole of Birmingham during the past five years; of 88 patients dying of toxæmia, 64 had too little antenatal care or none at all. Attendances at antenatal clinics are increasing, but many of the patients attend only once or twice. Dr. G. F. BUCHAN suggested that when a mother failed to keep her appointment an inquiry should be made at once at her home; she might have failed to attend because of a physical condition calling for immediate treatment. This is not always easy to arrange, as Dr. CASSIE explained; if the patient is not amenable the midwife cannot give effective supervision. Nevertheless, regular antenatal care is essential if early signs of toxæmia are to be detected.

One of the earliest indications of the pre-eclamptic state is a rise of blood pressure, yet this is a sign which the midwife of to-day does not know how to observe. It is Prof. BROWNE's hope that the midwife of the future will be trained to estimate the blood pressure, and that public health authorities will provide her with a simple apparatus for the purpose. It is not difficult to take a blood-pressure reading; the difficulties in the way, formidable no doubt, are of a purely administrative kind. Another early sign of toxæmia was mentioned by Dame LOUISE MCILROY in her Ingleby lecture, published in our last issue. She quotes the work of DAVIS, HARDING and VAN WYCK, BINGHAM, and others, showing that a sudden gain in weight in the latter part of pregnancy is significant of water retention in the tissues, and is an earlier clinical sign of toxæmia than œdema. The normal gain in weight during pregnancy is between 16 and 20 lb.; heavy women gain more than light. As a rough rule, it may be said that if a heavy woman is gaining more than 2 lb. a month, "latent dropsy" should be suspected, and she should be carefully watched. The increase of weight in BINGHAM's cases preceded not only the appearance of albumin in the urine, but the rise of blood pressure, so that this constitutes a valuable sign which anyone engaged in antenatal work can observe. Weekly weighing should be a routine measure.

Notification of eclampsia would possibly lead to earlier discovery, as Prof. BROWNE suggests. Certainly fuller records of every case, as advocated by Dr. BUCHAN, would lead to a better evaluation of the known facts. A hopeful promise of prevention is offered in Prof. MCILROY's concluding lecture, which appears on p. 345. She recommends for pregnant women the diet proposed by Mrs. MELLANBY, consisting of milk 1–2 pints, green vegetables once or twice daily, 1–2 eggs daily, sea fish—for the iodine content—at least twice weekly, and calf's liver once a week. For the rest the patient can choose her own diet, provided she does not over-eat. Prof. MCILROY's statement, "that most of the toxæmia of pregnancy can be prevented by a suitable mixed diet," is instructive. In mothers who are gaining excessive weight restriction of the diet is beneficial. Heartburn, Prof. McIlroy finds, is sometimes an indication of impending toxæmia, and is relieved by giving small dry meals with a low fat content. Hypertension, which is frequently present in toxæmia of the renal type, usually reacts quickly to treatment of the general condition, but she does not advise specific attempts to reduce the blood pressure by means of drugs. Hypertension probably has a protective function, though we look upon it as a warning sign. A sudden reduction of blood pressure by the use of drugs may precipitate heart failure.

[2] Report by Prof. J. B. Dawson. Dunedin: Crown Print. 1934.

THE SIGNIFICANCE OF GLYCOSURIA IN LIFE ASSURANCE

A DISCUSSION was held recently by members of the Insurance Medical Society upon the importance which should be attached to glycosuria and blood-sugar curves in relation to the duration of life. The speakers debated mainly the policy to be adopted by life assurance offices towards applicants who manifest these symptoms, and the discussion illustrated well the changes which have taken place comparatively lately in medical knowledge, while indicating also the difficulties which remain to be overcome. Dr. BATTY SHAW, who opened the discussion, said that in the past cases of glycosuria had been shunned by life assurance companies, but that recently a change of opinion had occurred. Some companies would accept healthy patients with occasional glycosuria at normal rates, while others rated them up. If the glycosuria occurred intermittently most of the cases were rated up, and cases in which glycosuria was always present were usually rejected. This policy he held to be in error, for his own figures showed that out of 865 accepted cases in which glycosuria had occurred intermittently before acceptance, 49 had died, and only seven of them from diabetes mellitus. In many cases the patients had been rated up because of the glycosuria. Mr. N. J. CARTER had stated that the Eagle Insurance Company had accepted a certain number of cases of glycosuria since 1917, and, while there had been 30 deaths from diabetes among the insured subjects since this time, only one of these had had glycosuria at the time of his original examination, and he had been accepted as a known diabetic; and, further, no patient with mild glycosuria without symptoms of diabetes had died of diabetes in the last 17 years. Figures given by Dr. THEODORE THOMPSON from the Royal Insurance Society were equally striking, as between 1908 and 1933 no deaths occurred from diabetes in cases where there was a personal history of glycosuria.

It has been known since the work of KLEMPERER in 1896 that glycosuria might occur even when the blood-sugar was normal. The observations were made on isolated blood-sugar estimations, as it was not realised until the work of JACOBSEN in 1913 that the blood-sugar increased after a carbohydrate meal. In 1915 GRAHAM, working on two of GARROD's cases, showed that the blood-sugar was always within normal limits although sugar was present in the urine to the extent of 4 per cent., and 20 g. of glucose were excreted in the 24 hours when an ordinary diet was taken. In the last 19 years the existence of a renal glycosuria has been fully established by numerous workers. The amount of sugar excreted may be quite small 1–5 g., or large, 10–30 g.; it may only be present after meals, or it may be present in every specimen. The amount of sugar depends on whether the threshold of the kidney is only slightly lowered, say to 150 mg. per 100 c.cm., or is lower than 80 mg. per 100 c.cm. The sugar-tolerance test, which has made the recognition of this syndrome possible, has been closely studied and the results are sometimes difficult to interpret. During the debate, EMBLEDON, CAMMIDGE, HIMSWORTH, LANGDON BROWN, H. W. COLLIER, PARKES WEBER, and GRAHAM discussed the difficulties which might be encountered and the mistakes which must be avoided in order to give a sound opinion on a sugar-tolerance curve. It was agreed that it is essential that the kind of blood which is used for the estimation should be stated. Capillary blood gives figures which may be 25, 50, or over 70 mg. higher than the venous blood, at the peak of the curve. The quotations from a paper by Dr. RABINOWITCH, read by Dr. COLLIER, lose much of their significance when it is realised that he worked with venous blood. The method used in the estimation of the blood-sugar should also be stated, as the Folin and Wu method gives figures which are 20 mg., on average, greater than those obtained with the Hagedorn-Jensen and MacLean methods. The patient's diet must also be considered. If the patient has either been starved or received a low carbohydrate diet, sufficient to produce a ketosis, the blood-sugar curve may be higher than usual and suggest that the patient has a low sugar tolerance. If the test is repeated after a high carbohydrate diet has been taken for a few days the curve may be quite normal. The majority of workers agree that the fasting blood-sugar should be less than 100 to 120 mg. per 100 c.cm. and should have returned to 120 mg. within two, or some say three, hours. The actual height of the peak seems to be immaterial, provided that the blood-sugar is below 120 mg. in the two hours. This is best instanced by the curve called by MACLEAN the "lag curve," or by SPENCE the "steeple curve." Abnormal curves may be caused by disturbing factors, and Dr. BATTY SHAW gave instances where an overdose of thyroid extract or a subacute attack of cholecystitis had caused curves which would be interpreted as being due to a definite diminution of sugar tolerance. It is wrong to test the sugar tolerance of a patient when he is suffering from any disease, as the disease may cause a glycosuria. The best-known instance of this is the glycosuria which may occur when a bad carbuncle is present; in these cases the sugar tolerance may be quite normal when the carbuncle is healed. However, there still remain some curves which are difficult to interpret, and one way of settling the matter is to use the method which GRAHAM used in confirming the diagnosis in his first cases of renal glycosuria. This method is well described by LEYTON in his book, "Diabetes Mellitus," recently reviewed in our columns[1]; it consists in giving the patient increasing amounts of carbohydrate to eat and seeing how much sugar is excreted.

Those who have worked on sugar-tolerance curves believe that patients with a renal glycosuria or with a typical lag curve should be accepted at the usual rates, provided there are no other contra-indications; the patients with doubtful curves may have to be re-examined in three months' time, and if the curve is then normal should be accepted at normal rates. They believe that it is unwise to accept a patient who has glycosuria unless a sugar-tolerance curve is first obtained, because some patients with mild true diabetes may have no symptoms for a little while after the onset of the glycosuria. Some of the insurance societies, however, find that patients dislike having to undergo a special test, and Dr. OTTO MAY suggested that as patients with occasional glycosuria rarely died of diabetes they might be accepted at normal rates or with only slight rating. He suggested as a working rule, "(*a*) occasional intermittent glycosuria and no symptoms—accept with slight extra; (*b*) persistent glycosuria and no symptoms—a moderate extra; (*c*) frank diabetes, i.e., glycosuria with symptoms—reject or a very large extra." This policy might suit the insurance societies but it would be unfair to the patients with renal glycosuria, who would fall under class (*b*) and would pay a moderate extra rate. The early cases of diabetes which are detected by the sugar-tolerance curve would pass undetected and only pay a moderate additional rate whereas they should pay a heavy rate.

The discussion was of great importance in showing the value of the sugar-tolerance test and also the care which must be taken in any biochemical test in order to prevent misleading reports. It is to be hoped that the insurance societies will continue to use them instead of reverting to rule-of-thumb methods.

PREVENTION[2]

A VOLUME setting out the principles of prophylaxis appears this week, being the second in the post-graduate series issued by THE LANCET. The work is composed of a series of lectures delivered at King's College Hospital Medical School, where the dean and the director of medical studies, by instituting the course, show themselves to have appreciated in a practical manner the growing feeling that the preventive aspects of medicine do not receive the attention that they should, while in educational curricula the importance attributed to them compares sadly with that which is given to clinical work. Sir GEORGE NEWMAN in the first chapter of the book expands his already expressed opinion that the doctrines of prevention should permeate the whole of the student's preparation, and points out that in the revision of medical training, now receiving the attention of the General Medical Council, the preventive side of medical work must be brought forward in a more emphatic manner than hitherto.

It is of the first importance that the mind of the student should be focused throughout his educational career upon the doctrines of prevention—in other words, that he should see from the beginning that it is the duty of the doctor to help his patients to maintain health as well as to regain it. But it will be recognised that all doctors, when faced with facts in their professional careers, act with this view fully before them; they have obtained hitherto from the public little endorsement of such a view. The patient comes to the doctor when he is ill, and often not until the time has gone by when relief from his troubles could have been obtained promptly, or—which is more vital—when permanent recovery could be established. To tell him that if he had lived a different life he might have escaped his present ordeal is felt to be an aggravation of his troubles, and counsel on the matter has been proffered only when a recurrence of the troubles might be expected. But to-day the situation is altered quite distinctly. The sick man himself may not, at any rate while he is suffering, reflect with any particular interest upon questions of prophylaxis, but the circle around him will do it for him and sometimes vociferously. For of recent time the public is aroused to knowing that much of the disease which persecutes us is preventable, and the doctor who can assist in this wholesome awakening finds his words welcome. And his ready audience will typify the modern attitude of all intelligent people. There is with us now a general demand for codes of healthy living, which if the doctor is not prepared to supply, the public will seek from sources less reliable. The first step to meet the demand must be to demonstrate to the sceptic among doctors that there are facts about preventive medicine which are established, and which cover—even when unsupported theories and fads are rigidly excluded—a considerable area of ground of which a map should prove useful. It is true that most, if not all, of these facts are individually familiar to the doctor, but it is not until they are collected that their cumulative weight becomes evident.

The authorities at King's College Hospital were fortunate in securing the excellent coöperation exhibited in this volume; the information afforded by persons of responsibility will enable the doctor to educate his environment on questions of vital hygienic importance. As is said in the preface of the book, the map of prophylaxis, which its pages form, "makes no pretence to be complete, but since each region is surveyed by a recognised authority, often by the original explorer, a vivid outline of the charted country is supplied." The survey shows what effective progress has been made in many directions which enable the doctor to exercise intelligent anticipation of evils to come, and to solve for the public understanding many of the doubts that exist as to the methods of conducting a healthy life.

ANNOTATIONS

THE COD-LIVER OIL TREATMENT OF WOUNDS

Two years ago at a surgical congress in Magdeburg, Prof. Wilhelm Löhr reported on the value of crude cod-liver oil in the healing of wounds. Applied to ulcers, burns, in fact any kind of abraded surface, followed by immobilisation of the part with a plaster bandage, the results were then very striking, and his subsequent experience at the Altstadt Hospital has only been more remarkable. Before he came to Magdeburg Löhr was a biologist, and it was as a biologist that he was first impressed with the effect of cod-liver oil given internally on the healing of wounds in children. He began to apply the crude oil to granulating surfaces, and noted the changes which went on underneath it. He was already aware that, like other oils, cod-liver oil is practically sterile and has some bactericidal action on the common pyogenic organisms. The oil proving too mobile for use alone he combined it with some indifferent fat to make an application of the right consistence,[1] which was found rapidly to permeate granulation tissue forming an emulsion with its secretion. Under this layer he discovered that bacterial growth was hindered and bacterial toxins rendered harmless. The practical result of applying this cod-liver oil salve to a mass of granulations is to change a pale oozing surface covered with detritus into the clean ruddy picture of healing. Tremendous activity with massive secretion of pus soon leads to the shedding of dead tissue and sharp demarcation between the healthy and dead. So violent is this action that it may be inadvisable at this stage to shut it in with an impenetrable layer of plaster, although this should be done as soon as it is safe to do so. On the other hand, the comparatively bacteria-free wounds of industry, common enough in the iron industry at Magdeburg, can safely be covered at once with a layer of oil and immobilised in a plaster bandage, when in this warm chamber healing of the almost sterile wound proceeds at an amazing speed. Any part in which the circulation is relatively deficient, as in chronic ulcers of the leg, can be treated with the occlusive bandage at once. The time of its application is regulated by the acuteness of the infection. Phlegmons and abscesses must first be laid open with the knife; in whitlows and infections of tendon and bone the opportunity must first be given for removal of the dead fragments. But in recent injuries of the fingers and burns of the second degree the immediate application of the occlusive oil bandage results in rapid healing without need of transplantation of skin. During the last three and a half years in the Altstadt no burnt surface has been sown with transplants, even though the epithelium has been destroyed over a surface as large as the back, and one doubts whether such success has attended any other method. Amputation stumps and the open wounds left after removal of a breast cancer with the diathermic knife are equally suited for the treatment, which can also be applied to dirty brain wounds and accidental bed-sores.

An additional claim for the treatment is that it is practically painless, and anyone who accompanies Löhr on a round through the wards can satisfy himself that this is the case. On the other hand there is a drawback which he does not seek to evade, and that is the aroma arising from wounds on which the dressing is left unchanged for days or weeks. The smell will be not unfamiliar in kind, if not in degree, to those who have followed Winnett Orr of Nebraska in treating compound fractures and other septic wounds of bone with a similarly occlusive dressing.[2] This may be unavoidable if, as Löhr believes, the physical properties of an oil are an important element, but it must make medical and nursing work in such wards a trial for those with sensitive noses. Remarkable success is claimed in acute osteomyelitis, which Löhr treats with free incision down to the periosteum combined with drilling or chiselling of the bone. The whole wound is then filled up with the cod-liver oil salve, the edges being brought loosely together with two or three stitches. No drain of any kind is inserted, the oil serving to keep the wound open until it has healed from the bottom. The first plaster bandage is left on for a fortnight and as a rule no sequester is then found. It remains to be seen whether the results are better than those of the Winnett-Orr method, of which painlessness is also a feature[3]; in the meantime they are such as to command respect and lead to imitation. Those who cannot see them for themselves will find a series of admirable pictures in recent published papers.[4]

X RAY TREATMENT OF ACTINOMYCOSIS

ACTINOMYCOSIS may be treated with iodides, by surgery, by irradiation, or by a combination of methods. Some form of surgery is often required; it may be no more than aspiration to establish the diagnosis or it may be an extensive and even mutilating operation undertaken in hope of extirpating the disease. The results of such operations are often highly unsatisfactory and the question arises how far X rays may be effective as an adjuvant or an alternative. Although much success has been reported with irradiation, its use is complicated by the fact that actinomycosis, if it is to be cured, requires a dose that approaches the maximum that the skin will tolerate. The problem has been to evolve a technique which will give certain cure without too much damage. The results are much more hopeful in cases of infection of the head and neck—e.g., jaw, face, tonsil, cervical glands—than in actinomycosis of lungs, liver, or intestine. R. Stewart Harrison,[5] in describing the various methods available, offers his own experience of two of them. The "saturation" method consists in giving a very large initial dose, approaching the maximum possible, and following this by two or three very much smaller ones at intervals of, say, two or three days each. H. Holfelder (whom he quotes) has reported 100 per cent. successes with this technique. In the

"disjuncted fractional" method, approximately the same dose is given, but in fractions with intervals between doses of one week to a month, so that the whole course may last six months. Harrison adopted this in 14 cases of actinomycosis of the head and neck that came under his care, and the results were uniformly good; but, as he found it necessary to use a high initial dose, the extent of the skin reaction was very considerable. This took the form of telangiectasis or pigmentation, and although lessened by a reduction of the initial dose, was not altogether avoided thereby. Massive initial doses can also produce a severe œdema and swelling locally that may cause dysphagia or dyspnœa. In the last 8 cases of actinomycosis of the head and neck that he had to treat he therefore tried a "protracted fractional" technique in which the massive dose is dispensed with and permanent skin changes do not occur. As he points out, the advantage here, apart from avoiding a scar, is that if the first course of treatment is not entirely successful, the chances of subsequent treatment by X rays are not destroyed by skin changes. In the protracted method a sufficient dose has been applied in a series of 4–10 irradiations given on successive days, and instead of weeks or months it takes only a matter of days. Of the 8 patients thus treated, 7 now show no signs of the disease and the eighth died of another malady. In the cases of actinomycosis of the internal organs, however, the results have not been so good. Harrison reports only on cases treated by the disjuncted fractional method, and these (8 in number) have all been unsatisfactory. He hopes to get better results by the protracted fractional technique. Iodides are largely used in the treatment of actinomycosis and Harrison thinks them useful in combination with other forms of treatment, but not likely to bring about a cure by themselves.

THE BRONCHIAL MUSCLE IN ASTHMA

AFTER a careful investigation of the intrinsic nerve-supply of the human lung, Dr. J. B. Gaylor,[1] of Glasgow, makes suggestions as to the functional significance of his findings. Perhaps the most interesting of these refers to the sensory nerve-endings (almost certainly vagal) which he and other observers find in the bronchial muscle. He points out that this muscle is not a continuous sheet, but arranged in more or less circular and oblique branching bands with spaces between, so that on contraction it must shorten as well as constrict the bronchi. Conversely, when the lungs are stretched in all directions by inspiration, the muscle must also be stretched both by the lengthening and the dilatation of the bronchi. The sensory endings lie chiefly at the junctions of the muscle bands and are very numerous where a bronchus branches; exactly similar endings are found in the carotid sinus, and the only stimulus which these two structures can have in common is that of tension. Gaylor suggests that the Hering-Breuer reflex, which brings about expiration when inspiration has reached a certain pitch, originates in stretching of the muscle bands and stimulation of these endings. In asthma, supposing the bronchi to be tonically contracted, the adequate degree of stretching in the muscle would not be attained until inspiration had exceeded its normal range, so that it would be unduly prolonged, as is actually the case, and expiration would be delayed. Once expiration had been initiated, the bronchi would tend to close down and obstruction would be particularly marked where branching occurred. This theory of asthma is incomplete, however, since it takes no account of the reverse phase of the Hering-Breuer reflex—namely, the initiation of inspiration when expiration reaches a certain pitch. Following the same argument, the stimulus for this should be shortening of the bronchial muscle, and inspiration should recur shortly after expiration has started. It is, of course, possible that some such nervous disturbance may contribute to the difficulty in expiration, but the whole theory is speculative and additions to it are hardly justified. For instance, sensory fibres also end in the epithelium, and while admittedly muscle stretch is more likely as an adequate stimulus, there seems nothing to disprove the possibility that the passage of air over the mucosa in some way initiates the Hering-Breuer reflex. Whichever set of sensory endings is chosen for the reflex, there is some difficulty in accounting for the function of the other; the balance of probability lies on Gaylor's side since he very reasonably supposes that the epithelial endings might subserve the cough reflex; their arrangement is such that they would be strongly stimulated by stripping of the epithelium. Local reaction and secretion, and possibly bronchial peristalsis, he believes to be brought about by axon reflexes for which there is ample provision. It should be emphasised that the paper in the main is an account of painstaking histological research, any appreciation or criticism of which would necessarily be of a technical nature. The more generally interesting and controversial physiological applications are advanced incidentally.

LICIT AND ILLICIT TRAFFIC IN DANGEROUS DRUGS

AT its latest meeting—the eighteenth of the series—the Advisory Committee of the League of Nations on Opium and other Dangerous Drugs reviewed the whole situation as regards international control. The main features of this situation are a progressive shrinkage in the production and distribution of the drugs for legitimate commerce, and a disquieting increase in the clandestine manufacture and traffic in opium, its derivatives, and other narcotics. A novel feature was disclosed in a process, discovered in Hungary, by which the opium alkaloids can be extracted direct from the dried poppy plant (poppy straw), without passing through the intermediary stage of raw opium. By this means morphine can be extracted from the poppy straw, which has previously been wasted, such morphine being capable of competing favourably with that derived from raw opium. This discovery is calculated to exert considerable influence on the future manufacture of opium alkaloids, and it was resolved by the advisory committee that the question, in all its bearings, should be discussed at the next session, in November of this year. A memorandum prepared by the secretariat of the League gave the average annual world-production of raw opium, for the years 1928–32, as 1385 tons. Moreover stocks, amounting to 3000 tons, were held at the end of 1932 in the various countries, excluding China. The producing countries, like Persia, are accordingly seeking new markets; others may conclude that the need for the promised limitation of production of the raw materials is strongly emphasised. Reference has already been made in our columns to the highly unsatisfactory position in Bulgaria with its increasing production of opium and its manufacture of enormous quantities of heroin in disregard of treaty obligations. Inasmuch as it was the exceptional imports of acetic acid anhydride into Bulgaria which led to the discovery of the clandestine production of heroin, of which acetic acid is a constituent, the advisory committee is recommending all Governments to furnish statistics of their imports and exports of acetic anhydride, together with their origin and destination. The lamentable situation in China was deplored by the representative of that country; not only is she the victim of illicit imports of morphine, heroin, and cocaine sent from other countries, but is herself a large producer of opium and has within her borders clandestine manufactories of the narcotic alkaloids. Manchuria and Jehol, now outside the jurisdiction of China, are, despite a Government monopoly system, increasing the poppy cultivation and in clandestine factories are manufacturing morphine and heroin, which are smuggled to the United States and other countries.

---

[1] Brain, 1934, lvii., 143.

From a recent answer given in the House of Commons it appears that the area under cultivation of the opium poppy in British India has now been reduced to 37,012 acres. The export of India opium, chiefly to States in the Far East, continues; some 2000 chests, of 140 lb. each, were exported in the year 1932, about half of which was dispatched to the Straits Settlements. The price realised is 4000 rupees per chest.

FOREIGN BODIES IN THE ABDOMEN FOLLOWING OPERATION

An extraordinary case of tolerance to the presence in the abdomen of a foreign body left behind in the abdomen is noted this week in our medico-legal columns. The frequency of this accident is the subject of an interesting article in a recent number of the *Policlinico*,[1] where Dr. G. Rizzo describes the case of a woman, aged 25, who had a laparotomy performed for pelvic trouble following an abortion. The wound had practically closed, but an abdominal fistula remained from which exuded pus and some blood also during menstruation. Pain, however, continued, and four months later she was admitted to hospital where examination showed a fistula above the pubes and a large mass to the right of the uterus about the size of a fœtal head. Laparotomy disclosed that the mesentery, cæcum, sigmoid, and a portion of the small intestine formed a large mass with the uterus and adnexa on the left side. After separation of the parts involved, a gauze tampon 7 × 5 cm. was found in the midst of the mass. Recovery was uneventful and the patient left the hospital 33 days after the operation.

The interesting fact in the story is that, as would be expected, radiological examination failed to show the presence of any foreign body, a failure that would not have happened in the case noted on page 381. The question is raised whether by any means a gauze tampon could be rendered visible to X ray examination. Reduer states that the frequency of the occurrence of a foreign body being left in the abdomen after operation is about one in a thousand cases. It is to render the diagnosis of foreign bodies which are invisible to X rays possible, and to relieve the surgeon from grave responsibility, that many surgeons have suggested the use of some material which would be visible to X rays during operations. Halban suggested placing a nickelised iron round each tampon, while Döderlein uses a bronze wire. Reduer himself proposed the placing into tampons and compresses some means of contrast which would have the same absorbent qualities and the same sterilising properties as gauze, such as a thread 2–3 cm. long, impregnated with some substance opaque to X rays, such as silicate of zinc, tannate of lead, or wolframate of zinc. He has shown by radiograms how satisfactory is this method, thanks to which large or small tampons become visible to X rays when left in the abdomen or other region of the body.

Dr. Rizzo asserts that every person subjected to abdominal operation should be exposed to radiological control. By this means the avoidance, sometimes catastrophic, of apparent cures after forgotten tampons may be eliminated or their consequences minimised, to say nothing of relieving the operator from accusations of neglect and protecting him from being mulcted in damages on the part of the patient.

FACTORY HEALTH AND HAZARD

Some knowledge of bygone reports would be needed for a full appreciation of the descriptions of modern industry given by the Chief Inspector of Factories in his annual report[1] which has just been issued. Factories are increasing in size rather than in number; single-storied buildings for the most part, they are well-constructed with adequate air space, good heating and ventilation, excellent lighting, and up-to-date sanitary arrangements. Electric drive is replacing steam in rolling mills and in the textile trade; electric welding is transforming shipbuilding and constructional engineering. At one large iron works more than 700 houses are to be erected for the employees; and we read that factory life raises the standard of personal hygiene among girls, and that the net result of industrial life upon women is good and getting better. Risk has arisen in the past as new organic compounds have been introduced, particularly as solvents; but now Imperial Chemical Industries Ltd. have arranged for each compound to be physiologically tested before it is brought into use. But all is not reformed. Bat's-wing gas burners, and even candles, still illuminate tenement factories in Sheffield, while the toll of avoidable accidents is unduly large, and will, as was pointed out in our columns last week (p. 338), remain so until more attention is paid to safety devices. It is certain that active safety committees can exert a beneficial influence upon both frequency and severity rates; one interesting scheme was the issue every week of packets of cigarettes to the group of workers that had no lost-time accident, each packet being contained in a wrapper bearing an appropriate safety-first slogan. This led to a particularly high standard of safety being reached.

Various occupations have no recognised hazard, but Dr. J. C. Bridge is inclined to regard this as due to lack of data which cannot be gathered until more whole-time doctors are attached to works; on the whole however he holds that industrial employment does not affect the worker adversely. Cases of lead poisoning remain few; but of two workers manufacturing lead arsenate, one exhibited definite symptoms of lead without any signs of being affected by arsenic, while the other developed arsenical poisoning without any symptoms of lead. Epitheliomatous ulceration from contact with coal-tar products claims many victims; there were 40 deaths. Periodical examination of those exposed to risk provides safety by affording prompt treatment; there was no fatal ending among 50 cases so examined, as compared with 3 fatal cases among 25 where no examination was offered. Cancer of the bladder is 38 times as frequent in chemical workers as in the male insured population, due apparently to contact with certain coal-tar derivatives. Fourteen cases of cancer of the nose, 13 of them fatal, among those employed at a nickel refinery works remain as yet unexplained. Further investigation of dusty trades has found in sand-blasting a grave risk of silicosis; fortunately, in most instances sand can be replaced by steel shot in the blast, and this almost eliminates the risk. Attention is called in the report to the way in which dust opaque to X rays may simulate fibrotic deposits in radiograms of the chest, and so introduce a difficulty in diagnosis. Diethylene dioxide, used in making artificial silk, gave rise to five deaths from acute hæmorrhagic nephritis with suppression of urine and uræmia; the toxicity of this compound was previously not recognised.

Notwithstanding the prevalence of unemployment, several instances are quoted of excessive hours of work: unbroken spells of 22½ and 37½ hours, 89¼ and 78 hours per week. The two-shift system has proved its value in emergency and has in a few industries been adopted as a regular method. Welfare accommodation, particularly at mess rooms, is becoming so general, although not compulsory, that workers conplain if it is not provided, thinking its absence to be illegal. The psychological effect of bright workplaces is receiving attention; in one case the walls, fronts of galleries, and doors are painted primrose, handrails light green, steel columns, beams, gantries, and roof trusses aluminium; in another machines are painted light blue to show up against a dark background, and the jibs of fixed cranes and runways are a brilliant red. Indeed, throughout the report there are instances of advance and progress, rather than, as of old, of backsliding and grinding the face of the labourer.

A REGIMEN FOR RHEUMATISM

THE idea of "soil and seed," as applied to disease of the joints, enables us to make a broad distinction between the mainly infective (arthritis) and those in which infection is reduced to a minimum (arthroses). For the latter group, which are sometimes termed degenerative, a failure of nutrient substances to construct or preserve normal bone and cartilage—i.e., a metabolic disorder—is often held responsible. Such a "faulty metabolism" might arise from gastro-intestinal disturbances resulting in interference with absorption of foodstuffs, and Burnett and Ober,[1] of the arthritis clinic of the Peter Bent Brigham Hospital, Boston, describe the regimen by which they try to get this absorption back to normal. Their emphasis is laid on the need for proper habits of mastication of food and for its unhurried passage through the colon in order that complete absorption may be obtained; indeed their desideratum is to obtain the dejecta completely formed and entirely segmented, which in their view signifies satisfactory digestion or "anabolic nutrition." By means of charcoal or millet seeds the intestinal rate was determined, and two-thirds of their patients were shown to have an irritable colon and rapid intestinal rate. The general plan of dieting adopted is to give little food at breakfast or lunch but a substantial amount at dinner; the total caloric value should be sufficient to supply the needs of those who are actively occupied. The diet must be complete and must contain a fair amount of vegetables to make the aliment alkaline. Fruit is taken according to requirement and not till the later meals of the day, so that the consistency of the dejecta after breakfast may be a guide. An essential is the omission of all laxatives, oils, or enemata. Two glasses of water are advised at each meal, one more on rising, and one at bedtime. Exercise is greatly restricted where there is much wasting, and adequate sleep is necessary. If the digestive fluids are deficient dilute hydrochloric acid, gastric enzymes, and enteric-coated pancreatic preparations may be useful. Injections of insulin are sometimes helpful to patients who are abnormally lean. The usual physical methods of treatment—rest, heat, massage, or exercise—are employed to reduce the swelling, alleviate the pain, and restore the action of the joints. Finally, as it takes months and years of anabolic nutrition to overcome the deficiencies in these cases, constant encouragement towards greater activity is very necessary. Of several hundred patients at the clinic, many could not be taught or would not coöperate; but of those who followed the instructions for at least five months more than a quarter are said to have been cured, with relief of pain and swelling and normal motility of the joints, while about half have improved.

GASTRO-JEJUNAL ULCERATION

EXAMINATION of the records of patients on whom gastric operations were performed 20 or 30 years ago is making it easier to understand the cause of gastro-jejunal ulceration. Mr. A. J. Walton, who has lately written in these columns [1] on the prognosis of peptic ulcers treated by operation, has also described [2] in detail his experience of this particular complication. In 1859 gastric operations which he personally performed, there were, he says, 31 cases in which gastro-jejunal ulcer subsequently developed—an incidence of only 1·6 per cent. They are divided into those in which operation was done between the years 1913 and 1922 inclusive, and those operated on in the ten years since. In the first ten-year period 765 cases show an incidence of 2·3 per cent. (18 developed gastro-jejunal ulceration) and this lends support to the assertion that the number of cases increases with the time over which the patients are followed. Such figures, however, cannot be interpreted aright without consideration of other factors, such as the experience of the operator and the nature of the operation. Walton does not find any evidence in his cases for an increased incidence with anterior gastro-jejunostomies, and his general conclusion is that gastro-jejunal ulceration is almost entirely a complication of gastro-enterostomy for ulcers in the region of the pylorus and the duodenum. In only 2 of his 31 cases did it follow partial gastrectomy, and he believes that the more extensive the gastrectomy the less chance there is of anastomotic ulcer. The nature of the original lesion is of paramount importance: thus anastomotic ulcer never follows an operation for carcinoma—a fact which in part at least explains its low incidence after gastrectomy. Of the ætiological factors hyperchlorhydria is generally considered to be the most important, and it is noteworthy that the average acidity of the gastric juice has been found to be higher with duodenal than with lesser curve ulcers, and to be relatively higher, again, in those cases of duodenal ulcer which later developed gastro-jejunal ulceration. Walton agrees with other observers that infection elsewhere is liable to increase the incidence of ulceration. He also finds some reason to believe that incomplete apposition of the gastric mucosa, such as may occur at the point at which the continuous mucosal suture is begun and ended, may determine the site of an ulcer—more especially when there has been excision of the redundant mucosa along the suture line. Unabsorbent sutures have not the importance in the production of these ulcers which was once attributed to them.

[1] Burnett, F. L., and Ober, F. R.: Amer. Jour. Med. Sci., July, 1934, p. 93.

[1] THE LANCET, July 7th, p. 37.
[2] Brit. Jour. Surg., July, 1934, p. 33.

Two clinical types are described by Walton. One shows hæmorrhage as the main symptom, and he states his opinion that hæmorrhage after gastro-enterostomy for duodenal ulcer always comes from a marginal ulcer and never from the original ulcer. The other shows symptoms of indigestion, more or less mimicking the original lesion, but with vomiting conspicuous and pain often referred to the left side and to the lower abdomen rather than the epigastrium. Taking all the cases together pain is much the most prominent symptom. For treatment Walton strongly advocates partial gastrectomy and quotes Finsterer as stating that if three-quarters of the stomach is removed recurrence never takes place. His own figures show 1 recurrence in 61 cases.

TREATMENT IN THE OXYGEN CHAMBER

A CHEMICAL study of the changes brought about in normal persons, and in patients suffering from cardiac and pulmonary disease, on breathing an atmosphere containing 45 per cent. of oxygen for periods of a week or more has been made by D. W. Richards and A. L. Barach.[1] The chief changes found in two normal subjects after a week in the oxygen chamber were a considerable fall in pulse-rate and a small increase in arterial oxygen saturation and in the level of the CO_2-dissociation curve. The patients investigated fell into three main groups—arterio-sclerotic heart disease, rheumatic heart disease, and pulmonary fibrosis with cardio-respiratory insufficiency. A majority had congestive heart failure with œdema, and all had failed to improve on usual measures such as rest, digitalis, diuretics, and oxygen by nasal catheter. On transference to the 45 per cent. oxygen chamber there was usually some relief of dyspnœa and restlessness within a few hours, and in some the relief was progressive, becoming complete in several days. This was accompanied by a raising of arterial oxygen saturation to normal levels, increase in the blood CO_2, diuresis, and increase in the urinary chloride, and a fall in pulse-rate and in venous pressure. The arterio-sclerotic and pulmonary groups gave a much better response than the rheumatic group. It is interesting to note that dilution of the blood appeared to occur as the signs of congestive failure cleared up; and Richards and Barach correlate this with the decrease of vital capacity of the lungs sometimes observed at this time, suggesting a further widening of the pulmonary blood depôt. When the changes brought about by treatment in the oxygen chamber are compared with those which accompany the relief of congestive failure without oxygen treatment, the main differences are found to be a greater quantitative increase in arterial oxygen saturation, increase in blood CO_2, and decrease in blood chloride in the oxygen-treated cases. This form of treatment seems to be useful in any case of cardio-pulmonary disease in which dyspnœa resists other measures, and anginal pain, too, is said to be relieved by it; presumably this refers especially to angina occurring at rest and apart from recent coronary occlusion. From the chemical point of view Richards and Barach state that, while a low arterial oxygen saturation is a certain indication, oxygen-want may be present when this is within normal limits. Cyanosis also is not a safe criterion of oxygen-want; thus the treatment may be beneficial when cyanosis is slight and of little use when it is conspicuous.

AIDS TO CHOLECYSTOGRAPHY

THE introduction of tetraiodophenolphthalein marked a great step forward in the diagnosis of gall-bladder diseases, but this method has the disadvantage that the drug is somewhat troublesome to administer and takes several hours to enter the gall-bladder. Attempts have been made to speed up the process, and S. Zanetti, of Bologna,[1] has used for this purpose a subcutaneous injection of 1 mg. of adrenaline an hour after the patient has taken 80–100 g. of sugar. In healthy persons, Zanetti says, the shadow appears two hours and sometimes less after the injection and lasts for several hours more. Its depth varies with the standard of hepatic and biliary function, and delay in appearance is, it is stated, of diagnostic importance, showing a failure to reduce glycogen or to concentrate bile rapidly which ordinary cholecystography would not reveal. Somewhat similar investigations have been made by D. Barbieri and F. F. Tosatti,[2] who have studied the rapidity with which the tetraiodide shadow is obtained in normal persons following the intravenous injection of a number of substances, including adrenaline, pituitrin, urotropine, histamine, acetylcholine, and hypertonic and isotonic solutions of sodium chloride. Of all these substances acetylcholine served to give the earliest shadow, the gall-bladder being visible within half an hour, and consistently and clearly seen within an hour, of the injection of the tetraiodide. The dose was 3 cg. of acetylcholine injected intravenously a quarter of an hour before the tetraiodide. Urotropine, they also found, caused some acceleration in the appearance of the shadow, satisfactory cholecystograms being obtained in 1 hour 45 minutes from the time of injection. With adrenaline, however, the gall-bladder only became visible after about 4 hours and 40 minutes, and Barbieri and Tosatti conclude that whereas acetylcholine, urotropine, and pituitrin all accelerate the procedure of cholecystography, adrenaline and histamine could not be shown to do so. Their results were obtained on 20 normal patients, and have not as yet been applied to cases of hepatic disease. The difference between these findings and those of Zanetti are not perhaps as surprising as appears at first sight, for the number of cases examined is relatively small, and much variation has been noted in normal persons when tetraiodide is employed alone.

THE BACKWARD AFRICAN NATIVE

IN December last the Secretary for the Colonies asked the governor of Kenya whether he was in favour of the proposal put forward by Dr. H. L. Gordon for a collaborative research into the nature and causes of native backwardness in East Africa A memorandum written by the director of medical services and approved by the director of education and the chief native commissioner has now been signed by the governor and sent to the Colonial Office. It is strongly in favour of the proposal. In a recent address to the Kenya Society for the Study of Race Improvement, Dr. Gordon pointed out that East African backwardness was formerly attributed entirely to nurture and not at all to nature; if this were true, research into the social heritage of the native would be sufficient. He believes, however, that it is only by inquiry into the biological heritage of the African that he can be given an appropriate place "within an East African State shared in by European, Asian, and himself." Observations made by Dr. Gordon and Dr. F. W. Vint which bear on the development of the brain of the African native were recently described in our columns (1934, i., 357).

PROGNOSIS

A Series of Signed Articles contributed by invitation

XV.—PROGNOSIS IN CRETINISM

CRETINISM is one of the diseases which were first, and for a long time, recognised in early life before adults were known to be also affected. It was described by Paracelsus in the fifteenth century, whereas it was only in 1871 that Hilton Fagge prophesied that adult cretinism might occur, and in 1873 that his senior colleague at Guy's Hospital, Sir William Gull, described a "cretinoid condition supervening in adult life in women," to which W. M. Ord, in 1877, gave the name myxœdema. The delay in the recognition of the adult form of thyroid deficiency and its correlation with cretinism may reasonably be explained (1) by the much more striking manifestations of cretinism, due to arrest of development and growth both in body and brain, the latter often amounting to mental deficiency; and (2) by the difference between (*a*) the large number of cretins in parts of Europe where goitre was endemic, and (*b*) the sporadic and relatively infrequent occurrence of adult myxœdema. The effect of thyroid insufficiency in the fœtus and infant before complete development and growth have taken place must obviously be more far-reaching than it is when the hormonic secretion fails in an adult. There are all grades from the endemic cretin idiot, through sporadic cretinism, myxœdema of infantile, childhood and of adult life, to benign or non-myxœdematous hypothyroidism. Though endemic cretinism was known in the fifteenth century the sporadic form (T. B. Curling, in 1850, recorded two cases probably of this nature) was not definitely described until 1871 by Hilton Fagge, when endemic cretinism had died out in this country. When, as in endemic cretinism, the thyroid insufficiency begins in fœtal life the damage is greater; secondary changes occur in the central nervous system and elsewhere. Changes in the parathyroids are suggested by the occurrence of cases of "nervous cretinism" with cerebral diplegia not only in endemic cretinism but occasionally also in the sporadic form. There appear to be transitions between the endemic and sporadic forms of cretinism, and some of the worst cases seen in this country may be of essentially the same nature as those seen in districts where goitre is markedly endemic. It may be difficult to decide whether a given case should be regarded as one of sporadic cretinism or of infantile or childhood myxœdema due to some post-natal thyroiditis. There is not any tendency for the disease to be self-limited and to undergo spontaneous cure; untreated cretins may live long, but remain dwarfs and mental defectives. The prognosis as regards improvement depends on life-long thyroid treatment.

From what has been said it follows that the earlier in life thyroid deficiency begins the less likely is well-marked benefit to result from thyroid treatment. Further, the earlier this treatment is started the better, generally speaking, are the prospects of success. There are, it must be admitted, exceptions to this rule; in endemic cretinism and in sporadic cases with spasticity the response to treatment, especially as regards mental improvement, is usually unsatisfactory; in this "nervous cretinism" the administration of parathyroid in addition to thyroid extract has been recommended (McCarrison). Otherwise the benefit due to thyroid treatment is striking, even dramatic, and rapid.

Treatment by thyroid preparations should begin as early as possible after the condition is diagnosed and be continued for life. Administration should be oral, and the proper dose must be determined for each patient, for this may vary considerably in different individuals. As some cretins are hypersensitive to thyroid, the first dose should be small—a total of ¼ to ½ grain in the 24 hours, preferably given in two instalments of thyroideum siccum B.P., or its equivalent of some other preparation. The cretin should then be carefully watched for symptoms of intolerance—namely, vomiting, diarrhœa, faintness, and fever. This intolerance has been overcome by a series of small doses (J. Thomson). If no toxic symptoms follow, the dose should be repeated on the third day so as to allow for the latent period before thyroid extract exerts its effect. The dose should then be increased every week until satisfactory results are obtained without toxic symptoms, such as malaise, headache, nervousness, sweating, and progressive loss of weight, which show that the amount is excessive. In patients otherwise doing well thyroid treatment often causes troublesome enuresis. For a baby a daily dose of two grains commonly acts well, and for older patients double that dose or more may be necessary to get the best results, which are obtained by amounts just short of those causing signs of intolerance. The most exact means of determining the dose is estimation of the basal metabolic rate, but as this is difficult in babies and young children careful clinical observation must be relied on.

If the treatment is interrupted the symptoms return after a few weeks, even when great progress towards the normal has been made; the treatment is substitutional and not curative.

As already mentioned the results of treatment vary, but usually after a few weeks physical improvement is quite obvious, especially in the facial appearance. Sometimes the coarse hairs drop out at an early stage to be succeeded by a better crop. Growth is particularly rapid at first. When treatment is begun in late childhood softening of the bones may follow, and necessitate rest. Eventually the one-time cretin may become physically indistinguishable from ordinary people, and be able to earn a living. Mentally, however, improvement is usually less perfect, and children are more or less backward for their age. There are exceptions; a cretin treated by Cockayne gained a scholarship. Females may conceive and have normal offspring.

Prophylaxis.—When a goitrous mother has had a cretin child it would be advisable to treat her with thyroid during subsequent pregnancies.

HUMPHRY ROLLESTON, G.C.V.O.,
M.D.
Consulting Physician, Victoria Hospital for Children.

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF NEUROLOGY, PSYCHOLOGICAL MEDICINE, AND MENTAL DISEASES

A MEETING of this section, with Dr. EDWARD MAPOTHER (London), vice-president, in the chair, was devoted to a consideration of the

Differential Diagnosis of Functional and Organic Nervous Disorders

Dr. GEORGE RIDDOCH said he proposed to use the word "functional" in this connexion as equivalent to psychogenic. In some disorders the signs present may indicate an organic change in the nervous system though the abnormal physical alterations underlying it cannot be demonstrated by the pathologist. The main burden in the differentiation of these conditions falls therefore on the clinician. The value of a careful history covering the whole of the patient's life is to be emphasised. The psychoneurotic will almost always have shown from childhood onwards an incapacity to strike a bargain with existence; this failure of adaptation should always be a requisite for diagnosis. Unless this search for a psychogenesis be made such symptoms as sleeplessness, fatigability, and headache may not be recognised in some cases as signs of an organic affection. Even where there are no physical signs, such a symptom as transient diplopia should make the physician suspicious of organic disease, as in disseminated sclerosis; in this condition emotional changes are not infrequent, and may be wrongly regarded as confirmatory of a functional disorder. Passing from symptoms to physical signs, one had to exclude the exaggerated reactions to fear which might, however, be due to hyperthyroidism. The physical signs in neurosis would be those of hysteria. Here diagnosis must rest on (1) the absence of signs of organic disease, and (2) the presence of positive signs of hysteria. There are a number of findings, such as papillœdema and optic atrophy or a true extensor plantar reflex, which are invariably of organic origin; among these are dysphasia, true nystagmus, absence of vestibular reactions, local muscular atrophy with electrical alterations following paralysis, and abolition of the tendon jerks. Certain sensory changes were likewise organic—e.g., homonymous or bitemporal visual field defects, especially if quadrantic, pain referred to the distribution of the spinal posterior roots, lightning pains of tabes, dissociations such as may be found in syringomyelia. Always, however, the observer must be certain of the adequacy of his methods of diagnosis, and he must be familiar with the normal variations. Where the plantar toe reflex is doubtful, the response in the quadriceps and hamstrings should be observed also. The differences between movements of voluntary withdrawal and what occurs commonly in severe spastic paralysis of organic origin should be easily recognised, once they have been observed.

The physical signs of hysteria, Dr. Riddoch said, are usually accompanied by a freedom from worry, which is indicative of the satisfaction the patient gets from this solution of his mental conflict. Since these symptoms depend on the patient's idea of what constitutes a paralysis or fit or disorder of sensation they do not conform to the rules of pathological physiology and anatomy. Hysterical paralysis is often selective. Voluntary movement appears to be impossible in the affected part, though there may be no wasting or reflex signs of organic significance. The muscles in question may be used in one voluntary movement and not in another. There is also display of excessive effort, shown by general violent exertion and also by strong contraction of the opposing muscles. Resistance to passive movement may be encountered; it must be distinguished from muscular rigidity due to pyramidal and extrapyramidal motor lesions. Contractures and disorders of gait should not present difficulty. The sensory changes are anomalous in that they do not conform to anatomical distributions. Sharpness of delimitation and response to suggestion are important points. The inevitable indirect consequences of organic sensory loss may be absent in hysteria—e.g., pupillary reaction to light brisk though blindness is complained of. In fits a number of points of distinction are available. In this connexion the possibility of confusing a hysterical amnesia with automatism following petit mal attacks must be considered. Chronic epileptics are often emotional; this characteristic is frequent in organic affections. Diagnosis finally must be recognised to be a matter not only of symptoms and signs but of the whole behaviour of the individual in the past as well as in the present. A neurotic, moreover, might develop organic troubles, and anxiety consequent upon physical disabilities might result in mental instability.

Dr. A. A. W. PETRIE said that the standpoint was shifting towards a search for physical causes. It was probable that in the future disorders now called psychogenic would be recognised as physiogenic. Consideration of the patient's whole make-up and circumstances often saved time in diagnosis: hypochondria illustrated the value of this inquiry. Neurasthenia was closely akin to the state of affairs seen after a debilitating illness. Any chronic associated factors such as anæmia, tuberculosis, or other chronic toxæmia had to be eliminated. It might be an early stage in a depressive psychosis. Myasthenia gravis might be mistaken for neurasthenia in rare instances. Encephalitis lethargica, however, was more likely to be mistaken for dementia præcox. Neurosyphilis had to be considered, especially when a neurasthenic attack occurred for the first time in middle age. In anxiety states there was often a mixture of sympathetic and parasympathetic symptoms. Where consciousness was lost epilepsy or some cardiac affection like coronary thrombosis might be suspected. Interparoxysmal symptoms were of value in clearing up the diagnosis. Hysterical reactions could be more quickly and accurately diagnosed if the situation of the patient received attention. Hysterical symptoms represented an idea of the patient tending to satisfy the subconscious purpose. The lesion would be usually a loss of function but associated with the petulant emotional reaction of the hysteric. The symptoms might be either on the psychological or the physical plane.

Convulsions might be difficult to diagnose if they occurred in an epileptic with hysterical manifestations; the combination with petit mal was often deceptive until unexplained enuresis or some other indication of the epilepsy was encountered. It must be remembered that slow-growing tumours might cause convulsions as long as 17 years before death. Localisation by mental symptoms was not trustworthy in these cases. In tumours of the frontal lobe the early appearance of mental symptoms led to errors in diagnosis. In attempting to distinguish between disseminated sclerosis and hysteria, the frequent coexistence of hysterical symptoms and those due to the organic lesion had to be considered; generally, also, the paraplegia, if it occurred, was more suddenly and dramatically complete in the hysteric. Hysterical paralysis might be followed by disuse phenomena. Even lack of control of the organic sphincters might at times occur. Usually, however, the general conduct was excellent apart from the disorder complained of. The psychological basis of a hysterical paralysis could often be traced. The behaviour of the patient during physical examination was of much help.

Fits at times, and in their early stages, represented definite symbolic movements on the lines of a compulsion neurosis. Sexual incompatibility might manifest itself as hyperæsthesia or other disturbances associated with dyspareunia; these could readily be interpreted when their basis was recognised. They might even be elaborated into hypochondriacal ideas with abnormal paranoid trends. Mutism and stupor were not always easy to diagnose; somnolent cases of encephalitis lethargica, narcolepsy, and cerebral tumour might resemble functional stupor. Many cases of cataplexy proved to be hysterical. Neglect of the psychological aspect in any case might lead to the placing of undue emphasis on individual symptoms, with consequent failures in diagnosis.

The CHAIRMAN said that Dr. Riddoch had seemed to incline towards the psychological point of view in his emphasis on the positive criterion of psychogenesis in functional disorders. The carrying of this principle to excess was in practice the main cause of failure to recognise organic conditions. Moreover, the discovery of an adequate psychogenesis might be a very lengthy process such as one would scarcely be able to undertake unless one were already sure the condition was a functional one. In psychoneurotic patients it was easy to be misled by an ætiological red-herring. In considering all the history it had to be borne in mind that the mental symptoms of incipient and insidious organic disease were related to the type of personality and to details of personal experience; they might be quite indistinguishable from those of functional conditions. Where the organic affection was acute or rapidly advancing one found reductive symptoms, but if it developed insidiously, symptoms of decontrol, of emotional imbalance might be the main ones; the patient then became more than ever himself. Moreover, he distorted experience in various ways identical with those which we called mental mechanisms. If one based one's diagnosis on the discovery of apparent psychogenesis in the history, one might thus be led into error. There were few people who had not had experiences which would suffice to account for a neurosis if one took the customary view of psychogenesis.

Dr. GREIG ANDERSON (Aberdeen) pointed out the difficulties that arose if one used such a broad definition of the term "functional" as that proposed by Dr. Riddoch; he instanced epilepsy and narcolepsy. The distinction between neurosis and psychosis was a valid and fundamental one. The ambiguous term "borderland case" should be abandoned because it suggested a transition from neurosis to psychosis. Organic nervous disorder was from the first irreversible, it showed a definite stability, and followed a definite course. One saw this if one contrasted the patient who had disseminated sclerosis with a psychoneurotic. A patient's statement of his symptoms should not be accepted at face value; it should be inquired into and analysed. The chronological sequence of the symptoms was of great importance—e.g., in cerebello-pontine lesions. He agreed with Dr. Petrie as to the great care that should be taken before diagnosing a psychoneurosis in a middle-aged person who had previously not shown any such condition.

Dr. HELEN BOYLE (Hove) thought that the meaning of the term "functional" required clarification. In a larger sense there was no distinction between functional and organic. There might be abnormal physical change due to functional disorder; instances of this were mucous colitis, indigestion, and hyperthyroidism following anxiety states. Psychogenic fits might be quite indistinguishable from organic ones. The person as a whole must be considered and the patient seen alone if errors of diagnosis were to be avoided. Even in organic disorders a good bedside manner might be therapeutic. Physiological dysfunction following a psychogenic disorder should be dealt with as well as the underlying cause. Careful investigation of the whole life must precede diagnosis, and here one was obliged to consider religion, mysticism, and philosophy. C. G. Jung had presented this general conception in an illuminating way.

Dr. FERGUS FERGUSON (Manchester) recalled that the term "functional" was sometimes used to imply that the patient had nothing the matter with him, could control his symptoms if he chose, and did not require treatment. Patients found such a diagnosis most provoking. In a series of cases he had found that errors of diagnosis were most often made in the presence of dementia paralytica, diffuse frontal tumour, Parkinson's disease, cerebral arterio-sclerosis, myasthenia gravis, cerebral injury, and neuritis. It was wrong to suppose that general paralysis could not be present unless there were grandiose and expansive ideas. The history in disseminated sclerosis was often more helpful than were the physical signs. In cerebral arterio-sclerosis it must be remembered that the symptoms were not only focal. The patient's age, the condition of his arteries, and his psychological abnormalities were to be regarded; the blood pressure was not always high. Peripheral neuritis affecting the upper limbs or the lower limbs elsewhere than in the sciatic nerve often was overlooked in diagnosis. The distribution of the pain, the presence of tender spots and, possibly, reflex changes were to be considered; often it occurred in people who also had an anxiety state.

Dr. R. D. GILLESPIE (London) said the discussion had shown how opinions varied according to one's point of view. Dr. Petrie had emphasised the swing towards the organic side, but there had also been a change of attitude in the opposite direction. He disagreed with Dr. Petrie as to the possibility of curing anxiety states by remedying faulty methods of contraception. The distinction between functional and organic must be insisted on. It was necessary to elucidate the psychological history, however tedious and lengthy this might be. All physical symptoms and signs should be presumed to be of psychological origin unless some definite organic disorder be present. Some misleading effects of emotional disturbance may be observed in specially predisposed persons. Signs conform to the patient's conception of the disease in a psychoneurosis, but they must be relevant to the complaint. The time relation is of importance in determining psychological causes but there may be a long delay; because of this latent period of rumination, more than a temporal relation must be sought in psychogenesis. The negative characteristics of a psychoneurosis were its unlikeness in symptoms and in natural course to any known disease. There might also be a multiplicity of symptoms in various systems. Statistical probability as to the nature of a particular symptom was also important—e.g., vertigo. Mental examination should be part of routine examination. There was a midway group of cases which illustrated how psychological factors might be as potent as physiological ones; they were additive though not necessarily mutually replaceable. Asthma illustrated this, as did eczema and prurigo. The differentiation should be, not into psychogenic and physiogenic, but into how much is psychogenic and how much physiogenic.

Dr. DOUGLAS GRANGER (Bournemouth) remarked on the frequency with which problems of this sort occurred in everyday general practice. The advanced chronic neurasthenic might tax one's skill in diagnosis; one had to exclude any associated chronic physical factor. Anæmia might prove very intractable in this regard, but it was important to recognise it; treatment of the anæmia had in his experience even averted the need for certification in one patient. Myasthenia gravis might at first be seen with only fatigability, though later indubitable. The basal ganglia were more often affected than was perhaps recognised; lesions here might be responsible for transient symptoms such as tremor. The apparent apathy of Parkinsonism was deceptive; these patients were often by no means apathetic.

Dr. L. A. WEATHERLY (Bournemouth), president of the section, recalled the advice given him when he was a young man—viz., to regard every case of hysteria as due to an abnormal love of sympathy, and to get such patients to discover some pain or other on to which they might displace their trouble.

Dr. AUBREY LEWIS (London) pointed out that in the course of an organic illness a clinical picture might be found that satisfied every positive requirement for a diagnosis of functional disorder. Instances of this might be found in compulsive phenomena after encephalitis lethargica, depressive states in early G.P.I., hysteria after carbon monoxide poisoning, agitated depression in cerebral arterio-sclerosis. Apparent occupational neurosis might be observed in an extrapyramidal disorder; concentric narrowing of the visual field in gunshot wounds of the brain. A satisfactory psychogenesis may often be found even in these organic cases. It was not sufficient to view such phenomena from an exclusively psychological or exclusively physiological standpoint. The common explanation was that there was a constitutional predisposition released by the physical noxa, or reacting towards the manifestations of this. But there were some cases in which evidence for such an explanation could not be demonstrated satisfactorily. The problem raised by these cases was of considerable importance for practice as well as for theory. It not only required some working notion of the nature of the interplay between environment and morbid potentiality which resulted in mental illness, but upon the answer to it in a particular case must depend the prognosis and in some measure the mode of treatment adopted. Illustrative cases from a series collected at the Maudsley Hospital indicated the danger of the assumption that there were any positive criteria of a psychoneurosis which could be taken to exclude an organic basis.

Dr. T. A. WILLIAMS (Bordighera) considered the terms used insufficiently precise. A psychoneurosis should never be diagnosed by exclusion; there must be positive psychogenetic signs. These may be discovered in an ordinary consultation; it did not require a lot of time. Not all cases were either physiogenic or psychogenic. Status lymphaticus and other disorders might be the cause of dubious diagnosis; the metabolism of the patient should be investigated and chemical changes looked for. Fatigue might be a sign of dissatisfaction in patients with failing activity. In America people were highly but not accurately educated in psychogenesis, more so than in England; cults such as Christian Science and Free Thought had prepared the way.

Dr. MURDO MACKENZIE (London) suggested that the dissensions between the psychiatrist and the neurologist were of very ancient date. Functional disorders had to be differentiated by neurological criteria which did not interest the psychiatrist as such. The conversion symptoms in hysteria could be removed by crude suggestion. Anxiety and neurasthenia were terms which could well be dispensed with by psychiatrists.

Dr. H. SIMMONS (Bournemouth) quoted a case which illustrated the value of "sympathetic neglect" in such patients.

Dr. JAMES COLLIER (London) remarked on the insight the old Greek physicians had shown into the nature of these conditions; at Epidauros the methods used were worthy of note. The cleverness of some functional manifestations should be emphasised. Fits might be wrongly diagnosed by the most expert neurologist.

Dr. RIDDOCH, in closing the discussion, agreed that the terms "functional" and "organic" were misnomers but held that they had practical value. It was in the early stages of arterio-sclerotic dementia or G.P.I. that one met anxiety and other functional syndromes. Even a single interview often provided one with much material in the way of total history which helped one in dealing with the disorder. Neither the neurologist nor the psychiatrist could remain exclusively in his own field.

Dr. PETRIE referred to the large issues raised in this discussion. He did not consider, as some speakers had, that neurosis and psychosis could be regarded as sharply defined and separate conditions.

SECTION OF RADIOLOGY AND ELECTROTHERAPEUTICS

THE president, Dr. J. H. DOUGLAS WEBSTER (London), being in the chair, Dr. W. J. TURRELL (Oxford) opened a discussion on electrotherapy in the treatment of

Diseases of the Genito-urinary System

The main forms of electrical current employed were, he said, the constant or galvanic current, interrupted currents of low frequency, and interrupted currents of high frequency. The constant current owed its main effects to the reflex action induced by the stimulation of the cutaneous nerve-endings by the electro-deposition of various ions. In its local or polar application it was one of the most valuable remedies available. A zinc rod introduced within the uterus and connected with the positive pole of a source of supply carried a series of zinc kations with the positive charge down to the mucous membrane, where the hydrogen of the tissues and blood continued the conduction. The mucous membrane thus formed a virtual pole at which the zinc ion formed an oxychloride of zinc by interacting with the tissues; this chemical decomposition and the subsequent caustic action of the new compound thoroughly and intimately destroyed the mucous membrane. If the indifferent electrode surrounded the whole circumference of the abdomen the destruction was complete and evenly distributed. When uterine contractions causing pain were excited the treatment was stopped—usually in about 15 or 20 minutes. Pain in the early stages indicated complications in the appendages, in which case the treatment was unsuitable. Zinc electro-deposition was undoubtedly better than curettage, as it required no nursing-home, anæsthetic, or confinement to bed. A similar method could be used for treating gonorrhœa.

Interrupted currents of low frequency were of relatively little use in genito-urinary conditions. The Smart-Bristow coil indirectly helped in malposition of the uterus by restoring tone to the abdominal muscles, and the faradic coil was useful for the treatment of incontinence of urine. The Morton wave current thoroughly pervaded the muscle or organ treated, and excited more powerful contractions with less discomfort than any other method. It was invaluable in prostate cases. Interrupted currents of high frequency were very valuable in diseases of the genito-urinary system. There was probably no specific wave-length at which any particular micro-organism could be destroyed, but an optimum wave-length at which it could be destroyed at a minimum voltage. Diathermy was extremely valuable for spasmodic dysmenorrhœa, and the short-wave high-frequency currents would probably prove to be of special value in these cases. The short waves exerted their effects solely by a condenser field action. No current actually passed through the skin and, as a result, the tissues of the body reacted evenly and uniformly.

ENLARGED PROSTATE

Dr. F. HOWARD HUMPHRIS (London) said that physiotherapy provided measures by which some prostate patients might be saved the risks of a major operation and reprieved from the miserable sentence of wearing a suprapubic tube or the unhappiness of leading a catheter life. In applying the static wave current a metal electrode was passed into the rectum and laid alongside the prostate. Its other end was connected with one side of the static machine and a current was passed through which was interrupted from 120 to 150 times a minute. At each interruption any muscle in contact with the metal contracted and relaxed. The method had no electrical or heating action but was purely mechanical. Patients had reported even after the first treatment that the sense of weight in the perineum was less, and that at the end of ten daily applications the discomfort and necessity for getting up at night had disappeared. The condition of the bladder was improved by the stimulation and consequent restoration of tone to the muscle-fibres which were continued on to it. The gland was soon reduced in size and lost its tenderness. The treatment did not render subsequent operation more difficult. Contra-indications were long-standing cases, residual urine amounting to more than 3 ounces, cystitis, or renal complications giving rise to back pressure in the kidneys. On the other hand, X rays would relieve the symptoms even if the size of the prostate remained the same. Diathermy was the method of choice in infective prostatitis. The rationale of the treatment depended upon the power of the diathermy current to destroy the organisms in situ, and the temperature should reach 105° or 106° F. It was passed between an electrode in the rectum and a pad on the abdomen or a metal ring round the waist. Physiotherapy would not entirely supersede operation, but besides the operative mortality it would also obviate a high post-operative morbidity.

Dr. D. D. MALPAS (Bournemouth) remarked that surgeons often discouraged pre-operative therapy; he quoted the remark of one, "I wish you fellows would leave these prostates alone. My fingers hurt for days afterwards!"

Dr. AGNES SAVILL (London) spoke on the treatment of discharge in female patients. She said that in pruritus or eczema of the vulva she had for many years treated the skin alone, without permanent success, and had found it necessary to treat the discharge also. This might be due to inflammation of the lining membrane either of the cervical canal or of the uterus. It could be cured by ionisation, but if the discharge was from the uterus the treatment should be applied as far as the fundus. The treatment of discharge from the cervix was sometimes exceedingly difficult, because the inflammation was so severe that an electrode could not be passed right up. This was a reason why physical treatment had become discredited. When there was much inflammation and œdema affecting the whole or nearly all the genital tract, ionisation was not sufficient, but diathermy was invaluable. It was also necessary to treat the general condition, which was like an allergic one—the exudative diathesis.

Dr. G. B. BATTEN (London) reported that Dr. Justina Wilson had been using diathermy with a 4·5 metres wave-length with good results for all staphylococcal infections.

Dr. HOWARD HUMPHRIS said that a wave-length of 3·6 metres was more powerful; the shorter the more lethal.

The CHAIRMAN remarked that diathermy of this frequency was used to kill animal tumours, and suggested that the coincidence might be significant.

CANCER OF THE BLADDER

Dr. A. J. DURDEN SMITH spoke of radium treatment in this condition. None of the methods of treatment was, he said, satisfactory, because surgery still failed in a large number of cases and most bladder cancers were beyond the reach of surgery when first seen. The local glands were involved late and, indeed, might not be involved even in quite inoperable cases. Early metastases were rare. Excision in many cases was not difficult. On the other hand, the patients were usually past middle life and in a poor condition, and excision generally involved transplantation of the ureter. Radium, however, could be used when the growth was close to the opening of the ureter. The best way of using radium itself was to insert needles into the base of the tumour, but radon seeds were far more satisfactory and were being more and more used. They could be left permanently in position, were easier to manipulate than needles, and were more adaptable. They could be inserted by the suprapubic route or through the cystoscope. The latter procedure required great patience, and bleeding was often an obstacle. Radiographs should be taken in 48 hours and again in four days to make sure that all the seeds remained in position. The patient need not remain in bed more than four or five days or in hospital more than a week. The suprapubic route had the advantage that a growth in any part of the bladder could be treated and inspected at operation, and that the introduction of the seeds was more accurate. The operative mortality was between 0 and 15 per cent., and 31 per cent. of the patients remained alive for three years or more after surgical operation. Some 60 per cent. of cases could not be cured by surgery at all. Of these 60 per cent. and 3 per cent. of papillary cancers and 20 per cent. of the infiltrating cases might be alive three years after radium treatment. The mortality was low and complications were rare. There might be a very slowly separating slough. Papillary carcinoma was sensitive to radium and amenable to treatment when not too extensive. The infiltrating type was more radio-resistant, and operable cases should be treated by the surgeon. An extensive inoperable case might be made more miserable than before by widespread interstitial irradiation. Cystoscopic implantation of seeds should be limited to papillary cases where the growth was not more than 2 to 3 cm. in diameter. Larger growths should be dealt with suprapubically.

Dr. R. G. **Hutchison** described a method of treating carcinoma of the penis by means of radium needles applied round a collar of rubber sponge which was fitted over the organ. The results, though slightly better than most of those hitherto recorded, were not very encouraging. Most of the cases of epithelioma of the bladder treated at Manchester were in advanced stages. The growth was exposed by a suprapubic incision and radium was implanted through the wound. Three out of nine patients were alive and well after two and before three years. The technique had been shortened by the use of gold seeds, which were implanted beneath the growth and wide of it in every direction. The seeds must be distributed accurately, and the suprapubic method was necessary.

Dr. **Roy Ward** (London), speaking on carcinoma of the penis and prostate, said that cases must be chosen with care, eliminating those with a marked degree of surrounding infiltration and much invasion of the substance of the organ. On the other hand, a hypertrophic carcinoma, however large, responded well. If no glands were palpable it was unnecessary to irradiate the inguinal regions; when glands were palpable these areas were irradiated with moulded plaques. Of 26 cases, 13 had had palpable glands and 13 had not, but the first group had seemed to do better, 3 being alive at the end of 4½ years with no sign of disease. Of the other group, only one was alive at the end of the fifth year. For carcinoma of the prostate interstitial irradiation was the most satisfactory method. Approach was made either through the bladder or through the perineum. Radium could relieve the symptoms for varying periods of time.

Dr. **Durden Smith** asked why in some of Dr. Hutchison's cases the penis had been amputated. Dr. **Hutchison** replied that in the early days of the treatment the dosage of radium had sometimes been incorrect. Amputation was now much rarer.

Dr. **Bernard Ward** (Birmingham) said his own experience of X rays had been most unfavourable. The treatment had often caused a severe reaction as the bladder tissue was very radiosensitive. He preferred to cut as free a way through as he could. The transurethral method gave the patient the maximum of comfort for the remainder of his life. He said, in answer to the Chairman, that he had applied radium seeds and needles through the perineum and by the suprapubic method. He had excised as much as possible of the prostate and had planted the radium in what was left of it. He had also applied radium in a mould fitting the remainder of the prostate cavity. All these methods had proved disappointing.

Dr. **Durden Smith**, in reply, said that implantation by means of the cystoscope was tedious and uncertain and advocated the suprapubic approach. The cystoscope should be kept for very small growths and for palliative measures.

X RAYS

Dr. G. **Harrison Orton**, after discussing units of dosage, said that no attempt should ever be made to give a single massive dose to the kidney, and that the effect of divided doses must be carefully watched. X rays might be recommended in advanced inoperable cases for, although they did not cure, they might bring about a marked reduction in size of the growth. In the bladder also operation was the treatment of choice, and X ray treatment had proved disappointing in cases where operation or diathermy had failed. Immediate post-operative radiation might increase urinary infection. On the other hand, simple enlargement of the prostate was often favourably influenced by X rays, but the results were neither certain nor constant. Quite a large dose was necessary. When the prostate was malignant X ray treatment compared favourably with surgery, as the operation was severe and not very successful. Sometimes the growth disappeared completely under radiation, but sometimes there was only temporary improvement. Great care must be taken to reduce urinary infection to a minimum, and unless this could be done X ray treatment was contra-indicated. All patients should be kept in a nursing-home and carefully watched during the treatment.

Some growths of the testicle were quite radiosensitive, but they should be removed surgically and X rays then given to the glands. Tuberculous epididymitis responded very favourably to quite small doses of X rays. Cancer of the cervix was undoubtedly favourably influenced, but a recurrence was the rule rather than the exception. Combined X ray and radium treatment offered a better prospect than either given alone, but he would not apply radiation to any operable case. He thought that radium should be applied six weeks to two months after X rays, not before them. Cancer of the body of the uterus was rather less favourably influenced; X rays were superior to radium. Some types of ovarian growth were radiosensitive, but the best use of X rays was post-operative. X ray treatment was most successful for certain non-malignant conditions, such as menorrhagias of the menopause, menorrhagias at other periods with no definite pathological condition of the uterus, menorrhagias associated with fibroids, and cases where, owing to dysmenorrhœa or other conditions, sterilisation was considered advisable. The dose might be reduced to some 25 per cent. and spread over three months, when the patient had practically no disturbance. Every case must be thoroughly examined by the gynæcologist before treatment.

Small doses of X rays were stimulating, and might be used for sterility, amenorrhœa, and other ordinary disturbances of menstruation. Treatment could do no harm and was successful in about a quarter of the cases. Finally, pruritus vulvæ responded often very favourably to small doses, although some patients would not respond at all.

Dr. S. L. **Mucklow** (Cheltenham) said that prostatic enlargement gave a favourable response to X rays in selected cases. He described his technique, which embodied Schall's locating device of placing a lead ball beside the prostate and screening. X rays were best suited to the soft elastic gland. In 25 cases he had had 20 successes.

Dr. Batten suggested that the contra-indication of two or three ounces of residual urine practically meant all cases of prostatic enlargement.

The Chairman doubted whether epidermicidal doses caused permanent damage to the skin. Coutard, he said, had not seen a case in ten years' practice. It was possible that the criticism had been applied to the treatment of malignant disease of the bladder, in which X rays had not been satisfactory through causing fibrosis. Coutard's method did not now produce this disadvantage. He pointed out that cure was not only a matter of local action, and mentioned experiments in progress at the Middlesex Hospital on injections to increase radiosensitivity. He said that the value of X rays in this condition should be far better known. Many old gentlemen would be much relieved and there would be far less post-operative misery. He warned physicians to follow up cases treated by X rays lest the original condition should prove to have been malignant.

SECTION OF ORTHOPÆDICS

At a meeting of this section, with Mr. Harry Platt (Manchester) in the chair, a discussion on

Adolescent and Senile Kyphosis

was opened by Mr. C. Lambrinudi (London). He described five clinical types of adolescent kyphosis. In the first the onset is insidious in a patient who has otherwise no symptoms. In the second the condition appears slowly in a debilitated child (often above the average height) and may be accompanied by fatigue and pain. A third type appears suddenly in a child who may have had an injury or been suddenly subjected to heavy muscular effort—the type described by Scheuermann as "apprentice kyphosis." Pain is a definite feature, often with a rise of temperature, tenderness of the spinous processes, and spasm of the back muscles. A fourth type is seen in tall, lanky children, with some measure of endocrine disturbance. Albanesi has collected a series of such cases with changes in the sella turcica and the limbs. A fifth type of case presents an acute onset after a severe pneumonia. The features common to all types are the constancy of involvement of the lower dorsal region, the absence of angular kyphosis, typical X ray appearances, and, in all types except the last, a tendency to actual shortness in the hamstring muscles.

The radiographic appearance varies with the stage of the disease. In the earlier stages the intervertebral discs are narrow. The adjoining margins of the bony vertebræ are irregular, the anterior margin may be blurred. The ossification in the epiphyseal plates may be irregular, with an erosion of the body producing the web-like appearance. At a later stage the upper and lower surfaces of the vertebræ in proximity to the narrow disc may be sclerosed. The epiphyseal plate may be fragmented. The typical punched-out appearance, attributed by Schmorl to a hernia of the nucleus pulposus, may now be seen.

The speaker dealt with the prevailing views of the ætiology of adolescent kyphosis and devoted much attention to Schmorl's theory of changes in the intervertebral discs. He regarded oft-repeated minor injuries, stresses, and strains as possessing greater significance than the circulatory, infective, or endocrine factors which had been adduced. The condition of the hamstrings was also an important factor; the examination of 400 school-children showed a definite correlation between adolescent kyphosis and short hamstring muscles. He described a spring mechanism whereby the elongation of the hamstrings permits of flexion of the spine as in touching the toes with the outstretched hands. Children with short hamstrings are peculiarly prone to injure the spine if compelled to undertake violent and jerky toe-touching exercises. Such movements are conducive to injury and rupture of the intervertebral disc and subsequent hernia of the nucleus pulposus with destruction of the neighbouring portion of the vertebral body.

Dr. Jacques Calvé (Berck-Plage) discussed the movements of the spine in general and laid emphasis on the clinical fact that the pain of adolescent kyphosis is not situated at the kyphos but in the region of the compensatory curves immediately above and below. For this reason therapeutic treatment should consist of strenuous efforts to correct the compensatory curves by mechanical means. Untreated cases of lower dorsal kyphosis develop an exaggerated lordosis above and below the hump. The lordosis must be reduced so as to prevent shortening of the spinal length. Dr. Calvé illustrated the method of application of the Minerva plaster jacket, with special attention to the disposition of pads to correct the lordosis. He showed that a patient in such a jacket could undertake exercises of the upper and lower limbs in the reclining position with a view to increasing slowly but surely the effective length of the spine. The jacket, provided with a window over the hump and pressure pads above and below, obviated the need for continuous recumbency. By means of diagrams the speaker indicated the relation between the position of the nucleus pulposus and the amount of flexion and extension in the dorsal and lumbar vertebræ. He emphasised the extent to which pain could be minimised by correction of the cervical and lumbar lordosis.

Prof. H. A. Harris (London) illustrated the emergence of the pattern of growth in the spine from the earliest embryonic stages to adolescence. The general scheme of growth and differentiation was described in terms of the craniocaudal gradient. The pattern of growth in the human spine is disproportionate in that there is from birth onwards a relative shortening of the cervical column and a considerable lengthening of the lumbar part of the spine throughout the whole period of growth. The dorsal part of the spine in proximity to heart, lungs, and sympathetic chain maintains a constant proportion of the total length of the presacral vertebræ. The spine varies within narrow limits at all ages, occupying 37 to 40 per cent. of the total body length, and the dorsal part of the spine maintains an equally steady relationship of about 37 per cent. of the total spinal length. Both the primary centres of ossification for the bodies of the vertebræ and the epiphyseal plates of cartilage, which acquire secondary centres of ossification near puberty, appear first in the lower dorsal region. The bony epiphyseal plates limit the growth in length of the vertebræ in precisely the same manner as the epiphyseal plates of the long bones limit growth in length. The prolonged childhood of man, the postponement of puberty, and the late age at which growth in the lower limbs is terminated are accompanied by a postponement of the time of consolidation of the bony vertebræ by union of the epiphyses. Radiograms of various domestic animals, such as the guinea-pig, pig, and goat, showed that the secondary epiphyseal centres of ossification are present even at birth in accord with the early onset of puberty and consolidation of the spine in these forms. A comparable process is seen in the union of the three parts of the innominate bone in all animals at puberty. The proportion of the total length of the spine occupied by bony vertebræ or fibrocartilage illustrates the disproportionate growth in the various parts of the spine. From birth to adolescence the total thickness of the fibrocartilaginous discs in the cervical and dorsal region is doubled, whereas in the lumbar region it is increased fourfold.

Certain types of congenital abnormality of the spine were illustrated, and emphasis was laid on perversions of growth, nutritional disease, and infection as a cause of kyphosis. Illustrated cases were shown which could not be interpreted in terms of Schmorl's theories of injury to the fibrocartilaginous disc. Senile kyphosis Prof. Harris described as a reversion of the spine to its original blastemal stage, the cycle presenting many points in common with those seen in the lower jaw and the vault of the skull. In childhood the fibrocartilages are relatively free from the infective processes, whereas the bone and epiphyseal cartilage are prone to various infections. After middle age the bony vertebræ are peculiarly susceptible to senile changes, particularly nutritional diseases of the type of osteoporosis and osteomalacia. The cartilaginous discs and ligaments of the spine are peculiarly susceptible to inflammation, calcification, and ossification as a result of chronic infections, such as pyorrhœa, leucorrhœa, and gonorrhœa.

Mr. Ross Smith (Bournemouth) considered in detail the differential diagnosis of adolescent kyphosis and spinal caries. He described cases in which infection was an undoubted factor. He refused to accept Schmorl's theory as the sole explanation of the condition and maintained that congenital weakness of the cartilaginous plates above and below the nucleus pulposus could hardly explain a kyphosis which was always delayed until puberty. The relation of senile kyphosis to arterio-sclerosis was mentioned and toxic and nutritional factors were regarded as necessary concomitants to senescence and trauma.

Mr. W. Mackenzie (Newcastle-on-Tyne) presented a brief historical survey of the gradual classification of different types of kyphosis during the last twenty years. He showed a series of radiograms of typical cases which corresponded to the analysis of kyphosis into its existing types.

Mr. Whitchurch Howell (London) discussed the rôle of infection in the adolescent and senile type of kyphosis. In senile cases chronic sepsis was by no means uncommon. He made a plea for the early recognition and treatment, by an orthopædic team, of cases in children, particularly since the condition was closely interwoven with the problem of disability attributed to accidents in industry. It was not enough to examine the overgrown, the underfed, or the chronically septic. The general examination at the school clinic should be directed towards the early recognition and orthopædic treatment of postural defects.

Miss M. Forrester-Brown (Bath) strongly supported Mr. Lambrinudi's views on the importance of short hamstring muscles as a predisposing factor to spinal injuries. She had traced numerous cases of sacro-iliac strain to the vigorous attempts of certain pupils to stretch their shortened hamstrings. Toe-touching exercises were a danger to the spine unless the necessary degree of suppleness was acquired gradually. Many cases of adolescent kyphosis which could not always be conveniently treated in the recumbent position responded well if placed in a light Goldthwait brace and subjected to a gradual course of abdominal exercises calculated to develop good compensatory curves.

SECTIONS OF OBSTETRICS AND PUBLIC HEALTH

Under the chairmanship of Prof. J. M. Munro Kerr (Glasgow) the sections of obstetrics and gynæcology and the section of public health combined to consider the question: are we satisfied with the

Results of Antenatal Care

Dr. J. S. Fairbairn (London) said the object of the meeting was to review antenatal work, to see where its weaknesses lay, and to re-state its aims and the attitude of mind in which it should be approached, as well as the principles underlying its practice. The antenatal clinic, he said, deserved much of the credit for the impulse leading up to a general recognition of "midwifery as a branch of preventive medicine"—a slogan that had a wide vogue for a time, although all it implied was not understood and certainly not acted upon. In midwifery our first and chief duty was to learn what can be done by constructive physiology, that is, the adoption of measures tending to promote normal function throughout the processes of reproduction. After that came the "preventive" part, strictly speaking, being the removal or correction of possible causes of interference with physiological action. Lastly, came the watch for early evidence of disordered function and the effort to restore the normal before more serious or permanent trouble arises; for example, the testing of urine to discover albuminuria and the conditions underlying it.

Dr. Fairbairn referred to the importance of psychological reactions in pregnancy affecting the mother's health, a problem which had scarcely entered the philosophy of antenatal care, although it was now generally agreed that the largest factor in the failure to complete expulsion was the emotional effect of anxiety and fear and the early fatigue which followed in their train. Supervision of the pregnant woman must be thorough and continued; it called for varied forms of service from various types of worker and for close contact between them all. It was so integrated with the rest of midwifery practice that it could not be separated without both suffering. Its segregation in the public antenatal clinics has been open to criticism on this score, though the policy was forced on local authorities by the Act of 1918. In spite of team-work and a certain degree of uniformity in practice, our large maternity hospitals were not free from lack of coöperation: there was one member of the staff for the prenatal, another for the intranatal, possibly a third for the postnatal care of the mother, and certainly another for the mother and infant in the infant welfare clinic. The ideal supervisor of the mother and her infant throughout reproduction was the family practitioner; but, if he is to fulfil his part adequately, he must have assistance from a midwife working under his direction to undertake the observational, educational, and mothercraft services given by health visitors, social workers, and other officers in hospitals and public clinics.

Dr. G. F. Buchan (Willesden) analysed the objectives of antenatal care and considered where the present methods failed. He felt sufficient emphasis was not laid on the basic need for adequate nutrition; that there was not sufficient effort made to follow up women who failed to keep their appointments for antenatal examination; that hospital beds were not available in sufficient numbers for antenatal care. Present methods had not effected any material change in the healthiness of the offspring. The obstetrician would have to extend the scope of his work to include the child under four weeks and to correlate antenatal work and confinement with the condition of the child at birth. He spoke of the importance of adequate records; since at present the best methods of supervision were not in general use and no standard method had been laid down or applied, it was impossible to assess the value of antenatal care from the gross results. He thought a new kind of specialist was required; one whose functions would be first antenatal care in its wide sense, having regard to both the mother and the unborn child; secondly, the confinement; and thirdly, the care of the mother and child for a period after the birth. A wider specialism on these lines would secure better results than specialisms limited to the narrower fields of obstetrics on the one hand and pædiatrics on the other.

Prof. F. J. BROWNE (London) said that although the mortality of infants under one year had fallen, the neonatal mortality showed no corresponding decrease. The death-rate from eclampsia had changed but little during the last 12 years, although there was a distinct reduction in the last two years. And yet eclampsia was almost entirely preventable. One reason why antenatal care failed to influence statistics of morbidity was the increase in recent years of primary as compared with subsequent births. Much of the present antenatal care was, however, inadequate and ineffective. It was so easy to become slipshod when abnormalities were comparatively rare. It was difficult at present to assess the quality of antenatal work done by midwives. Was it too much to hope, he asked, that all the midwives of the future might be trained in the estimation of blood pressure? There was, he thought, much to be said for the whole-time clinic officer. They were usually keen and nowadays they must have had post-graduate experience in maternity work. They were less likely than general practitioners to be hurried. They could devise a follow-up system to ensure regular attendances, and as they saw so many patients they should become more skilled in diagnosis than the practitioner. Unfortunately their work suffered, both in interest and usefulness, from the fact that they were not allowed to give treatment. Effective antenatal care meant institutionalisation; the time was coming when none but normal midwifery (and perhaps low forceps cases) would be undertaken in the home.

Dr. ETHEL CASSIE (Birmingham) said it was useless to feel disappointed with a remedy which had never been properly applied. Whether at antenatal clinics or elsewhere antenatal care did not reach the standard laid down by Circular 145/M.C.W. (1929) and this was put forward not as an ideal but as a practicable minimum. In Birmingham in the year 1916 561 women attended 250 sessions; in 1932 8174 women attended 1892 sessions—representing no less than 50 per cent. of the women whose homes are reached by health visitors. But the standard of this antenatal work was for the most part not high enough, although as good as any in the country. This was shown in the records of stillbirths, maternal mortality in childbirth, and from puerperal sepsis. If antenatal care had not lowered maternal mortality it was because it had not yet had a fair chance of doing so. At a city maternity home where antenatal care was carried out at a high standard and where the medical officers were able to insist on patients carrying out directions, the maternal mortality-rate was low, the stillbirth-rate remained the same as that of the city as a whole, while the neonatal mortality improved. It was, she thought, essential that the obstetrician making himself responsible for antenatal care should be as much a physician as a surgeon; the tendency to combine obstetrics with gynæcology had led to some neglect of the expectant mother. Among the factors which delayed progress was the inadequate training of the medical student and midwife in obstetrics and infant care.

Discussion on these papers was opened by Dr. E. H. T. NASH (M.O.H. Hounslow) who spoke of the difficulty experienced by administrators in deciding on the relative value of schemes.—Mr. ALECK BOURNE (London) considered too much had been expected of antenatal care; good obstetrics was all-important.—Dr. GAUTIER SMITH (Bournemouth) emphasised the psychological aspect of obstetrics.—Dr. W. H. F. OXLEY (London) insisted on antenatal work being done by general practitioners and deplored the failure of antenatal clinics to reduce maternal mortality.—Mr. L. C. RIVETT (London) felt that the bulk of the work should be done by the midwife.—Dr. JANE TURNBULL (Ministry of Health) gave some figures illustrating the insufficient antenatal care given where the mother had died in childbirth. Such care should cover home supervision, home helps, and the provision of nutrition in necessitous cases.

The CHAIRMAN remarked on the differing aspect of the problem in cities and rural areas. He was of opinion that midwives should be responsible for normal midwifery in consultation with doctors. The best arrangement was for municipal midwives to work through the antenatal clinics. General practitioners should join in the scheme, possibly combining other specialties with antenatal care. The rural problem would require an extension of present methods with the practitioner playing the chief part.

BUDAPEST

(FROM OUR OWN CORRESPONDENT)

RACIAL AND PROFESSIONAL SALVATION

THE minister of public health recently warned us that any nation whose birth-rate falls to 18 per 1000 of the population is likely to become extinct, and pointed out that the Hungarian birth-rate does not stand far above this danger line. Though equal, probably, to that in other countries where the standard of living is similar, it is lower than that of the Balkans or eastern nations. In 1932 the number of live births per 1000 of the population was 23·4, and in 1933 21·5, while the corresponding death-rates were 17·9 and 14·6. Compared with 1929 the number of live births shows a decrease of 3·6 per 1000, but as there is also a decrease of 3·2 in the death-rate the real decrease in the population would only be 0·4. In Germany there was a decrease of 0·5, and except in Italy there has been a similar decrease in every other European country. Economic conditions are undoubtedly an important cause, but that there are other factors is shown by the fact that the birth-rate had fallen even in the richest classes of society. The problem is one which, like the *egyke* or one-child system which prevails among the peasants, can be overcome only by moral suasion.

As for the medical profession, the number of practitioners in Hungary is 9000 for a population of something more than 9,000,000, and in the present economic distress the country is unable, in the minister's view, to maintain so many. In rural districts, he said, there was 1 doctor to 900 inhabitants; in Budapest the rate was 1 per 300. Three hundred patients could not support a doctor and the minister believed it was necessary for the State to help the medical profession—not by limiting the number of new doctors to be trained, but by increasing the scope of medical work. Medical men should no longer be asked to do preventive work gratuitously, but new positions should be created for them; and they should be appointed to many positions now held by laymen; for example, in most villages at present there were lay coroners.

AN UNUSUAL PUNISHMENT

Last winter Dr. X, a military surgeon, attempted to induce abortion in a girl of 19, and she died of hæmorrhage due to the operation. Post mortem it was found that she was not pregnant at all, and that death was due entirely to clumsy malpraxis. A court martial in Debrecen sentenced him to 15 months' imprisonment, forbade him to practise medicine for two years, and ruled that he must undergo a thorough course in pathological anatomy and pass an examination in that subject before taking up his work again.

A MEDICAL DIRECTOR OF OPERA

The *Praxis Medici*, a Rumanian monthly medical journal, reports that Dr. Victor Papilian, professor of anatomy at the University of Cluj, the capital of Transylvania, has been appointed managing director of the Cluj opera. Prof. Papilian has not resigned his chair and for the present at least will fill both positions.

BRUSSELS

(FROM A CORRESPONDENT)

A BILL TO REGULATE THE SALE OF ALCOHOL

A CABINET crisis which has interrupted the parliamentary session in Belgium has delayed a discussion of the Bill on "Alcoholic Beverages," which bade fare to be interesting. The position is as follows: Under the existing legislation, beer or wine may be sold or drunk on the premises in all licensed establishments; but the sale of distilled beverages is forbidden in smaller quantities than 2 litres, and the drinking of it on the premises is never authorised. It is thus impossible, at the restaurant, to take a "fine" (liqueur) after dinner, though it is easy, on returning home, to take as much of it as one wishes. A Bill, due to parliamentary initiative, has been presented, which will grant to public establishments the retail sale of alcoholic beverages. This Bill has met with enthusiastic supporters and equally stubborn opposers. The medical profession as a whole are hostile to it, fearing its consequences upon the public health, but certain members of the profession and certain political groups are partial to it. The chances for the Bill are almost even, the attitude of the Government being as yet undecided.

THE LATE KING ALBERT

The Committee of the *Journées Médicales de Bruxelles*, under the leadership of its former presidents, have laid a wreath on the tomb of King Albert I., its protector and friend, in the crypt of Laeken, which had been especially opened for this ceremony by royal permission. This manifestation of loyalty to the dynasty had been organised for the very day fixed for the opening of the fourteenth session of the Congress of the Journées Médicales; the function, however, was cancelled because of the national mourning. When it took place it acquired a considerable importance owing to the presence of delegations from the Academy, the Medical Faculties, the Army Sanitation Corps, the Medical Federation, the principal medical institutions and organisations, the learned societies, and the medical press. The ceremony was short but moving. After the wreath had been placed on the royal tomb a minute of silence was observed, and for a short instant the thoughts of all dwelt on the memory of a great king.

BATHING AT OSTEND

The civic authorities of Ostend have granted the right of the sea-bathing on the sands to a private individual, who will thus be able to impose a tax on bathers and price upon cabin locations. Now the remarkable installation was seen in Ostend last year of the "Palais des Thermes," an ultra-modern, hydrotherapeutic establishment, laid out with much thought for comfort and elegance, comprising a large swimming-pool and a miniature sea-bath, while equipped also for the treatment of certain medical affections. The concessionaire declares himself wronged, as the town from which he holds his permit is exploiting the opportunities of its own bathing establishment. This he holds to be disloyal competition, and the case is engaging the law courts.

MEDICINE AND THE LAW

Forceps Left in Patient's Body

AN inquest was held at Southwark on August 2nd upon a woman in whose body a pair of surgical artery forceps, 5 inches long, had been left during an operation for appendicitis thirteen years earlier. Her appendix had been successfully removed in 1921, and there was evidence that thereafter she had been able to do her household duties and to travel without discomfort though she suffered from vague pains from time to time. She had undergone no operation since 1921. On July 16th of this year she was admitted to St. Giles's Hospital, Camberwell, suffering from abdominal symptoms; an X ray examination showed the presence of the forceps. An operation was then performed to remove the forceps, which had ulcerated their way through the intestines. The patient, who was 70 years old, died a few days later. The coroner, Mr. A. Douglas Cowburn, examined several medical witnesses as to the practice of checking instruments in the operating theatre. He was told that forceps were counted in groups of ten before use and were checked afterwards, the theatre sister being responsible. Summing up the evidence to the jury, Mr. Cowburn said that a blunder had been committed 13 years ago and the fact could not be ignored. He considered, however, that the surgeon who conducted the original operation in 1921 ought not to be held blameworthy in the circumstances. It was obvious that the instruments had been miscounted. A surgeon's task, remarked the coroner, was comparable to that of the commander of an army; he could not possibly supervise every detail without so prolonging the operation as to enhance the risk to the patient. The coroner's jury returned a verdict of death by misadventure, thus negativing any implication of criminal negligence on the part of the surgeon.

A lesser degree of negligence suffices to fix liability for damages in a civil action than is required to justify a sentence of punishment in criminal proceedings. In a civil action, indeed, it might be impossible to dispute that the leaving of forceps in a patient's body is prima-facie negligence. In the legal phrase *res ipsa loquitur*—though the task of removing every swab and forceps is not always so simple as lawyers may think. There would remain, of course, the usual difficulty for the plaintiff to fix the negligence upon a particular person. If the sister miscounts the instruments, is the surgeon liable? On the one side it is argued that the surgeon is responsible for the subordinates who act under his orders and that he must pay for their negligence. On the other side it is argued that a surgical operation is a matter of teamwork, the surgeon being deemed not the army commander but the colleague *primus inter pares*. A similar dispute has occurred where damages are claimed for burns caused by hot-water bottles. The issue is decided on the particular facts of each case and the judges have hardly had the chance to lay down a general rule. The hospital, it is well established, can escape liability by pleading that its only duty was to take reasonable care in appointing its medical staff. In Hillyer *v.* St. Bartholomew's Hospital, where this principle was laid down, Lord Justice Farwell observed that the nurses and carriers assisting at an operation cease for the time being to be the servants of the hospital "inasmuch as they take their orders during that period from the operating surgeon alone." The dictum seems to hint that the nurse's error is the surgeon's liability; but Lord Justice Kennedy made an exception for "purely ministerial or administrative duties," which words might possibly include the routine checking of instruments. Whatever the doubts as to the legal liability, all will be agreed that every possible step must be taken to eliminate the risk disclosed at the recent Southwark inquest. It is interesting to learn that a number of medical students attended the inquest and that the coroner was careful to show them the forceps as an object-lesson.

Diphtheria Patient leaves Hospital

William Simms, suffering from diphtheria, was admitted to the Tolworth Isolation Hospital. Three days later the night nurse found that he had disappeared. The facts were reported to the police who found him at his home in Surbiton. He was fined £1 at Kingston on August 9th for the offence of "exposing himself while suffering from a dangerous infectious disease without taking precautions against spreading it in a public place." The police, it appears, had forcibly to restrain him from embracing his wife. Simms explained to the magistrates that his wife was expecting a child and he was anxious to see her. The chairman reminded him that his conduct might have serious consequences to the health and even the life of his own people. Prosecuting counsel said that these proceedings under the Public Health Act were believed to be the first of their kind. Though not unprecedented, such cases are fortunately rare.

PANEL AND CONTRACT PRACTICE

A Survey of the Year

THE fifteenth annual report of the Ministry of Health contains the usual survey of insurance practice for the past year. The scope of compulsory insurance has remained unchanged. A warning is issued against paying contributions for relatives or others who may be working, but who are not employed within the meaning of the Act, in the hope of obtaining benefit in due course. The tendency to do this arises from the threefold benefits of health insurance, contributory pension, and unemployment insurance. Contributions so paid cannot be refunded. There have been two decisions of interest as to employment under the Act. House-to-house salesmen engaged by a firm selling vacuum cleaners and who were paid by commission were found to be employed under a contract of service and therefore insurable. Skippers of trawlers working from an east coast port are not employed by way of manual labour. Voluntary contributors continue to increase: 460,000 (398,000 men, 62,000 women), as compared with 420,000 (362,000 men, 58,000 women) in 1932.

DEPOSIT CONTRIBUTORS

The number remains in the neighbourhood of 230,000, there being a slight increase in the number of entrants and exits in 1933. The number of women is increasing, ten years ago the proportion was about one-third, now it is nearly one-half. There is a special section of deposit contributors to provide for persons unable by reason of *ill-health* to join an approved society. They receive the ordinary benefits of the Acts and are not limited to the amount standing to the credit of their individual accounts as in the case of ordinary deposit contributors. Their membership on Dec. 31st, 1933, was 6908, an increase of 103 over the previous year. Expenditure on benefits is necessarily heavy, but in spite of increasing membership the amount fell from £20,000 in 1932 to £18,500 in 1933. The reduction in rates paid to women would account for some of this, but the liberal use of the regional medical service has been a contributory cause; 434 cases were referred, and in 60 per cent. of the cases incapacity was confirmed.

REFERENCE TO REGIONAL MEDICAL OFFICERS

There were 503,254 references for advice as to incapacity for work in 1933, of which only 2485 came from doctors; 60 per cent. of them related to women. Those actually examined numbered 268,157 (last year 626,853). The number who required a final certificate before the date of examination was 139,170, and 94,127 did not attend for examination. Of the persons examined 188,693 were reported as incapable and 79,464 (just under 26 per cent.) as not incapable. The number of cases examined by the regional medical staff is less than half that of the previous year. It would appear therefore that the agitation against unnecessary references has borne fruit, and that societies are learning to discriminate which cases should be sent for another opinion. It is not impossible that some insurance doctors have tightened up their certification standards. Sixty-four appeals about incapacity for work were decided by referees appointed by the Minister.

EXTENT OF MEDICAL SERVICE

There were 15,500 doctors in insurance practice, medicine was supplied by about 10,000 chemists' shops, and insured persons entitled to medical benefit numbered 15,150,000. Medical benefit cost £8,420,000, £6,077,000 was paid to insurance doctors, £1,863,080 f the balance to insurance chemists. The remainder was allotted as follows: £203,000 to insurance octors on account of mileage, £196,000 to doctors for medicine and appliances, £63,900 on account of nsured persons taking benefit through approved nstitutions, nearly £9000 was set aside to enable ountry doctors to attend post-graduate courses, £7250 was paid on account of own arrangers.

There was an increase of nearly 6 per cent. in the number of insurance prescriptions dispensed as compared with 1932, rising from 56,081,507 to 59,338,504, the number of prescriptions per insured person increasing from 4·19 to 4·56. The average ingredient cost increased from 3·594 to 3·643 pence, and the total cost per insured person of drugs and appliances from 2*s.* 9½*d.* in 1932 to 2*s.* 11½*d.* in 1933. The increase is thought to be due to influenza early in the year. Referees decided during the year that virol was not a drug, that an arch support was an appliance within the meaning of the Act. The following additional appliances were made available as part of medical benefit: brushes and droppers when required for the proper administration of any drug forming part of medical benefit; lubricant for use with urethral catheters.

Of the 990 cases referred as to whether a particular service was within the range of medical benefit, the local medical committee agreed with the insurance committee that 49 were within the scope of the Act and that 941 were outside. Referees decided that four cases of psychotherapy fell outside the scope of the Act, the committees having disagreed on the subject.

Ethics and Contracts at Home and Abroad

"The term 'contract practice' is anathema to the vast majority of individual practitioners in this country," says the *Journal of the American Medical Association* (July 28th, p. 263); "yet . . . conceivably there are situations in which the practice of medicine under a contract may be necessary or desirable." The Association defines contract practice as:

> "the carrying out of an agreement between a physician or a group of physicians, as principals or agents, and a corporation, organization or individual, to furnish partial or full medical services to a group or class of individuals for a definite sum or a fixed rate per capita."

It recognises that such practice is not in itself unethical; "the decision as to its ethical or unethical nature must be based on the ultimate effect for good or ill on the people as a whole." Certain features or conditions may be introduced into its working which would be against the public good and therefore unethical from a professional standpoint. Instances of this are solicitation for patients, either by the corporation or by the practitioner; underbidding to secure the contract, which naturally leads to inadequate remuneration and eventually produces a poor medical service; and interference with reasonable competition in a community, which may prevent free choice of doctor—a condition which is one of the foundation principles of general practice.

The judicial council of the American Medical Association have now issued the following statement:

> "It is unprofessional for a physician to dispose of his professional attainments or services to any lay body, organization, group or individual, by whatever name called, or however organized, under terms or conditions which permit a direct profit from the fees, salary or compensation received to accrue to the lay body or individual employing him. Such a procedure is beneath the dignity of professional practice, is unfair competition with the profession at large, is harmful alike to the profession of medicine and the welfare of the people, and is against sound public policy."

In this country there is still a definite dislike of contract work, whether by medical men or by business firms. In business the remark may often be heard that such and such work was done by contract and so was hurried, or the best materials were not used; and elaborate precautions are almost always necessary to make certain that the terms of the contract are faithfully carried out. Even in this sphere, where possibilities of requirements and their costs are largely known, it does not always follow that the cost by contract will be less than it would have been by piecework performed under honest conditions. The contract is generally made in order to know the limit of financial liabilities, with the hope that at the same time the standard of work will be as good as if payment were being made for the actual work done.

When we come to medical contracts the profession is in a very much worse position than the business contractor. The contracting medical man does not know at all (under National Health Insurance for example) how much work he will be required to do. He does not even know what duties he may have to perform under his agreement, for more duties may be added without any corresponding addition to his remuneration. The same argument applies to other forms of medical contract work. A medical officer of health will have a terrific amount of work to do if an epidemic of small-pox occurs in his area, but his remuneration will not be increased one penny. The house surgeon who receives his £100 a year at some county hospital will not receive any more if he is called up every night in a week for emergency work than if he were able to stay in bed at rest. These unknown liabilities are in the terms of the contract and generally accepted by the profession, but what business men would undertake such liability? The doctor's position is not much better when he is under no employer, but has himself made a contract. The contract patient who demands his services may and often does urgently require them, but such patients are also very apt to make calls, for inadequate reasons, that would not be made if they had to pay for them.

Contract practice would be much more popular in the profession if it could in some way be protected against this sort of thing. Many patients could afford, say, 3*d.* for a bottle of medicine and provision could easily be made for those who could not afford it. If this had to be paid to the chemist by every insured person who required medicine the cost of drugs supplied would be greatly reduced, for only those who really wanted the medicine would then obtain it. So, too, emergency visits and night visits cause a wholly abnormal amount of wear and tear on the doctor's energy (to say nothing of his car), and he needs protection from them by some single-payment system. The present all-in capitation system of payment was chosen in the first instance by the profession because of its simplicity, but, human nature being what it is, it does give rise to apprehension by both doctors and patients that neither are obtaining a fair deal.

METROPOLITAN HOSPITAL SUNDAY FUND.—At a meeting of the council recently it was stated that the year's collections amounted to £61,000, a reduction of £3000 on the preceding twelve months; the broadcast appeal produced only £300 as against £900. The newly constituted ladies' committee will begin work in the autumn.

CORRESPONDENCE

THE "GAS WEDGE" IN THE ÆTIOLOGY OF FISTULA-IN-ANO

To the Editor of THE LANCET

SIR,—Fistula-in-ano has so long been described as "the result of abscess" that this theory of its causation has come to be accepted as fact. But why an abscess in this region should insist on opening both into the lumen of the bowel and on to the skin, and why it so frequently produces such tortuous and branched channels has not been very satisfactorily explained.

The following are references from recent editions of standard surgical works :—

> "Fistula-in-ano.—This term is somewhat loosely applied to all conditions in which suppurating tracts are found in the neighbourhood of the anus and the lower end of the rectum. Many of these are merely sinuses which have but one opening. Fistulæ are usually due to rectal or perirectal suppuration, but sometimes result from the ulceration of simple, syphilitic, malignant, stricture of the gut, the inner opening being either above, in the substance of, or below the stricture. This is more likely to be the case when the fistulæ are multiple."—Rose and Carless, "Manual of Surgery," 14th ed., 1933, p. 1229.
>
> "Perianal Fistula.—Fistula formation with perianal abscess as a rule only results if the abscess be allowed to burst. The fistula may end blindly internally, or may communicate with the anal canal below the external sphincter."—Russell Howard, "The Practice of Surgery," 4th ed., 1933, p. 819.
>
> "Fistula-in-ano (anorectal fistula) is a persistent, burrowing, and often tortuous sinus, the result of an unhealed abscess. Nearly one-third of all rectal cases are fistulas. (Tuttle.)"—Da Costa, "Modern Surgery," 10th ed., 1931, p. 1098.
>
> "The most frequent cause of a fistula about the anus is ischiorectal abscess."—Ashhurst, "Surgery Principles and Practice," 4th ed., 1931, p. 937.
>
> "A fistula is a suppurating tract opening both on to the cutaneous surface and into the lumen of the bowel. A sinus, on the other hand, has only one opening, which may either be on to the cutaneous surface, the cutaneous sinus, or into the lumen of the bowel, the rectal sinus. Both the sinus and the fistula when of rectal origin are always preceded by one or other variety of perirectal abscess."—H. S. Clogg in Choyce's "System of Surgery," 1932.

Having observed some cases in which fistula-in-ano developed without history or appearance of abscess, I was led to question the accepted statement, and I now believe that rectal flatus is the primary ætiological factor in producing these channels. Large quantities of gas collect in the lower bowel and are often held under considerable pressure. This acts in a manner similar to the air in an overcharged tyre with weakened outer cover, in which the inner tube protrudes in the areas lacking adequate support. Likewise in the anorectal section of the bowel the gas under pressure drives a protrusion in the line of least resistance. Each recurrence of this pressure advances the protrusion, so forming a channel into the tissue from the lumen of the bowel, a sinus. Obstacles may be met and so turn the course of the sinus as it progresses in the line of least resistance. Some resisting bands may so cross its path to cause it to branch. Such a sinus is open to invasion of infection and will act as a favourable incubator for the invading organisms, so it is not surprising that abscess is frequently associated with fistula-in-ano. The gas wedge continues to drive the protrusion to an outlet whether abscess has formed or not. The gas pressure is the vis a tergo.

Contributing causes can be found in factors which (1) tend to weaken the textural support to the bowel, and (2) those which favour increase of flatus. Both of these are prone to be more common in patients past 40, since there is a tendency then for more fat to be stored in the connective tissue so weakening the textural support which it offers, and the sedentary life, imposed at this age, fosters constipation and gas accumulation. Any ulceration of the bowel, by weakening it, may readily be the starting-point for the gas wedge to produce a fistula-in-ano.

I am, Sir, yours faithfully,

Harley-street, W., August 13th. R. YOUNG KENNY.

DOES THE PUNISHMENT FIT THE CRIME?

To the Editor of THE LANCET

SIR,—Yet another of those instances of sexual offences by elderly men has been published recently in the daily papers. Such offences are probably more common than is generally known as a certain number of the offenders contrive to sojourn abroad and so escape publicity. Many of such cases occur in men of great intellectual attainment who have spent useful lives in the public service, and their lapses are, in reality, due to periodic disordered impulses combined with failure of mental control. These offences are so repellent to all decent-minded individuals that the punishment inflicted appears to the man in the street to be scarcely adequate; but surely the medical man cannot regard with equanimity the spectacle of a poor old gentleman who has led a useful life being sent to prison because an enlarged prostate and arterial degeneration have led to an offence which with ordinary control he would never have committed. Naturally, one appreciates the difficulty in drawing the line, but this would appear to lie in the determination of loss of control.

Surely it is just as cruel and medieval to send paretic exhibitionists and arterio-degenerate delinquents to prison and disgrace as it once was to put lunatics in irons. An attendant or a mental home appears to be more suitable and would save much private and public distress.

I am, Sir, yours faithfully,
F. A. PHILLIPPS, M.D.

Lower Sloane-street, S.W., August 13th.

BUYING CENTRES

To the Editor of THE LANCET

SIR,—I am assuming that your correspondent, "A Visitor," intended his letter last week, under this heading, to be helpful to the buying centre at the Medical Section at British Industries House, but as more than one correspondent of mine is doubtful as to this, I wish to assure him and your readers that since the official opening of the House the attendance of potential buyers has been very satisfactory. On the day on which his letter was dated I enclosed for your information an exact list of those who visited the Section on July 30th. It will be seen that there were 13 persons, all of them connected with hospitals and five of them from abroad. This list is by no means exceptional. Every day there is a goodly number of serious inquirers and, what is even more to the point, the exhibitors are highly satisfied with the progress of affairs up to date, in a period which, it must be remembered, is the holiday season.

It must not be forgotten that the Medical Section is not a retail affair, but is intended to deal with wholesale buyers and those able to influence buying. There is a visitors' book which each visitor is invited to sign and which he may inspect if he so chooses. Every week a list of visitors with information as to their inquiries is sent to each tenant of the section.

Speaking as chairman of the Medical Advisory Council of the section I may say that my colleagues and I are in no way interested in the financial side of this enterprise (though obviously unless it succeeds on the financial side it cannot succeed on any other side), but we believe that there is a real need for a place at which hospital and institutional requisites can be seen and compared with as little trouble as possible, and that the directors of British Industries House have performed a service to our profession in opening this section. This opinion is fortified not only by the letter of your correspondent, and by the opinions expressed by visitors from all over the world, but also by the recent issue of the report of the committee of the Public Health Congress on Hospital Equipment. This influential committee strongly emphasises the need for standardisation of institutional requirements and the economies which could be effected by expert buying. It is obvious that the Medical Section at British Industries House should further both.

Medical men and all interested in hospitals and other medical institutions are cordially invited to visit the section.

I am, Sir, yours faithfully,

ALFRED COX,

Chairman, Medical Advisory Council.

British Industries House, Marble Arch, W., August 14th.

⁂ We know that our correspondent wished to be helpful, and we indicated, in a note to his letter, how well the use of the centre should meet many needs of medical institutions and individual doctors. The value of the centre should be widely recognised. The list, referred to as enclosed, is accurately summarised.—ED. L.

PITUITRIN FOR HERPES ZOSTER

To the Editor of THE LANCET

SIR,—I can lend support to Dr. Francis Gillett's account in your last issue (p. 307) of the effect of pituitrin on herpes zoster by reporting a case which I treated just two weeks ago. It was one of great severity involving two dorsal roots; the pain had been uninfluenced by barbiturates, opiates, salicylates, bromides, iodides, chloral, whole-blood injections, and by attempts to anæsthetise the nerves. On the eleventh day I gave an injection of 0·5 c.cm. pituitrin and the patient had his first restful night. Two days later a further injection was necessary, and after another 48 hours, as slight pains had recurred, an injection of Pitocin was given to determine whether the pressor factor was a necessary agent, as the disadvantages of pituitrin are obvious, whereas pitocin can be given with impunity. It is impossible to infer anything from my last injection as the illness was subsiding, but it would be interesting to try the effect of pitocin on an early case. The use of so small a dose of pituitrin per injection probably accounted for the less dramatic relief of pain in my case, probably also for the absence of the undesirable symptoms mentioned by Dr. Gillett.

I am, Sir, yours faithfully,

S. CHARLES LEWSEN.

College-crescent, London, N.W., August 14th.

INDUSTRIAL DERMATITIS

To the Editor of THE LANCET

SIR,—Dr. Arbour Stephens, in his letter in you last issue, raises once more the interesting questio of the relation between lowered bodily resistanc and the incidence of disease.

That dermatitis should occur in the physicall unfit is not a matter for surprise, as the surface hor cells—the natural protectors of the skin—share i the general state, and especially where food is scant (particularly in fats) or the diet unbalanced, thes cells are quick to suffer in function. It has bee observed that workers newly returned to work afte a period of unemployment seem particularl susceptible to industrial irritants. But this susceptibility from lowered resistance is not of course confine to dermatitis; it is true of other maladies, industria or not.

While agreeing with the general proposition, cannot, however, endorse Dr. Stephens' statemen that "in many if not most of the industries associate with the production of industrial dermatitis th workers are exposed to small quantities of carbo monoxide," nor have we proof of Dr. Stephens contention that industrial cancer occurs only amongs workers who have been exposed to the inhalation o CO gas over prolonged periods. On the contrary the experimental work of Argyll Campbell woul suggest the reverse.

I am, Sir, yours faithfully,

SIBYL HORNER.

Home Office, London, August 14th.

CORONARY THROMBOSIS AND AFTER

ANOTHER PERSONAL STORY

To the Editor of THE LANCET

SIR,—I found, for personal reasons (which intrude), the letter signed "Learn and Live" in TH LANCET last week very interesting and comforting I am 47 years of age. A year ago I disposed of m practice and took a post as ship surgeon. Of lat I had put on a great deal of weight; my friend twitted me, suggesting that after a few months o a ship I should need a crane to get off her. I was very heavy smoker.

On board I indulged in very strenuous exercise— deck tennis, running round the deck, and swimming I began to feel muddled in the head and develope slight pain in the chest. Both these things I ignore and continued my exercise. One night, after bein asleep for two hours, I woke up with an alarmin pain in my chest, which lasted about two hours. took things very easily for the next four days, bu attended to my work. On the fourth day a mos severe attack came on and lasted all night. Sinc then my history is the same as that narrated b "Learn and Live." In fact I was most interested t note the large psychological factor. I can wall miles, but going upstairs, an annoyance, or a competitive game (such as yacht racing), or feelin *compelled* to do anything, bring on pain at once. have reduced my weight to normal by careful dieting and taking no liquid at meal times. Nitrites d not ease the pain; I find two hours sleep in th afternoon keeps me free. The notes furnished b "Learn and Live" form quite the best account o coronary thrombosis I have read.

I am, Sir, yours faithfully,

August 13th. A. B. C.

OBITUARY

BERTRAM COLLINGWOOD, O.B.E., M.D. Camb.

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON

We regret to announce the death of Prof. Collingwood which occurred in London on August 9th in the 64th year of his age.

Bertram James Collingwood was born in Sunderland in 1871, went to Caius College, Cambridge, as an undergraduate, in 1889, and took honours in the Natural Science Tripos in 1893. He proceeded then for his medical education to St. Mary's Hospital, and graduated as M.B., Ch.B. in his university in 1900, just previous to the outbreak of the South African war. In South Africa he did good service as a civil surgeon in connexion with the prevalence of typhoid fever which had such a disastrous effect on our forces, and at the conclusion of hostilities his bent towards physiological work was confirmed by his appointment as assistant to Prof. A. D. Waller, who was then working at the Imperial Institute in the physiological laboratory of the University of London, which owed its origin largely to his own efforts and the generosity of his family. The work with which Collingwood was first associated was an investigation into the various dangers of chloroform anæsthesia. Waller's researches following directly upon the report of the Hyderabad Chloroform Commission. These investigations showed the dangers not to depend so much on the total dose administered as on the percentage of vapour in the inhaled air, and Collingwood devised an apparatus for the delivery of chloroform vapour of known dilution with air, which was described in the *Transactions* of the Medico-Chururgical Society. In association with Waller he communicated to the *Journal of Physiology* papers on the respiratory quotient and carbonic acid estimation, while his individual papers to the same journal included articles upon chloroform apnœa and the absorption of chloroform in anæsthesia, and a description of an apparatus for recording respiration. He published also in the *Transactions* of the Medical Society of London a useful investigation into the ætiology of pulmonary emphysema.

PROF. COLLINGWOOD

[Photograph by Elliott & Fry

In 1904 Collingwood was appointed demonstrator in physiology at St. Mary's Hospital, a post which he filled until 1907, and during this time he proved himself to be a gifted teacher, while he continued his investigations along lines he had already made his own, as well as into other allied problems of the physiology of respiration. So that he had earned high recognition for physiological research when in 1909 he was appointed to the chair of physiology at University College, Dublin. The National University of Ireland had not long been founded, and the difficult task was imposed on all members of the medical staff to get level with the work of organisation essential to the new institution. Collingwood's share in this activity was especially onerous. He proved a stimulating and energetic teacher; his influence in the promotion of research was marked; his classes increased rapidly in size, while his tact and obvious goodwill made him popular with colleagues and students. He developed into a first-class teacher and displayed the qualities as lecturer and demonstrator which later became so conspicuous on his return to London.

Collingwood's services in the late war commenced in 1915 after the first gas attacks upon our troops. He became at once engaged on researches into antigas measures. These were undertaken originally at the R.A.M.C. laboratory, Millbank, but in 1916, with a commission as major in the R.A.M.C., he was appointed chemical adviser to the Irish Command; this position he held till the termination of hostilities, being not only unsparing in his endeavours to make a success of antigas training, but able to make valuable suggestions to the Chief Chemical Adviser of the Home Forces. After the armistice he was retained by the Command, became largely active in the organisation of the scientific side of the Army education scheme and was appointed O.B.E.

For a brief period he now returned to Dublin, but in 1920 he was appointed professor of physiology in the University of London with a chair at St. Mary's Hospital, the position which he was holding at his death. Here it was soon seen that the reputation as thinker, lecturer, and teacher which he had brought with him from Dublin was fully deserved, and he enhanced it by his work at St. Mary's. His teaching aimed always at the application of physiological principles to the treatment of disease, in accordance with the now generally accepted ideal of the medical curriculum, and his wide knowledge of physiology was manifested especially in his expositions of the chemistry of the body. His help and his criticisms were always available to those who worked under him, and, as he was both kind and tactful in rendering assistance to these, he was able to inspire among his fellow workers and his students a zeal for original research. Further, like his famous uncle, Lewis Carroll, he had a humorously whimsical side to him, and this was frequently apparent in his lectures to the considerable appreciation of his audiences. At St. Mary's he was instrumental in establishing the Waller research memorial to commemorate the life work of his old teacher and colleague, who himself had served on the educational staff of St. Mary's for 15 years. At the end of 1932 Collingwood used his influence as a lecturer in the United States in the service of St. Mary's, the object of the lectures being to raise funds for the establishment and endowment of the "Wonder" children's ward in the hospital. This ward is a memorial to Lewis Carroll.

Collingwood's communications to the *Journal of Physiology* of later years include papers in collaboration with H. L. F. Buswell on the tension of carbon dioxide in alveolar air and on chloroform narcosis, and some valuable researches concerning the calcium content of the blood and the influence of variations in its amount on coagulation. In the same journal, in collaboration with M. T. MacMahon, he wrote on anticoagulants of blood and on thrombrin and antithrombrin. To the *British Medical Journal* he communicated in collaboration with Sir William Willcox a paper on the use of alcohol vapour mixed with oxygen, a subject which he had discussed in the *Transactions* of the Royal Academy of Medicine in Ireland.

Prof. Collingwood married in 1917 Grace Jane Wilkinson, the daughter of Dr. C. Wilkinson, and leaves a widow and three children.

WILLIAM EDWARD COLLINS, C.M.G., M.B. Lond.

HON. CONSULTING SURGEON TO WELLINGTON HOSPITAL

Colonel the Hon. W. E. Collins, whose death was reported from New Zealand on Saturday, August 11th, at the age of 81, was particularly associated with the work of the New Zealand Red Cross Society, and his death will be regretted by all connected with the movement as well as by a large circle of friends.

Born at Monghyr, in India, in 1853, he was the son of the late Dr. J. G. Collins, of the East India Army, and received his early education at Cheltenham, afterwards proceeding to St. George's Hospital for his medical training. He qualified with the diploma of the Royal College of Surgeons in 1876, graduated M.B. Lond. in the following year, and in 1878 sailed for New Zealand, where, at Wellington, his zeal for his profession and his skill as a surgeon soon gained for him an extensive practice. He joined the New Zealand military forces in 1880, and the institution of the Volunteer Bearer Corps of the volunteer movement owed much to his initiative. During the late war he was given command of H.M. hospital ship *Mahino* on its first commission in 1915. Later he commanded the *Marana* in 1916 and in 1918. He received the C.M.G. in 1917, and retired the following year. He was chairman of the executive of the British Red Cross Society, to the work of which he was devoted and of which he was made an honorary life member two years ago in recognition of his great service to the cause. A member of the senate of New Zealand University since 1904 he was an examiner in surgery for three years, while he had been on the honorary staff of Wellington Hospital for 30 years and a consulting surgeon for nine years. In 1914 he was chairman of the special committee on syphilis which was set up by the Australian Medical Congress. He had been a member of the Legislative Council of New Zealand since 1907 and was appointed C.M.G. in 1917.

Keenly interested in all forms of athletics, cricket, and tennis, football specially appealed to him, and he played for England against Scotland in the Rugby games of 1874–5–6, and took part in the England *v.* Ireland contest during the last two years mentioned.

Colonel Collins married in 1886 Isabel Georgina, daughter of Dr. David Warren, of Melbourne, by whom he had one son and one daughter.

GEORGE ALEXANDER MOORHEAD, F.R.C.S.I., M.R.C.P.I., D.P.H.

We regret to record the death of Dr. Moorhead, of Tullamore, which occurred in Dublin on August 3rd in his seventy-ninth year. He had undergone a serious operation a few weeks before his death, and made a brave but unsuccessful struggle for recovery.

George Alexander Moorhead obtained his first medical qualifications at the age of 21 from the Irish Royal Colleges; in 1881 he became a Member of the Royal College of Physicians, and in 1893 a Fellow of the Royal College of Surgeons. He spent his whole professional life in his native town of Tullamore, where he was for many years dispensary medical officer and medical officer to the district hospital. He conducted a large practice for which, indeed, both by his attainments and by his natural capacity, he was well equipped. In 1907 he took the diploma of D.P.H. of the Royal Colleges, and as medical officer of health of Tullamore he was an active sanitarian, the many improvements in draining and housing in the town being due mainly to his initiative and work.

Apart from his profession, much of his leisure was spent in horse-breeding and racing and his stable produced some notable winners. Dr. Moorhead is survived by his wife and a large family of sons and daughters, of whom the eldest son is a member of the medical profession. His death will be felt in a wide circle of patients and friends.

THE LATE DR. ROBERT LAWS

Dr. Robert Laws, whose death we recorded with a summary of his work last week (see p. 318), played such a significant rôle in Central Africa that the following notes on his career, supplied by G. D. S., are welcome.

"Dr. Robert Laws, whose death in a London nursing-home from peritonitis occurred on August 6th, was one of the really great missionaries of modern times. For 52 years he laboured in Central Africa. He first went out in 1875 as medical officer with the original expeditionary party sent by the Free Church of Scotland to carry on the work of Livingstone, who had but recently died. Laws's boyhood's ambition was to follow in Livingstone's footsteps. And the mission which Laws founded and under whose wise and energetic direction it grew and flourished is world-known as the Livingstonia Mission.

"When Laws heard of the plan to establish a mission on the shores of Lake Nyasa he said 'This is the work I have been preparing for all my life.' It was the beginning of a new epoch for Central Africa, when he entered the waters of Nyasa on the little steamship *Ilala*—the first steamship to navigate any of the big lakes. The missionaries found a land all but ruined by constant tribal warfare as well as by the raids of Arab slavers. Their settlements and civilising influence paved the way for the entry of the British Government in 1891 and for a rapid growth of native prosperity, with the return of peace and the spread of Christian education. When Laws retired in 1928 he left behind him a prosperous and peaceful Christian community, numbering 20,000 church members (where 50 years before there had not been a single Christian), with nearly 700 schools, churches, thriving workshops, stores, farms and gardens, dispensaries, and a hospital.

"Laws's versatility, energy, and competence in all departments of pioneer life were almost incredible. He was not indeed a great preacher, but he was a fine schoolmaster and organiser. A skilful translator, he compiled the first dictionary, grammar, and New Testament in the Njanja tongue. He was a good seaman, an expert tracker of game, and incidentally an excellent cook. He thoroughly enjoyed the life of an explorer. He knew how best to establish friendly relations with the wildest of savages, was often peacemaker in their feuds, and many miserable slaves owed to him their release. For civil administration, too, he had talent, and for years many of the natives would recognise no other tax-gatherer than the doctor. His services as physician and surgeon were constantly in request.

"He devised an admirable system of book-keeping, was a good amateur printer, and organised a most efficient postal service. He became, moreover, an experienced and successful gardener and farmer, and to him Central Africa owes the introduction of many new foodstuffs and of improved breeds of stock and methods of afforestation. Much more than a 'Jack of all trades' he seemed master of all. As a carpenter, builder, and architect he excelled. He acquired and put into practice the elements of road engineering. At the age of 49, when on furlough, he entered as a student in a technical college to make himself proficient in electrical engineering. Later on, during his year at home as Moderator in the Scottish Church, he took a three months' medical course to gain the latest knowledge in this field.

"A graceful tribute to the work of Dr. Laws was paid by the Government of Nyasaland soon after his retirement, when it decided, in recognition of the service he had rendered to civilisation in the Protectorate, to rename Mount Nyamkhowa after him. Now it is Mount Laws, which stands 7000 ft. high, within the Livingstonia Mission estate and looks across Lake Nyasa to the Livingstone Range, which perpetuates the name of that other missionary who was Laws's hero and inspiration.

"Laws was married in 1879 at Blantyre, Nyasaland, to Miss Margaret Gray, who was his able and devoted helpmate until her death in 1931. Their only daughter, Miss Amelie Laws, is a graduate in medicine."

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

THE following appointments have been made: Surg. Lts. H. J. Bennett to *Cyclops* and to *Ramillies;* and S. I. Ballard to *Ramillies* and to *Cyclops.*

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Comdr. H. G. Ungley to *Effingham.*

Surg. Lt. W. H. C. Watson to *Victory* for R.N.B.

Proby. Surg. Sub.-Lt. (D) A. C. Fuller to *Victory* for R.N. Hosp., Haslar.

ARMY MEDICAL SERVICES

Lt.-Col. R. P. Lewis, from R.A.M.C., to be Col.

ROYAL ARMY MEDICAL CORPS

Maj. R. A. Flood to be Lt.-Col.

The undermentioned Lts. (on prob.) are confirmed in their rank: M. S. W. Bisdee, P. O'Shea, R. W. Scott, and J. D. P. Macpherson.

Capt. E. G. Dalziel to be Maj.

Lt. (on prob.) M. W. Allen resigns his commn.

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Off.: Col. W. Bennett (late R.A.M.C.) and Col. L. Wood (late R.A.M.C.).

ARMY DENTAL CORPS

The undermentioned Lts. (on prob.) are confirmed in their rank: K. H. Coulton and J. E. C. Robinson.

TERRITORIAL ARMY

R. J. C. Hamilton (late Offr. Cadet, Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lt.

O. R. L. L. Plunkett (late Cadet Lce.-Corpl., Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE

The following appointments are confirmed: Majs. B. R. Tandon, P. V. Karamchandani, and R. K. Misra.

Capts.: K. R. Sahgal, M. S. Gupta, A. N. Chopra, D. N. Chakravarti, S. Annaswami, T. B. Pahlajani, Assa Singh, R. R. Bakshi, B. D. Khurana, D. C. Chopra, Jaswant Singh, Sangham Lal, A. K. Gupta, V. Srinivasan, D. P. Mitra, T. D. Ahmad, M. Jafar, A. M. Chaudhuri, P. V. Bamford, H. D. R. Zscherpel, K. Jilani, J. R. Dogra, S. Narain, F. M. Khan, D. Datt, M. G. Saincher, B. L. Taneja, S. W. H. Askari, Hoe Min Sein, D. P. Nath, and H. H. Mahmood.

The undermentioned appointments are made: To be temp. Lts.: Mohan Lal Gujral, Baij Nath Bhandari, Mohan Singh, Mir Naeem Mahmood, Shaikh Sultan Alam, Beharilal Kapur, Des Raj Sharma, Partap Singh Bassalvi, Mohd. Muzaffar-ud-Din Chughtai, Ghulamahmad Niazmohammad Ahmadi, Prince Mohan Kaul, Amarendra Krishna Dev, Mohammad Akram, D. Satyanarayana Raju, Gurbuxsh Singh, and Balwant Singh Bindra.

The undermentioned officers retire: Lt.-Cols. K. S. Singh and T. F. Owens.

ROYAL AIR FORCE

Flight Lt. B. W. Cross is promoted to the rank of Squadron Leader.

Group Capt. E. C. Clements is placed on the retd. list.

RESERVE OF AIR FORCE OFFICERS

The undermentioned are granted commissions as Flying Officers in class DD: T. G. Hovenden and R. D. Bruce.

COLONIAL SERVICE

Dr. R. Austin has been appointed Medical Officer and District Officer, St. Vincent, and Dr. C. H. Parkin, Radiologist, Jamaica. Dr. J. L. Lochhead, late Medical Officer, Nigeria, becomes Medical Officer, Gambia, and Dr. J. M. Semple, Medical Officer, Zanzibar, Senior Medical Officer, Uganda.

DEATHS IN THE SERVICES

Col. Charles Robert Tyrrell, C.B., C.B.E., late R.A.M.C., who passed away in his sleep at Folkestone on August 12th at the age of 75, was a Middlesex man who qualified in 1881 with the membership of the Royal College of Surgeons of England and the licentiate of the Society of Apothecaries. He entered the Army in the following year, and in 1897–98 saw service on the North-West Frontier of India (despatches and medal with clasp). He retired in 1912, but was re-employed during the late war. From 1914 to 1917 he was at the War Office, and for one year afterwards was commissioner of medical services at the Ministry of National Service. Col. Tyrrell was made a Knight of Grace of the Order of St. John of Jerusalem in 1913, received the C.B. in 1917, and the C.B.E. two years later. In 1900 he married Agnes Laura, daughter of the late James Livesey, by whom he had one son.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 4TH, 1934

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 0; scarlet fever, 2400; diphtheria, 1088; enteric fever, 36; acute pneumonia (primary or influenzal), 438; puerperal fever, 46; puerperal pyrexia, 97; cerebro-spinal fever, 10; acute poliomyelitis, 16; acute polio-encephalitis, 1; encephalitis lethargica, 6; dysentery, 14; ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on August 13th–14th was as follows:—Small-pox, 0; scarlet fever, 1431; diphtheria, 1446; measles, 612 (last week 650); whooping-cough, 269; puerperal fever, 25 mothers (plus 6 babies); encephalitis lethargica, 268; poliomyelitis, 1; "other diseases," 243.* At St. Margaret's Hospital there were 22 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 13 (1) from measles, 9 (1) from scarlet fever, 13 (5) from whooping-cough, 39 (6) from diphtheria, 48 (18) from diarrhœa and enteritis under 2 years, and 8 (1) from influenza. The figures in parentheses are those for London itself.

Manchester and Sheffield each reported a death from enteric fever. Only three towns (Sunderland, Tynemouth, and Birmingham) had as many as 2 deaths from measles. Four fatal cases of diphtheria were reported from Liverpool. Liverpool, again with 5, showed the highest number of deaths from diarrhœa, Gillingham 3, no other large town more than 2.

The number of stillbirths notified during the week was 280 (corresponding to a rate of 41 per 1000 total births), including 49 in London.

---

* Last week this figure should have been given as 247.

MEDICAL NEWS

University of Cambridge

On August 4th the following degrees were conferred:—

M.D.—C. G. H. Campbell, J. K. Monro, W. G. Oakley, B. C. Tate, K. H. Uttley, J. M. Graham, and A. W. Langford.

M.B. and B.Chir.—J. D. Fergusson, W. H. Lewis, Kenneth Robson, Alan Kekwick, and A. C. Rumsey.

M.B.—P. T. Cooper and C. M. Carr.

B.Chir.—R. C. F. Catterall, A. H. Dunkerley, M. K. Martyn, and C. J. Martin (by proxy); W. A. Elliott, M. W. L. Owen, T. A. Ratcliffe, A. M. Barrett, J. R. Chambers, J. G. Connell, T. B. L. Bryan, J. F. Edwards, R. E. K. Levick, C. G. Pantin, R. J. Still, E. A. M. Halsted, L. A. Hawkins; and J. P. S. Peck.

University of London

Dr. Amy M. Fleming has been appointed to succeed Dame Louise McIlroy in the university chair of obstetrics and gynæcology tenable at the London (Royal Free Hospital) School of Medicine for Women.

Dr. Fleming, who is 37 years of age, is at present senior assistant in the gynæcological department of the University of Glasgow. She was educated at Glasgow, where she graduated as B.Sc. with special distinction in 1919, and M.B. in 1922, proceeding to the degrees of M.D. and D.Sc. in 1927 and 1933. In 1924, after holding appointments in anatomy and urology, she became external assistant in the obstetrical and gynæcological hospital of the University of Tübingen. She also spent three months in 1923 working in the maternity hospitals of Vienna, and visited other continental cities between 1925 and 1929. In 1925 she joined the staff of the Royal Samaritan Hospital for Women, Glasgow, and in 1928 she was the first woman to be appointed to the staff of the Glasgow Royal Maternity and Women's Hospital, where she is now assistant surgeon and acting pathologist and director of the laboratory. Since 1923 she has been engaged in research work with the aid of grants from the Carnegie trust, the Muirhead trust, and the Medical Research Council, and has published observations on the peripheral innervation of the uterus and other subjects. She is an examiner for the Central Midwives Board for Scotland, and was elected a member of the British College of Obstetricians and Gynæcologists in 1931.

London Hospital Medical College

A post-graduate course will be held at this college from Oct. 17th to Oct. 20th, and the old students' dinner will take place on Oct. 18th at 7.30 P.M.

A Congress of Medical Wine-lovers

The second national congress of the Médecins Amis des Vins de France will be held at Béziers from October 25th to 28th, under the honorary presidency of Mr. Gaston Doumergue, the French premier. The secretary of the congress may be addressed at 72, Allée Paul Riquet, Béziers.

Experiments on Living Animals

Dr. J. A. Giles has reported to the Home Office on experiments performed in Great Britain during the year 1933 under the Cruelty to Animals Act of 1876. The total number of licensees holding certificates under the Act was 1647, of whom 398 performed no experiments. Of the 603,240 experiments performed during the year, 140,000 were performed by 308 licensees for Government departments and public health authorities, while 254,000 experiments by 66 licensees were made in the preparation of serums and the testing of drugs. Of the 575,055 experiments without anæsthetics most were inoculations and feeding experiments, a certain number consisting of oral administrations, inhalations, external applications, and abstraction of body fluids. It should be noted that Certificate A which allows experiments to be performed without anæsthetics is granted only for such as are attended by no considerable pain. The certificate is in fact not required to cover the operative procedure but to allow of the subsequent course of the experiment. "It must not be assumed," Dr. Giles remarks, "that the animal is in pain during the whole of this time. In cases of prolonged action of an injected substance, even when ending fatally, the animal is generally apparently well, and takes its food as usual, until a short time before death. The state of illness may only last a very few hours, and in some cases it is not observed at all." Only three irregularities were reported during the year, all of them trivial, and the result of misunderstanding of the regulations. Dr. Giles works under an advisory committee of which Lord Tomlin is chairman, composed of Dr. H. Morley Fletcher, Sir Farquhar Buzzard, Mr. W. Sampson Handley, Sir D'Arcy Power, and Mr. Wilfred Trotter.

From Theatre to Hospital

The Surrey Theatre, in Blackfriars-road, has been sold to the adjoining Royal Eye Hospital, and it is intended to build a new hospital on the site. Since the theatre, long the home of "transpontine melodrama," was opened in 1782 it has twice been burned. "Black-Eyed Susan" was first produced there a century ago.

An Artificial Slum

A slum alley built from materials collected in a London clearance area will be a feature of the nineteenth (biennial) Building Exhibition which is to be opened at Olympia, London, on Sept. 12th, by Lord Balfour of Burleigh. It will form the entrance to the "new homes for old" exhibit, which will include a survey of recent housing developments and the relation of housing to town planning.

Memorial to David Livingstone

A statue to Dr. Livingstone was unveiled by his nephew, Mr. H. U. Moffat, a former premier of Southern Rhodesia, on August 5th, at Victoria Falls. The memorial has been erected by the Federation of Caledonian Societies of South Africa. It is the work of Mr. W. Reid Dick, R.A., and takes the form of a bronze figure of the explorer standing on an immense base of Rhodesian granite. The ceremony was relayed in the National programme, and wireless listeners in this country were able to hear the speeches and the roar of the water.

A New West Riding Mental Hospital

The mental hospitals board of the West Riding has decided to build a new institution for 1000 patients. A site has yet to be found; about 100 acres will be required, and the locality is to be selected with a reference to the incidence of lunacy in the various areas of the West Riding. A further 559 beds are to be provided in existing institutions by converting buildings at present used for other purposes, and by adding an admission block at Menston Hospital.

Tunbridge Wells Hospital

On August 8th, at the first meeting of the governors of this new large institution by which the Tunbridge Wells and Counties General Hospital and the Tunbridge Wells Eye and Ear Hospital have been amalgamated, the Marquess of Abergavenny was elected patron and the Marquess Camden president. In reply to criticisms Mr. J. B. Snell, on behalf of the building committee, said the cost of erecting a modern hospital was £1000 per bed. The institution had 204 beds, and would therefore have been justified in spending £204,000, whereas the total cost of the building had, in fact, only been £180,000. The committee felt the change from 165 beds, as was originally proposed, to 204 beds was wise, and would meet the requirements of the hospital's area for many years to come. The upkeep of the hospital would be approximately £500 per week.

University of Durham College of Medicine

A special post-graduate course is announced by the college between the dates of Sept. 10th and 21st inclusive. The courses include, among others, lectures and demonstrations on Orthopædic Surgery (Mr. C. Gordon Irwin), Ophthalmology (Mr. J. S. Arkle), Pædiatrics (Dr. J. C. Spence), Diseases of the Throat, Nose, and Ear (Mr. W. F. Wilson), Pathology and Bacteriology (Prof. S. McDonald and Prof. E. M. Dunlop), Neurology (Dr. C. N. Armstrong), and Gynæcology (Dr. E. F. Murray). The majority of the classes will be held in the Royal Infirmary, where Dr. W. E. Hume, Dr. H. Drummond, Dr. A. G. Ogilvie, Mr. F. C. Pybus, and Mr. R. J. Willan will give medical and surgical demonstrations. Dr. J. A. Charles will lecture on infectious diseases at the City Hospital, and Prof. R. P. Ranken Lyle and Mr. H. Harvey Evers will give gynæcological instruction at the Princess Mary Maternity Hospital. For the time chart of the various days, and the locale of the lectures and demonstrations information should be sought from the registrar of the College.

experienced and successful gardener and farmer, and to him Central Africa owes the introduction of many new foodstuffs and of improved breeds of stock and methods of afforestation. Much more than a 'Jack of all trades' he seemed master of all. As a carpenter, builder, and architect he excelled. He acquired and put into practice the elements of road engineering. At the age of 49, when on furlough, he entered as a student in a technical college to make himself proficient in electrical engineering. Later on, during his year at home as Moderator in the Scottish Church, he took a three months' medical course to gain the latest knowledge in this field.

"A graceful tribute to the work of Dr. Laws was paid by the Government of Nyasaland soon after his retirement, when it decided, in recognition of the service he had rendered to civilisation in the Protectorate, to rename Mount Nyamkhowa after him. Now it is Mount Laws, which stands 7000 ft. high, within the Livingstonia Mission estate and looks across Lake Nyasa to the Livingstone Range, which perpetuates the name of that other missionary who was Laws's hero and inspiration.

"Laws was married in 1879 at Blantyre, Nyasaland, to Miss Margaret Gray, who was his able and devoted helpmate until her death in 1931. Their only daughter, Miss Amelie Laws, is a graduate in medicine."

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

THE following appointments have been made: Surg. Lts. H. J. Bennett to *Cyclops* and to *Ramillies*; and S. I. Ballard to *Ramillies* and to *Cyclops*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Comdr. H. G. Ungley to *Effingham*.

Surg. Lt. W. H. C. Watson to *Victory* for R.N.B.

Proby. Surg. Sub.-Lt. (D) A. C. Fuller to *Victory* for R.N. Hosp., Haslar.

ARMY MEDICAL SERVICES

Lt.-Col. R. P. Lewis, from R.A.M.C., to be Col.

ROYAL ARMY MEDICAL CORPS

Maj. R. A. Flood to be Lt.-Col.

The undermentioned Lts. (on prob.) are confirmed in their rank: M. S. W. Bisdee, P. O'Shea, R. W. Scott, and J. D. P. Macpherson.

Capt. E. G. Dalziel to be Maj.

Lt. (on prob.) M. W. Allen resigns his commn.

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Off.: Col. W. Bennett (late R.A.M.C.) and Col. L. Wood (late R.A.M.C.).

ARMY DENTAL CORPS

The undermentioned Lts. (on prob.) are confirmed in their rank: K. H. Coulton and J. E. C. Robinson.

TERRITORIAL ARMY

R. J. C. Hamilton (late Offr. Cadet, Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lt.

O. R. L. L. Plunkett (late Cadet Lce.-Corpl., Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE

The following appointments are confirmed: Majs. B. R. Tandon, P. V. Karamchandani, and R. K. Misra.

Capts.: K. R. Sahgal, M. S. Gupta, A. N. Chopra, D. N. Chakravarti, S. Annaswami, T. B. Pahlajani, Assa Singh, R. R. Bakshi, B. D. Khurana, D. C. Chopra, Jaswant Singh, Sangham Lal, A. K. Gupta, V. Srinivasan, D. P. Mitra, T. D. Ahmad, M. Jafar, A. M. Chaudhuri, P. V. Bamford, H. D. R. Zscherpel, K. Jilani, J. R. Dogra, S. Narain, F. M. Khan, D. Datt, M. G. Saincher, B. L. Taneja, S. W. H. Askari, Hoe Min Sein, D. P. Nath, and H. H. Mahmood.

The undermentioned appointments are made: To be temp. Lts.: Mohan Lal Gujral, Baij Nath Bhandari, Mohan Singh, Mir Naeem Mahmood, Shaikh Sultan Alam, Beharilal Kapur, Des Raj Sharma, Partap Singh Bassalvi, Mohd. Muzaffar-ud-Din Chughtai, Ghulamahmad Niazmohammad Ahmadi, Prince Mohan Kaul, Amarendra Krishna Dev, Mohammad Akram, D. Satyanarayana Raju, Gurbuxsh Singh, and Balwant Singh Bindra.

The undermentioned officers retire: Lt.-Cols. K. S. Singh and T. F. Owens.

ROYAL AIR FORCE

Flight Lt. B. W. Cross is promoted to the rank of Squadron Leader.

Group Capt. E. C. Clements is placed on the retd. list.

RESERVE OF AIR FORCE OFFICERS

The undermentioned are granted commissions as Flying Officers in class DD: T. G. Hovenden and R. D. Bruce.

COLONIAL SERVICE

Dr. R. Austin has been appointed Medical Officer and District Officer, St. Vincent, and Dr. C. H. Parkin, Radiologist, Jamaica. Dr. J. L. Lochhead, late Medical Officer, Nigeria, becomes Medical Officer, Gambia, and Dr. J. M. Semple, Medical Officer, Zanzibar, Senior Medical Officer, Uganda.

DEATHS IN THE SERVICES

Col. Charles Robert Tyrrell, C.B., C.B.E., late R.A.M.C., who passed away in his sleep at Folkestone on August 12th at the age of 75, was a Middlesex man who qualified in 1881 with the membership of the Royal College of Surgeons of England and the licentiate of the Society of Apothecaries. He entered the Army in the following year, and in 1897–98 saw service on the North-West Frontier of India (despatches and medal with clasp). He retired in 1912, but was re-employed during the late war. From 1914 to 1917 he was at the War Office, and for one year afterwards was commissioner of medical services at the Ministry of National Service. Col. Tyrrell was made a Knight of Grace of the Order of St. John of Jerusalem in 1913, received the C.B. in 1917, and the C.B.E. two years later. In 1900 he married Agnes Laura, daughter of the late James Livesey, by whom he had one son.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 4TH, 1934

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 0; scarlet fever, 2400; diphtheria, 1088; enteric fever, 36; acute pneumonia (primary or influenzal), 438; puerperal fever, 46; puerperal pyrexia, 97; cerebro-spinal fever, 10; acute poliomyelitis, 16; acute polio-encephalitis, 1; encephalitis lethargica, 6; dysentery, 14; ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on August 13th–14th was as follows:—Small-pox, 0; scarlet fev[illegible], 1446; measles, 542 (last week 650); [illegible] puerperal fever, 25 mothers (plus 6 ba[illegible] myelitis, 1; "other diseases," 243.* At [illegible] there were 22 babies (plus 8 mot[illegible] neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 13 (1) from measles, 9 (1) from scarlet fever, 13 (5) from whooping-cough, 39 (6) from diphtheria, 48 (18) from diarrhœa and enteritis under 2 years, and 8 (1) from influenza. The figures in parentheses are those for London itself.

Manchester and Sheffield each reported a death from enteric fever. Only three towns (Sunderland, Tynemouth, and [illegible] any as 2 deaths from measles. Four fatal [illegible] re reported from Liverpool. Liverpool, [illegible] the highest number of deaths from [illegible] no other large town more than 2.

The number of stillbirths notified during the week was 280 (corresponding to a rate of 41 per 1000 total births), including 49 in London.

Liverpool Royal Infirmary.—Two H.S.'s to Spec. Depts. Each at rate of £60.

Liverpool, Royal Southern Hospital.—Res. Orthopædic H.S., M.O. to Spec. Dept., and Res. Anæsthetist. Each at rate of £60.

Macclesfield General Infirmary.—Second H.S. At rate of £150.

Manchester Babies Hospital, Burnage-lane, Levenshulme.—Sen. Res. Medical Officer. At rate of £125.

Manchester, Booth Hall Hospital.—Two Asst. M.O.'s. Each £200.

Manchester [illegible] *Diseases of the Throat and Ch*[illegible]

Manchester [illegible] Clinical Laboratory. £350.

Manchester, St. Mary's Hospitals.—Hon. Surgeon for Children's Dept.

Margate and District General Hospital.—Res. M.O. £150.

Middlesbrough, North Riding Infirmary.—Third H.S. At rate of £125.

Middlesex Hospital, W.—Radiologist. £500. Also Asst. Radiologist (Diagnostic). £100.

[illegible]—Two Surg. Regs. Each £250.

[illegible] *Hospital.*—Sen. Res. H.S. £300.

[illegible] *al Victoria Infirmary.*—Jun. Surg.

[illegible] *wich Hospital.*—Cas. O. and H.S. [illegible] pec. Depts. £120.

Poplar Hospital for Accidents, East India Dock-road, E.—Second Res. O. £175.

Port Elizabeth, Provincial and City Infectious Diseases Hospitals. Med. Supt. £1000.

Preston County Borough.—Asst. School M.O. £500.

Prince of Wales's General Hospital, N.—Res. Jun. H.P., and Two Res. Jun. H.S.'s. Each at rate of £90.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Res. M.O. At rate of £150. Also H.P. and Cas. O., H.S. and Cas. O. Each at rate of £110.

Queen Mary's Hospital for the East End, Stratford.—H.S.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.

Reading, Royal Berkshire Hospital.—Res. Anæsthetist. At rate of £150.

Rhondda U.D.C.—Asst. M.O. £500.

Richmond, Surrey, Royal Hospital.—Jun. H.S. At rate of £100.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. and Asst. H.S. At rate of £150 and £100 respectively.

Royal London Ophthalmic Hospital, City-road, E.C.—Out-patient Officer. £100.

Royal Naval Medical Service.—Ten M.O.'s.

Royal Northern Hospital, Holloway, N.—Clin. Asst. for Aural Dept.

St. Albans and Mid Herts Hospital and Dispensary.—Res. H.S. £150.

St. Albans, Cell Barnes Colony.—H.P. £155–£165.

Sheffield Children's Hospital.—H.P. At rate of £100.

Shrewsbury, Royal Salop Infirmary.—Cas. O. and Res. Anæsthetist. At rate of £160.

Stoke-on-Trent, [illegible] *Infirmary.*—H.S. and Asst. H.S.

Surrey County [illegible]

Swansea Count [illegible]

Swansea General and Eye Hospital.—Cas. O. At rate of £150.

Tilbury Hospital, Essex.—H.S. At rate of £140.

Walsall, Manor Hospital.—Jun. Res. Asst. M.O. £150.

Warwick, King Edward VII. Memorial Sanatorium, Hertford Hill.—Jun. Asst. M.O. £200.

Warwickshire and Coventry Joint Committee for Tuberculosis.—Asst. Tuber. O. £600.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.

West Bromwich and District General Hospital.—H.S., H.P., and Cas. O. Each at rate of £200.

West London Hospital, Hammersmith-road, W.—H.P. Also 2 H.S.'s to Special Depts. Each at rate of £100.

Wigan, Royal Albert Edward Infirmary and Dispensary.—Hon. Asst. Surgeon.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Fochabers (Morayshire), and at Manchester, W.C. (Lancs.).

Births, Marriages, and Deaths

BIRTHS

ANDERSON.—On August 12th, at St. John's Hill, Shrewsbury, the wife of Frederick A. Anderson, M.D., of a son.

MEAD.—On August 12th, at Victoria-road North, Southsea, the wife of Dr. Kenneth V. Mead, of a son.

TAYLOR-JONES.—On August 11th, at West Cross, Tenterden, Kent, the wife of Dr. T. H. E. Taylor-Jones, of a daughter.

DEATHS

COLLINGWOOD.—On August 9th, at Marlborough Hill, N.W., Bertram Ja[illegible] D., O.B.E., Professor of Physiology,

ELLIOTT.—On A[illegible] Shrubbery, Stoneygate, Leicester, Charles Coyne Elliott, M.D., F.R.C.S.E., aged 58 years.

HILL-WILSON.—On August 8th, after a long illness, Dr. A. E. [illegible] n, W.

LOW[illegible] s, Sussex, [illegible] P., aged 58, [illegible] uneral will leave 344, Finchley-road, Hampstead, Friday, August 17th, for the Liberal Jewish Cemetery, Pound-lane, at 10.30. No flowers by request. (American papers please copy.)

MASON.—On August 12th, at Oakwood, Walton-on-Thames, Arthur Henry Mason, M.R.C.S., L.R.C.P., aged 74.

MOORHEAD.—On August 3rd, at a nursing-home, Dublin, George A. Moorhead, F.R.C.S.I., of *Tullamore*, in his 79th year.

TYRRELL.—On August 12th, Charles Robert Tyrrell, C.B., C.B.E. (late R.A.M.C.).

WINTLE.—On August 8th, at Bath, Colston Wintle, M.R.C.S., L.R.C.P., J.P. for Bristol.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

INDEX TO "THE LANCET," VOL. I., 1934

THE Index and Title-page to Vol. I., 1934, which was completed with the issue of June 30th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

NOTES, COMMENTS, AND ABSTRACTS

"HEART" LATHAM

By Major Greenwood, D.Sc., F.R.C.P., F.R.S.
PROFESSOR OF EPIDEMIOLOGY AND VITAL STATISTICS IN THE UNIVERSITY OF LONDON, AT THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

"I was told," wrote Sir Thomas Watson, whose years and honours permitted him to use a freedom which in others *might* have been thought disrespectful, "by a profound classical scholar, who was possessed with the strange curiosity to read all the printed Harveian Orations, that subsequently to the date of Sir George Baker's, that by Dr. P. M. Latham was one of the very few the Latinity of which he could praise." [1]

Between Baker's oration (1761) and P. M. Latham's (1839) 24 Harveians were printed and one wonders whether that of Dr. John Latham (1794), Peter Mere Latham's father, was also one of the very few praiseworthy exercises in Latin prose. Ability to write decent Latin prose was one of the points in which Peter Mere Latham resembled another hero of the London College of Physicians, John Freind; some might think it the only point. What else could there be in common between the jolly, enjoying, English gentleman of the very early eighteenth century, who cracked his joke and his bottle, served in Spain with Peterborough, and was actually sent to the Tower, and the "very small, spare man . . . with an instinctive shrinking from remediless suffering, which, I remember hearing, led him sometimes to fail in keeping appointments for consultations in cases that were beyond hope, and this was perhaps an indication of one of the few defects in his character—a reluctance to encounter pain or to engage in struggle even when his convictions would have led him to do so." [2]

As I think I shall be able to show, there were other points of resemblance between the physician who died more than 200 years ago and the physician with whom men now living may have spoken.

Peter Mere Latham was born in 1789, the son of a physician who reached the highest rank in his profession and also lived to a venerable age. He was educated at Oxford and St. Bartholomew's Hospital, elected physician to the Middlesex Hospital in 1815 and to St. Bartholomew's Hospital in 1824 (when he resigned his office at the Middlesex Hospital). For the next 17 years he was an active, perhaps the most active, member of the Bart.'s staff, but in 1841 he resigned his office on account of ill-health, although he continued to practise in London for another 24 years, not retiring until 1865, when he was long past 70, and he survived until 1875, dying in the eighty-seventh year of his age. Those who are interested in such matters will remark a parallel between the careers of father and son. John Latham at the age of 46 in leading consulting practice "was worn out by the hard labour of his early success. He was believed to be consumptive, and he retired into the country, it was thought to die." (This and the following quotations are from a biography of John Latham by his son Peter.) "Under the influence of country air and complete relaxation from the cares and toils of professional business" John Latham recovered. He returned to London, moved from Bedford-row to Harley-street, "and here for years he enjoyed, with a more moderate practice, a larger share of health than he had known during the days of his greater labour and greater success." He did not in fact retire from practice until he was in his sixty-eighth year, and lived in retirement another 14 years. "He was singularly temperate, when temperance was hardly yet thought to be a virtue: he was most pure in life and conversation when to have been otherwise would have provoked no censure; and he was not ashamed to be religious when religion had yet no recommendation or countenance from the world."

"The son was also (I am now quoting from Munk, who derived his information from Peter Latham's pupil, Charles West) the Christian physician. Side by side with the pharmacopœia on his consulting room table, in the little book-stand, stood hidden in the plainest binding his Greek Testament and Bishop Andrews' 'Devotions,' and he loved them both." The father's physical weakness we have been told was a tendency to consumption, that of the son, "emphysema of the lungs and severe paroxysms of asthma." Should any of our medical psychologists go further into the family history of the Lathams, I cannot doubt but that very striking proofs of mutually incompatible hypotheses will easily be discovered.

WORKS AND OPINIONS

Peter Mere Latham's literary output was considerable. An edition of his works was edited for the New Sydenham by the late Robert Martin. The clinical lectures on diseases of the heart, which earned the nickname "Heart" Latham, were once popular in the profession. So far as the practice of competent physicians is concerned, in a large majority of the illnesses described by Latham the passage of 90 years has brought no fundamental change in methods of diagnosis or treatment. For that very reason his book is hopelessly obsolete; one can learn the facts better from books of to-day and there is not sufficient contrast between what was thought then and now either to flatter our vanity or to excite our antiquarian curiosity. The author's literary skill, although distinguished, is not distinguished enough to make him immortal on that account. In spite of the decay of what was once called humane learning, medical men of our own time, such as Osler and Allbutt, have written in the same vein as well as Latham.

It is, however, worth while to quote some passages of this book in order to illustrate Latham's medical philosophy. I take the following from his lectures on acute rheumatism.

> "Acute rheumatism has experienced strange things at the hands of medical men. No disease has been treated by such various and opposite methods. Venaesection has wrought its cure, and so has opium, and so has calomel, and so has colchicum, and so have drastic purgatives. I speak of these remedies in the sense which medical men imply when they talk (as they sometimes do) of this, that, or the other thing being their 'sheet anchor'; meaning that they rest upon it alone for the cure of the rheumatism, and employ other remedies either not at all, or for very subordinate purposes. And indeed I bear my testimony to the success of each of these different remedies, so far as that; under the use of each, I have seen patients *get* well. . . It is not possible that the treatment of disease shall be ever set at rest by the consent of physicians, or that fixed and uniform plans and remedies shall ever be adopted in cases bearing the same *nosological* name and character. At least it cannot be until each disease has its own specific antidote, or until each has

---

[1] This, and other quotations not separately specified, is from the New Sydenham Society's Edition of Latham's Works.

[2] Munk's Roll of the Royal College of Physicians, vol. iii., p. 188.

disclosed some seminal principle from which it springs, and shown where it is: some principle, too, it must be which is within reach, and which is destructible and easily destroyed. . . For the treatment of acute rheumatism, above all other diseases which can be named, is a thing to put the physician and medicine itself to the trial of what they can really do. Here are no specifics at hand. All proceeds upon rational calculations; upon the right choice of purposes to be fulfilled, and the right choice of means to fulfil them. . . Let me repeat my testimony to the success of this practice in acute rheumatism; the practice, namely, of choosing some single indication, and steadily pursuing it to its fulfilment. It is a very rational practice. . . . Well, then, I am persuaded that when the physician is called upon to perform great things, even to arrest destructive disease, and to save life, his skill in wielding the implements of his art rests mainly upon the right understanding of simple and single indications, and of the remedies which have the power to fulfil them. To know that, in any case of acute rheumatism, the cure of the entire disease is accessible through the blood-vessels alone, by subduing their too forcible action; or accessible through the nervous system alone, by moderating its disquietude, and abating pain; or accessible through the stomach and bowels and liver alone, by stimulating them to a very large amount of secretions: and to know, moreover, that in any cases venaesection alone will fulfil the first purpose, or opium alone will fulfil the second, or calomel and aperients alone will fulfil the third: to know all this is the best preliminary step towards enabling us to deal safely and successfully with other and more numerous cases, which need a more complex method of treatment, and require that all these important purposes be pursued simultaneously, and all these great remedies be made confederate for the cure of the disease."

It will be seen that Latham's philosophy was essentially pragmatic. He had no more use than Freind for any subtle disquisition on the essential nature of a "disease." He flourishes a little over the "seminal principle of diseases" (meaning, no doubt, the *causa efficiens*, or biological excitant of an illness) and holds that the "highest office of medicine is to minister to diseases (again meaning illnesses) which by themselves, or by their incidence, go directly and rapidly to the destruction of life." Actually he is doing what all physicians must, in 90 per cent. of cases, do, treating symptoms, taking events as they come, and—this is what distinguishes the genuine physician from the charlatan—not pretending to himself that he is doing anything more.

THE CHANGES OF A CENTURY

Anybody who thinks that in 1933 physicians do much better need only refer to any modern treatise. Take, for instance, Strümpell and Seyfarth's "Practice of Medicine"[3]; it will be found that the passage of 80 years has not led to any fundamental change in the conception of acute rheumatism from the clinical aspect. In respect of treatment, shortly after Latham's death a new specific medication replaced colchicum —viz., salicylic acid—which, as sodium salicylate, had a considerable vogue, but owing to its production of some disagreeable symptoms has been to a great extent replaced by acetyl salicylic acid (aspirin) while the latter has again been replaced in some clinics by phenyl-quinolin carbonate (atophan). These remedies usually, it is said, cause the symptoms to disappear, but—

> "it is only in the minority of cases that the course of the disease is at an end. There very frequently occurs, sooner or later, a relapse, with renewed pain or even effusion in one or more of the joints. . . It is an unfortunate fact that the efficacy of all remedies against acute rheumatism is limited. . . Much discussion has taken place on the possible influence of salicylic preparations and atophan upon the occurrence of complications, especially cardiac lesions. At any rate, it is certain that the latter cannot be prevented by these remedies and quite often make their appearance during the administration."

So far as treatment is concerned the physician of 1934 can relieve pain more frequently than the physician of 1844, that he can "cure" the disease more frequently does not appear. This is a simple illustration not buried in technicalities; the principle it illustrates is a general one.

Those who assert that there are no forms of illness which the pure *medical* clinician can diagnose and treat more efficiently than his great grandfather are simply liars or ignoramuses. Were they to confine themselves to saying that in seven out of ten cases of the *kind* of acute bodily illness which leads to the calling in of a Fellow of the College of Physicians in 1933, he can do nothing essentially different from what Latham would have done 100 years ago, they would be within the mark.

From this one does not, unless very unintelligent, conclude that in 70 per cent. of cases the visit of a physician is useless now and was useless a century ago. Latham explained his duty:

> "According to popular notion, cure is the aim and end of all treatment, and the result and complement of successful treatment. But let cure and treatment now be taken to denote different things, so far as the aims and objects of the physician are concerned in his management of disease. Let cure be looked upon as concerned with the disease as such, and having little or no regard to the individual patient whom it befalls. Treatment is concerned with the individual patient, and leaves his disease to take care of itself. . . It is an instructive fact that, as the knowledge of disease has increased, the practice of medicine has been less and less conversant with cures and more and more conversant with treatment. . . And thus the present state of our knowledge has come to warrant the conclusion that the number of diseases is very small which are capable of cure by a proper remedy of their own, and which exclude the need of other remedies addressed to conditions belonging to the individual patients; whereas the number in which the converse obtains would embrace the vast majority of human maladies."

The physician is valuable not because of his grasp of general principles, but because of his nice observation of particular idiosyncrasies of human beings.

It is in his insistence upon this aspect of medicine that Latham becomes I will not say modern but very relevant to modern matters of controversy. He was an unsparing critic of medical education. In early middle life, in the lectures he published in 1836, he devoted much attention to the subject. It was the theme of his latest writing, published in the *British Medical Journal* in 1864, when he was 75. In 1836 Latham wrote:

> "Depend upon it, what all men indiscriminately are told they *ought* to know, all men indiscriminately will soon *pretend* to know, be it never so extravagant; and when every medical man in every town and village throughout England, be he physician, surgeon or apothecary, shall, in right of his profession, claim the homage due to vast learning and science, there will not be wanting some Molière or Le Sage to hold us all up to the just ridicule of mankind."

Twenty-eight years later he begins his article with these words:—

> "'Science is his forte, omniscience is his foible.' This was spoken by one well able to instruct mankind; and with such a lucky way of doing it, that he could wrap up wisdom in a witticism. And this was one of the wisest and wittiest things he ever said. He aimed at some individual, and perhaps hit him and made him smart. Had he aimed at our profession, would he have hit it?

---

STUDENTS' GUIDE—SESSION 1934-1935

THE GENERAL MEDICAL COUNCIL

POWERS, DUTIES, AND CONSTITUTION

THE General Council of Medical Education and Registration of the United Kingdom is, first, a registering body: no person, even though his qualifications have been obtained by examination, is a *legally qualified* medical practitioner until his name appears on the Medical Register. Secondly, it is a standardising body, ensuring that there is a definite minimum of medical education and scientific examination. Thirdly, it is a penal and disciplinary body, having power to remove from the Register any practitioner convicted of felony or misdemeanour or adjudged guilty of professional misconduct. Fourthly, to the Council is committed the codification of pharmaceutical remedies. The duties of the Council are thus primarily of a public nature, and its construction shows its fitness for its fourfold responsibilities.

The Council consists of 39 members, of whom 18 are appointed by universities and 9 by licensing corporations; 5 members are chosen by the Crown on the advice of the Privy Council, and 7 others are elected by the members of the medical profession as Direct Representatives. The Crown members and the university representatives need not be medical men, and one layman appointed by the Privy Council now sits on the Council. Three members are appointed for dental business by the Privy Council under the Dentists Act, 1921, under which the powers and duties of the General Medical Council with regard to the keeping of the Dentists Register and the administration of the Dentists Acts were largely transferred to the Dental Board of the United Kingdom.

The Educational Curriculum

Professional Education.—The course of professional study after registration as a student occupies at least five years. The Final Examination in Medicine, Surgery, and Midwifery must not be passed before the close of the fifth academic year of medical study.

REGISTRATION OF MEDICAL STUDENTS

Before registration as a student every candidate must produce evidence that (*a*) he has attained the age of 17 years; (*b*) that he has passed a recognised examination in general education; and (*c*) that, *in addition thereto*, he has passed, or obtained exemption from, an examination, theoretical and practical, in elementary physics and elementary chemistry conducted or recognised by a licensing body. The standard of General Education required is approximately that of University Matriculation or entrance examination in the Faculties of Arts or Pure Science. Examinations, other than Matriculation, must be of the standard prescribed in Section 2 of the Regulations below.

An approved course of instruction in elementary biology at a secondary school or other teaching institution recognised by a licensing body may admit a student to the professional examination in elementary biology upon registration as a medical student. The student should in every case write beforehand to the Body whose qualification he desires to obtain, and, although it is not necessary to pass in Biology before registration as a student, application should be made at the same time to the Body selected to ascertain their requirements.

The candidate commencing medical study should apply to the registrar of the division of Great Britain and Ireland in which he is residing, according to a prescribed form copies of which may be had on application to the several licensing bodies, medical schools, and hospitals, or at the offices of the Council; and should produce proof that he, or she, has fulfilled the first three conditions.

MAINTENANCE OF REGISTER OF MEDICAL STUDENTS

1. The Education Committee prepares and issues from time to time a list of examining bodies whose examinations in general education fulfil the conditions of, and are recognised by, the Council.

2. The Council has recognised the undernoted university examinations which are conducted in Great Britain and admit to the Faculties of Arts or Pure Science, or to other Faculties, subject to the conditions specified below:—

Oxford University, Responsions; Cambridge University, The Previous Examination. The Matriculation Examinations of the following Universities: Birmingham, Bristol, Durham, Leeds, Liverpool, London, Victoria of Manchester, Sheffield and Wales, and the Entrance or Preliminary Examination of the Universities of Scotland.

The condition prescribed by the Council in Faculties other than Arts or Pure Science is that:—

The certificate shall bear evidence that the candidate has passed at the Matriculation or Entrance standard in the following subjects, viz.: (*a*) English. (*b*) Mathematics, Elementary. (*c*) A language other than English. (*d*) *A fourth subject, as defined in the regulations of the* particular Examination, to be chosen from the subjoined list, viz.: History, Geography, Physical Science, Natural Science, Botany; Latin, Greek, Hebrew, French, German, or other language accepted by the University.

3. Subject to the condition prescribed above (Section 2), the Council will recognise those of the examinations conducted by recognised authorities in Great Britain which are accepted by any one or more of the above-named Universities as equivalent (under prescribed conditions as to "credits" or "grades"), for purposes of Entrance or Matriculation, to an Examination named in the preceding list (Section 2). In School or Leaving Certificates, the four required subjects must have been obtained at not more than *two* sittings. Such Examinations are:—

Bristol University: Higher School Certificate Examination; School Certificate Examination. Cambridge Local Examinations Syndicate: Higher School Certificate Examination; School Certificate Examination. Central Welsh Examination Board: Higher Certificate Examination; School Certificate Examination. Durham University: Higher Certificate Examination; School Certificate Examination. London University: Higher School Certificate Examination; General School Examination. Northern Universities Joint Matriculation Board: Higher Certificate Examination; School Certificate Examination. Oxford and Cambridge Schools Examination Board: Higher Certificate Examination; School Certificate Examination. Oxford Delegacy for Local Examinations: Higher School Certificate Examination; School Certificate Examination. Scottish Education Department: Leaving Certificate Examination.

4. The Council will continue to recognise certain Examinations conducted by Educational Bodies, other than those (mentioned in Section 3) whose Examinations are accepted by any one or more of the Universities of Great Britain. Recognition will not be extended under this Section to any Examination unless the Council is satisfied (*a*) that in scope and standard it is equivalent to a recognised Matriculation or Entrance Examination of a University of Great Britain, (*b*) that it fulfills the condition prescribed by the Council (Section 2), and (*c*) that the Examination has been completed at not more than two sittings. Such Examinations are:—

The College of Preceptors (England): Senior Certificate (with *credit*). The Educational Institute of Scotland: Preliminary Medical Certificate.

5. Subject to the prescribed condition (*Section 2*), the Council will recognise the Entrance Examination to the School of Physic of the University of Dublin, and the Matriculation or Entrance Examinations of the National University of Ireland, the Queen's University of Belfast, the Irish Royal Colleges of Physicians

and Surgeons; and also the Senior Grade or Leaving Certificate of the Department of Education of the Irish Free State, the Senior Certificate Examination of the Ministry of Education of Northern Ireland, and all examinations accepted by any one or more of the Universities of Great Britain or Ireland, as equivalent, for purposes of entrance or matriculation, to the above-named University Examinations.

6. Subject to the prescribed condition (Section 2), the Council will recognise all Examinations of Colonial or Foreign Universities which are accepted by any one or more of the Universities of Great Britain as equivalent, for purposes of entrance or matriculation, to an examination named in the list of examinations recognised by the Council (Section 2).

7. The Council will recognise the Final Examinations for Degrees in Arts or Science of any University of Great Britain or Ireland or of the British Dominions.

8. The registration of medical students shall be placed under the charge of the Branch Registrars.

9. Each of the Branch Registrars shall keep a register of medical students.

10. The Branch Registrar shall enter the student's name and particulars in the Students Register, and give him a certificate of such registration.

11. Each of the Branch Registrars shall supply to the several licensing bodies, medical schools, and hospitals, in that part of Great Britain or Ireland of which he is Registrar, blank forms of application for the registration of medical students.

12. A copy of the Medical Students Register prepared by each of the Branch Registrars shall be transmitted, on or before Dec. 31st in each year, to the Registrar of the General Council, who will distribute the list to the licensing bodies, medical schools, and hospitals.

All applications for special exceptions to the foregoing regulations as to registration shall be addressed to the Registrar of the General Council, and shall be decided by authority of the Education Committee, who shall report thereon to the Council.

MEDICAL SCHOOLS AND COLLEGES

The Universities, including their Colleges and Medical Schools, and Schools of Medicine at which Medical Study may be commenced in the United Kingdom are set out seriatim in the following pages.

Medical Registration in Ireland

By legislative agreement between the Governments of Great Britain, of the Irish Free State, and of Northern Ireland—the powers and duties of the General Council of Medical Registration and Education are continued as heretofore in respect of qualifying bodies in the Irish Free State, and of medical practitioners qualified in the Irish Free State. Side by side with this a Medical Council has been set up in the Irish Free State with the duty of establishing and controlling a Register for the Irish Free State. Practitioners whose names are on the General Register, and persons who pass a qualifying examination in the Irish Free State, will be registered on the Irish Free State Register on payment of the prescribed fee. The Irish Free State Medical Council have, over those whose names are on the Irish Free State Register, the same disciplinary powers as are possessed by the General Council over those whose names are on the General Register. To possess the privileges of a qualified practitioner in the Irish Free State it is necessary to be registered in the Irish Free State Register.

The net result of the change in the law as regards the practitioner qualifying in the Irish Free State in the future is that: (1) if he intends to practise only in the Irish Free State he need only register in the Irish Free State Register; (2) if he intends to practise in Great Britain he will register in the General Register; and (3) if he is in doubt where he will practise he will register in both Registers. He will, as he registers in one Register, or in both Registers, put himself under the disciplinary control of the one Council or of both Councils. No practical inconvenience is caused, and practitioners qualified in the Irish Free State in future will not find themselves deprived of any former privileges or rights.

Dental Board of the United Kingdom

Anyone who is on the Medical Register is entitled to practise as a dentist, although he cannot register as such without a degree or licence in dentistry; but it is a distinct advantage to take a special dental qualification, otherwise few dental appointments at general or special hospitals or dispensaries are available, and, unless the practitioner is on the Dentists Register, no work can be undertaken under the National Health Insurance (Dental Benefit) Regulations.

Under the Dentists Act, 1921, the powers and duties of the General Medical Council under the Dentists Act, 1878, and under the Medical Act, 1886, which related to the keeping of the Dentists Register and the administration of the Dentists Acts were largely transferred to the then newly constituted Dental Board of the United Kingdom. The registration of dental students at the commencement of their dental studies, and the power to erase a name from the Dentists Register, remain with the Council, but the inquiry into disciplinary cases rests with the Board, upon whose findings the Council acts.

The Dental Board consists of a chairman and 12 members. The chairman is appointed by the Privy Council. Other members of the Board are appointed by the Minister of Health, the Department of Health for Scotland, the Governor of Northern Ireland, the General Medical Council (3), four members are elected as representatives by the dentists possessing degrees or Licentiate in Dentistry and practising in England and Wales, Scotland, and Ireland, and two by dentists registered under the Dentists Act, 1921.

REGISTRATION OF DENTAL STUDENTS

The General Medical Council's Regulations in regard to the registration of dental students have recently been revised. The new regulations came into force on Oct. 2nd, 1933, and provide that the registration of dental students shall be carried on at the General Medical Council Office in London, in the same manner as that of medical students, and be subject to the same regulations as regards age and preliminary examinations; but professional study may commence either at a recognised dental hospital or school, or by pupilage with a registered dental practitioner.

Candidates for a diploma in dental surgery should produce certificates of having been engaged for at least four years in professional studies, and of having received during 24 calendar months instruction in dental mechanics. It is recommended that instruction in dental mechanics be taken at a recognised dental hospital and school. If any part of such instruction be taken by the candidate as a pupil with a registered dental practitioner, the time required to be devoted to it shall be at least twice the time required for the corresponding instruction taken at a dental school. Two years' bona-fide apprenticeship with a registered dental practitioner, after registration as a dental student, may be counted as one of the four years of professional study. When a student can show evidence of regular pupilage for not less that two years in dental mechanics to a registered dentist, prior to the passing of the prescribed preliminary and scientific examinations, he may antedate his registration for a period not exceeding one year prior to the passing of these examinations.

Offices

The address of the Registrar, to whom further communications should be addressed, is as follows: The Registrar of the General Medical Council, 44, Hallam-street, Portland-place, London, W.1. The offices of the Dental Board are at the same address.

A memorandum on the procedure to be adopted by those who desire to enter the profession of medicine, with notes on costs and prospects, and a similar memorandum in regard to dentistry, may be obtained on payment of 1s. each.

MEDICAL EXAMINING BODIES AND SCHOOLS IN ENGLAND AND WALES *

UNIVERSITY OF OXFORD

THERE are two degrees in Medicine, *B.M.* and *D.M.*, two in Surgery, *B.Ch.* and *M.Ch.*, and a diploma in *Ophthalmology.* The examinations are open to men and women alike.

Only Graduates in Arts of the University are eligible for the Medical and Surgical degrees. The most convenient course for the B.A. degree for intending graduates in Medicine is to take Responsions, the Preliminary Science Examinations mentioned below, and the Final Honour School of Animal Physiology.

To obtain the degrees of B.M. and B.Ch. the following examinations must be passed: 1. Preliminary subjects: Physics and Chemistry, Zoology, and Botany. 2. Professional. (*a*) First Examination: Subjects—Organic Chemistry, unless the candidate has satisfied the examiners in Part I. Chemistry in the Honour School of Natural Science; Human Physiology, unless he has obtained a First or Second Class in Animal Physiology in the Honour School of Natural Science; Human Anatomy. (*b*) Second Examination: Subjects—Medicine, Surgery, Midwifery, Pathology, Forensic Medicine and Public Health, Materia Medica and Pharmacology. The First and Second Professional examinations are held in June and December. The First B.M. Examination may be passed at any time after the Preliminary Scientific examinations. Anatomy and Physiology must be passed at the same time—Organic Chemistry may be taken separately.

At any time after passing *First B.M. Examination*, the candidate can, on producing certain certificates, present himself for examination in the subjects of Pathology, Forensic Medicine and Public Health, Materia Medica and Pharmacology; but cannot, unless he is already a registered medical practitioner, enter for Examination in Medicine, Surgery, and Midwifery, until the eighteenth term from his matriculation, nor until a period of at least thirty-three months has elapsed from the date of passing the First B.M. Examination. He must pass in Medicine, Surgery, and Midwifery at one and the same time.

Before admission to the Examinations in Pathology and Bacteriology, and Materia Medica and Pharmacology, of the *Second B.M. Examination*, the student must produce certificates of having attended courses of instruction including practical work in Pathology, Bacteriology, Post-mortem Clerking, and Pharmacology, either in Oxford or in another recognised Medical School. Before admission to the remainder of the Second B.M. Examination, he must produce a number of other certificates, including evidence of having acted as Clinical Clerk and Dresser, each for six months in the Wards, of instruction in Midwifery and of attendance on Labours, of instruction in Infectious Diseases and in Ophthalmology, of proficiency in Vaccination and in the administration of Anæsthetics, and of three academic years of hospital practice.

The degree of Bachelor of Surgery (B.Ch.) is granted with that of B.M. after passing the above examinations.

The degree of Doctor of Medicine (D.M.) is granted to Bachelors of Medicine of the University who have entered upon their thirtieth term from Matriculation, and have submitted a dissertation which is approved by judges appointed for the purpose by the Board of the Faculty of Medicine. The degree of Master of Surgery (M.Ch.) is granted after examination to Bachelors of Surgery who have entered upon their twenty-first term, and who are members of the surgical staff of a recognised hospital, or have acted as dresser or house surgeon in such a hospital for a period of six months. The examination, which includes Surgery, Surgical Anatomy and Pathology and Surgical Operations, is held annually in June, after the Second B.M. Examination.

Travelling Fellowship, Scholarships, and Prizes.—A Radcliffe Travelling Fellowship is awarded annually after an examination held in February. It is tenable for two years and of the annual value of £300. The examination is in Physiology, Pathology, and Hygiene, and is partly "practical." Candidates must be graduates in Medicine of the University. The holder must travel abroad for the purpose of medical study. Application should be made to the Radcliffe Examiners, Department of Medicine, University Museum. A Schorstein Research Fellowship of the value of £200 a year, tenable for two years, is offered in alternate years. Candidates must be graduates of the University, under 35 years of age, and must hold a registrable medical qualification. Their research must be carried out in one of the Medical Departments at Oxford. A Christopher Welch Scholarship of usually £200, tenable for four years, is awarded annually after examination. Candidates must be men undergraduate members of the University, who have not exceeded the twelfth term from their matriculation, or been admitted to any degree in the University. They may offer any one of the subjects, Animal Physiology, Botany, Zoology. A George Herbert Hunt Travelling Scholarship of the value of about £100 is awarded every second year to enable a Bachelor of Medicine to undertake three months' study abroad. A Rolleston Memorial Prize is awarded once in two years to members of the Universities of Oxford and Cambridge of not more than ten years' standing for an original research in some Biological subject, including Physiology or Pathology. The Radcliffe Prize, founded by University College (1907), is of the value of £50 and is awarded biennially (alternating with the Rolleston Memorial Prize) for research in some branch of medical science. The Theodore Williams Scholarships are awarded annually in the subjects of Anatomy, Physiology, and Pathology; the two first are of the value of £50 a year for two years, the last of the value of £60 a year for two years. A Radcliffe Scholarship in Pharmacology, of the value of £50 for one year, is awarded annually by the Master and Fellows of University College. Scholarships at certain London hospital medical schools are awarded each year on the nomination of the Regius Professor of Medicine or of the Dean of the Medical School. The Scholarships and Exhibitions in Science which are offered by most Colleges are open to those who intend to pursue Medicine. The value of these scholarships varies, according to the candidate's need, between £30 and £100 a year; the exhibitions vary in value from £30 to £80 per annum. The number of scholarships and exhibitions in Science offered annually is about forty. There are also Medical Scholarships of the value of £100 a year at University College and at Pembroke College. The Welsh Memorial Prize for Anatomical drawing is awarded annually, and is of the value of about £4.

More detailed information may be obtained from the University Calendar; from the Examination Statutes, latest edition; from the Regius Professor of Medicine; from the Professors in the departments of medical science; and from the Dean of the Medical School, Department of Medicine, University Museum, Oxford.

Radcliffe Infirmary and County Hospital

There are 385 beds. Courses of instruction are given in connexion with the Oxford University Medical School. These include (1) a course in Practical Medicine by the Regius Professor of Medicine; (2) clinical lectures by the Litchfield Lecturers in Medicine and Surgery; (3) tutorial instruction and demonstrations in special Regional Anatomy (medical and surgical), methods of Medical and Surgical Diagnosis, and Surgical Manipulation; and (4) pathological demonstrations and instruction in post-mortem work are given by the Pathologist. Opportunities are offered to students who wish to act as surgical dressers and clerks. A post-graduate [illegible] is held in the hospital in the autumn of each year.

---

* For special diplomas see p. 454.

UNIVERSITY OF CAMBRIDGE

There are two degrees in Medicine, *M.B.* and *M.D.*, two in Surgery, *B.Chir.* and *M.Chir.*, and a Diploma in *Medical Radiology and Electrology*. Students of Girton or Newnham College are admitted to the examinations for these degrees and the diploma.

The student must enter a College, or become a Non-Collegiate student, and keep nine terms (three years) by residence. He must pass the Previous Examination of the University before he comes into residence or therefrom obtain exemption, particulars of which may be obtained from the Registrary. He may then devote himself to medical study in the University. Or he may, as nearly all students now do, proceed to take a degree in Arts by passing the Examinations for the Ordinary B.A. degree, or an Honours degree by passing one or more Tripos Examinations. The Natural Sciences Tripos is taken most frequently by medical students, as some of the subjects are practically the same as those for the M.B. course.

For the degree of Bachelor of Medicine (M.B.) five calendar years of medical study are required either in Cambridge or at one of the recognised Schools of Medicine. The first three years are spent in Cambridge till the student has passed the examination for Part I. of the Natural Sciences Tripos and the *First Examination* and other preliminaries to the *Final Examination*. Hospital practice may be attended at Addenbrooke's Hospital, Cambridge. The laboratories for Botany, Chemistry, Physics, Biology, Zoology, Human Anatomy, Physiology, Biochemistry, Pathology, Bacteriology, Pharmacology, and Psychology are well equipped. Addenbrooke's Hospital, the Infectious Diseases Hospital, the Cambridge Research Hospital, and the Field Laboratories are utilised for study and research.

The *First M.B. Examination* includes (1) General and Inorganic Chemistry, (2) Physics, (3) Elementary Biology, and (4) Inorganic Chemistry. These parts may be taken together or separately. After the First Examination, and tests in Pharmacology, Physiology, and Anatomy, comes the *Final Examination*, divided into two parts: (1) Principles and Practice of Surgery (including Special Pathology and Midwifery and Diseases Peculiar to Women); and (2) Principles and Practice of Physic (including Diseases of Children, Mental Diseases, Medical Jurisprudence), Pathology (including Hygiene and Preventive Medicine), and Pharmacology (including Therapeutics and Toxicology). The examinations are partly in writing, partly oral, and partly practical, in the hospital, in the dissecting room, and in the laboratories. An Act has then to be kept by the candidate reading an original dissertation composed by himself, and being examined orally, on some subject approved by the Regius Professor of Physic. Candidates who have passed both parts of the Final M.B. Examination are admitted to the registrable degree of Bachelor of Surgery (B.Chir.) without separate examination and without keeping an Act.

The degree of Doctor of Medicine (M.D.) may be taken by a graduate of the University of eight years' standing who has passed the Final M.B. Examination. An Act has to be kept, consisting of an original Thesis with viva-voce examination; and an examination, oral or written or both, on the field of Medicine within which the Thesis falls may be allowed or required.

Candidates for the Degree of Master of Surgery (M.Chir.) who are M.A.'s may be admitted to the examination after they have become legally qualified under the *Medical Acts* to practise surgery. Others may be admitted to the examination when two years at least have elapsed after they have completed all that is required of candidates for the Degree of B.Chir. Candidates are required to pass an examination in Principles and Practice of Surgery, Surgical Anatomy and Surgical Operations, and Pathology, and to write an extempore essay on a Surgical Subject. (The examination is held in February.)

A Diploma in Medical Radiology and Electrology is granted. Candidates must hold a recognised medical qualification.

Scholarships and Prizes.—Medical studies are endowed by the numerous Natural Science scholarships at the various colleges, information about which can be obtained from the respective Tutors. There are Natural Science scholarships at most of the Colleges and prizes in the ancillary medical subjects. Some of these are entrance scholarships; some may be gained by students already in residence, and where suitable candidates are not forthcoming among such students the emoluments may be allotted to members of other Colleges. Valuable scholarships instituted on behalf of Medicine are the Tancred Studentships in Physic, tenable at Gonville and Caius College. The successful candidates must enter at the college within a month or remove there if they are members of any other college. Students are required to take the degree of M.B. as soon as they are of sufficient standing but may hold a Studentship for a further three years. Thus a student elected previous to admission to college can draw the emolument, the annual value of which is about £100, for eight years. Full particulars can be obtained from Mr. E. T. Gurdon, 28, Lincoln's Inn-fields, London. Among other scholarships and prizes may be mentioned the Balfour Studentship, for research in Biology, of the value of £300 a year for three years, not restricted to members of the University; the Frank Smart Studentship and Prizes for Botany and Zoology; the Shuttleworth Studentship for Zoology or Physiology tenable at Gonville and Caius College; and the Marmaduke Shield Scholarship in Human Anatomy. The one University prize in Medicine, the Raymond Horton Smith Prize, is awarded to that candidate for the degree of M.D. who presents the best thesis for the degree during the academical year, provided that he has taken honours in a Tripos Examination. The E. G. Faernsides Research Scholarship and several very valuable studentships are also awarded.

An abstract of the Regulations and Schedules of the range of the examinations in Chemistry, Physics, Biology, Pharmacology, and General Pathology may be obtained upon application to the Registrary, The Registry, Cambridge.

Addenbrooke's Hospital

267 beds. Clinical lectures in medicine and surgery, in connexion with Cambridge University medical school, are given at this hospital during the academical year; and practical instruction in medicine and surgery is given in the wards and out-patients' rooms by the physicians and surgeons daily during the term time and vacations.

UNIVERSITY OF LONDON

The University of London was constituted in 1836, reconstituted under the Act of Parliament, 1898, as a teaching as well as an examining body, and again reconstituted under Act of Parliament, 1926. All the metropolitan medical schools are constituent colleges, while Clinical Units have been established at St. Bartholomew's, the London, St. Mary's, St. Thomas's, University College Hospital, and the Royal Free.

A revision of the medical curriculum is in prospect. The Senate of the University has invited representatives of the Universities of Oxford and Cambridge and of the English Royal Colleges to meet in conference representatives of the Medical Faculty of the University with a view to devise constructive measures in remedy of difficulties which have been widely known to exist in London or elsewhere.

Internal and External Students.—All the examinations of this University are open to men and women alike. Matriculated students of the University may be either internal or external. Internal students of the University are students who are registered as pursuing a prescribed course of study, or an approved course of research, in a school of the University, or under teachers of the University. Centres for eliminary and intermediate medical studies have een established by the University at University and ing's Colleges. External students in addition to atriculating must register as preparing for an amination leading to a Degree or Diploma within e purview of the Council for external students.

UNIVERSITY COLLEGE

University College is a University centre for the aching of medical sciences. The College Faculty Medical Sciences comprises the departments of hysics, chemistry, botany, and zoology (the Pre-minary Medical Sciences);. also the departments anatomy and embryology, and physiology, bio-hemistry, and pharmacology (the Intermediate edical Sciences). Post-graduate and research work undertaken in all departments. The completion of he building scheme by the erection of the section for natomy, histology, and embryology, together with rther extensions to the department of physiology, iochemistry and biophysics, and also pharmacology ew accommodation for the department of zoology hich the generosity of the Rockefeller Foundation nade possible, provides exceptional facilities for esearch and post-graduate study. The opportunities or investigation in human and comparative embryo-ogy and neurology, in histology, radiology, anthro-ology, biochemistry, and experimental physiology nd embryology may be mentioned. In the depart-nent of zoology and comparative anatomy, the study of genetics accompanies that of comparative physio-ogy and animal behaviour. Arrangements exist for the close correlation of the work of the Faculty with University College Hospital and Medical School. Women students are admitted.

Scholarships and Prizes.—The first four items on the present list provide a complete intermediate course at University College, and, in the case of (*a*), the later clinical stages at University College Hospital. The money value and subjects at examinations are as follows: (*a*) Bucknill Scholarship, 160 guineas; (*b*) and (*c*) two Entrance Exhibitions, 55 guineas each, Chemistry, Physics, Botany, Zoology, and an English essay; (*d*) Entrance Scholarship, £30 a year for three years; (*e*) Ferriere Scholarship, £25 for three years, tenable at University College Hospital Medical School, awarded to a student who has done his Anatomy and Physiology at University College and has completed the 2nd Medical Examination; (*f*) Cluff Memorial Prize, £15 biennially, Anatomy, Physiology, Pharmacology, and Chemistry; (*g*) Schafer Prize in Physiology, £18 triennially; (*h*) Sharpey Physiological Scholarship, £115, Biological Sciences; (*i*) Bayliss-Starling Scholarship, £120 a year, Physiology, Biochemistry; (*j*) Percy F. Macgregor Research Scholarship in Embryology, £50; (*k*) Morris Bursary for sons of deceased professional men, by nomination, tenable for two years, £20 a year; and (*l*) two Gold Medals awarded annually in Anatomy and Physiology. For information apply to the Secretary, University College, Gower-street, London, W.C.1.

KING'S COLLEGE

The Medical Faculty at this College of the University gives instruction in the subjects of Medical Science for all the usual Preliminary and Intermediate Examinations in Medicine and Surgery. Through the four associated hospitals, students of the College have clinical facility of over 1000 beds, but they may also proceed to any other teaching hospital in London for final studies for the degrees of the University.

The Medical Faculty of the College provides a general University education in touch with other faculties, classes of which medical students are permitted to attend. There are many College ocieties, clubs, and functions, in which students of all faculties have opportunity of meeting each other. The College has a large athletic ground at Mitcham, upon which is a new pavilion.

The First Year subjects are taught in the large Departments of the Faculty of Science and those for the Second and Third Years in the new Medical Department which was opened recently, consisting of the Hambleden Department of Anatomy and an extension to the department of physiology, at a cost of £70,000. These new buildings and others of recent years, provide the College with a completely new and modern Medical Department which embodies the newest ideas in laboratory construction and equipment.

Scholarships and Prizes.—Two Warneford Entrance Scholarships of £30 each for four years. Examination in April, subjects selected from Divinity, Classics, Science. One Sambrooke Scholarship of £30 for three years. Examination in April, subjects selected from Classics, Science. Worsley Scholarships: £100 in five annual instalments of £20. *At the end of the First Year* of study, one Warneford Scholarship of £30 for four years, subjects as for First M.B., the Rabbeth Scholarships (£30 and £15), the Carter Gold Medal and Prize in Botany, and the Hare Prize in Zoology are open for competition. *At the end of the Third Year*, the Hughes Prize in Anatomy, the Huxley Prize in Physiology, the Inchley Prize in Pharmacology, and the Jelf Medal are open for competition. The Layton and the Berridge Research Studentships (£150 and £100 per annum respectively), the Daniell Scholarship in Chemistry (£40), Warneford Prizes (£25 and £15), Leathes Prize, Barry Prize, &c., are also open to Students of this Faculty. The majority of the Scholarships and Prizes are open to Regular Students only. For information apply to the Dean of the Medical Faculty.

The Medical Faculty of the University

Medical students of the University of London who are pursuing their medical curriculum in the metropolis will proceed to one of the recognised medical schools connected with the University. The schools are described in detail in the next section. These hospitals are St. Bartholomew's Hospital, Charing Cross Hospital, St. George's Hospital, Guy's Hospital, King's College Hospital, the London Hospital, St. Mary's Hospital, the Middlesex Hospital, St. Thomas's Hospital, University College Hospital, Westminster Hospital, and the London (Royal Free Hospital) School of Medicine for Women. Students of St. George's, Charing Cross, and Westminster Hospitals take their preliminary medical studies at King's College. Students of the London Hospital usually attend East London College for the subjects of their first medical examination. Various schools and hospitals are also recognised as schools of the University in special departments, and students may pursue their studies at other approved universities and medical schools.

The Faculty of Medicine of the University grants the joint degrees of M.B., B.S. (*Bachelor of Medicine and Surgery*), the higher separate degrees of M.D. (*Doctor of Medicine*) and M.S. (*Master of Surgery*), and the degree of B.D.S. (*Bachelor of Dental Surgery*) and the degree of B.Pharm. (*Bachelor of Pharmacy*); the two higher degrees being open only to candidates holding the M.B., B.S. degrees of the University. The curriculum for the M.B., B.S. degrees is five and a half years from the time of matriculation, with certain exceptions which must be looked for in the official regulations of the University.

A. *Internal Students.*—For the Bachelor's degrees in Medicine and Surgery a student must normally, after registration as an internal student, have: (1) Attended prescribed courses of study for five and a half years in one or more schools of the University. (2) Passed the following examinations, under the conditions mentioned below: (*a*) the First Examination for Medical Degrees in Inorganic Chemistry, Physics, including Mechanics, and General Biology; (*b*) the Second Examination for Medical Degrees: Part I., Organic Chemistry; Part II., Anatomy, Physiology, and Pharmacology; (*c*) the Third Examination for Medical Degrees, or M.B., B.S. Examination in Medicine, Surgery, Obstetrics and Gynæcology, Pathology, Forensic Medicine, and Hygiene.

B. *External Students.*—For the Bachelor's degrees in Medicine and Surgery an external student must (1) have passed the Matriculation examination or have been exempted therefrom not less than five and a half years previously; (2) have passed subsequent examinations similar to those required of an internal student; and (3) have been engaged in professional studies during the five and a half years subsequently to Matriculation and four and a half years subsequently to passing the First Examination for Medical Degrees at one or more of the medical institutions or schools recognised by this University for the purpose, one year at least of the four and a half years to have been spent in one or more recognised institutions or schools in the United Kingdom.

The First Examination for Medical Degrees (Inorganic Chemistry, Physics, including Mechanics, and General Biology) will take place twice in each year commencing on the Monday following Dec. 5th and on the first Monday in July. It must be passed not less than nine months after matriculation.

The Second Examination for Medical Degrees (Part I.): Organic Chemistry.—This examination will take place twice in each year, commencing on the Thursday following the second Monday in March and on the Thursday following the first Monday in July. No candidate will be admitted to this examination until he has completed the First Examination.

The Second Examination for Medical Degrees (Part II.) takes place twice in every year, commencing on the Tuesday following the third Monday in March and on the Tuesday following the first Monday in July. No candidate will be admitted to the examination unless he has passed the First Examination for Medical Degrees at least 18 months previously, and has passed Part I. of the Second Examination for Medical Degrees

The Third or M.B., B.S. Examination.—The M.B., B.S. examination takes place twice in each year, commencing on the second Monday in November and on the first Monday in May. No candidate will be admitted to this examination unless he has completed the Second Examination for Medical Degrees, together with a course of study summarised below, nor within three years from the date of passing the Second Examination, Part II., in Anatomy and Physiology. The course of study comprises introductory courses in (1) Clinical Medicine; (2) Clinical Surgery; (3) Clinical Pathology; and the following: Experience as Clinical Clerk; course in Clinical Medicine; (*a*) Fevers, (*b*) Children's Diseases, (*c*) Venereal Diseases, (*d*) Mental Diseases (at a recognised Asylum), (*e*) Dermatology, (*f*) Vaccination, (*g*) Materia Medica and Pharmacy; Experience as a Surgical Dresser; course in Clinical Surgery; Ophthalmology; Oto-Rhino-Laryngology; (*a*) Operative Surgery, (*b*) Applied Anatomy, (*c*) Administration of Anæsthetics, (*d*) Dental Surgery, (*e*) Orthopædic Surgery, (*f*) Mechano-therapeutics; Obstetrics and Gynæcology; Lying-in Hospital; the conduct of at least 20 Labours; Ante-natal Clinic; Experience as a Clinical Clerk in Gynæcological Work; General Pathology, Morbid Anatomy, Bacteriology, and Chemical Pathology; Work in the Post-mortem Room; Clinical Laboratory; Forensic Medicine; Hygiene. He must have attended the Medical and Surgical Practice of a recognised hospital for two years, and have held the posts of clinical clerk and surgical dresser for periods of six months each. Candidates will be examined in Medicine, Pathology, Forensic Medicine and Hygiene, Surgery, Obstetrics, and Gynæcology. The subjects may be divided into two groups—namely: (1) Medicine, Pathology, Forensic Medicine, and Hygiene; and (2) Surgery, Obstetrics, and Gynæcology, and may be taken either separately or together.

Doctor of Medicine.—The examination for this degree takes place twice in each year, commencing on the second Monday in December and on the first Monday in July. Candidates may present themselves for examination in one of the following branches—namely: (1) Medicine; (2) Pathology; (3) Psychological Medicine; (4) Midwifery and Diseases of Women; (5) Hygiene; and (6) Tropical Medicine. Any candidate may transmit to the Registrar a thesis for approval and may be exempted from a part or from the whole of the written examination.

Master of Surgery.—The examination for the degree of Mastery of Surgery takes place twice in each year: (1) Surgery; (2) Dental Surgery; (3) Ophthalmology; (4) Laryngology, Otology, and Rhinology. A thesis may be submitted as for M.D.

Doctor of Philosophy.—A Degree of Ph.D. has been instituted in non-clinical subjects for Internal and External Students in the Faculty of Medicine. Candidates for this degree must hold, in a branch of study akin to that in which they propose to proceed to the Ph.D. Degree, the Degree of M.B., B.S., or B.D.S., or B. Pharm., or B.Sc.

Bachelor of Pharmacy.—This is a three years' course.

Full details of the prescribed curricula can be obtained free on application to the Academic Registrar, or for External Degrees from the External Registrar, University of London, South Kensington, S.W. 7.

MEDICAL SCHOOLS OF THE UNIVERSITY OF LONDON [1]

St. Bartholomew's Hospital and College

The hospital contains 762 beds, of which 692 are for patients in the hospital at Smithfield and 70 at the Alexandra Hospital, Swanley. Special departments have been organised for diseases of women and children, the eye, ear, larynx, and skin, as well as for orthopædic and dental surgery, and for electro-therapeutics and X ray work. Whole-time Clinical Units under professors of medicine and surgery have been established. A new surgical block of ten wards, with accommodation for 250 patients, and connected with a block of five new operation theatres is now in use. Clinical Units in medicine (*and surgery*) have been established under whole-time directors.

Ten house physicians and ten house surgeons are appointed annually, are provided with rooms and board, and receive £80 a year as salary. A resident midwifery assistant, an ophthalmic house surgeon, and a house surgeon for diseases of the throat, nose, and ear, and a house surgeon for orthopædic surgery are appointed every six months, and are provided with rooms and board and receive a salary of £80 a year. Three resident administrators of anæsthetics are appointed, the senior for one year at a salary of £150, and two juniors for six months with a salary at the rate of £80 per annum, with board and rooms. An extern midwifery assistant is appointed every three months, and receives a salary of £80 a year. The clinical clerks, the obstetric clerks, the clerks to the medical out-patients, the dressers to the surgical in-patients and to the out-patients, and the dressers in the special departments are chosen from the students.

There are quarters for the resident staff, casualty, medical, surgical, and special out-patient departments, casualty wards, dispensary, and clinical lecture theatre. There is a chemical laboratory attached to the College as well as a laboratory devoted to instruction in public health. A block is devoted to pathology, and contains the post-mortem room as well as extensive laboratories for bacteriology, clinical pathology, and pathological chemistry. *The Medical College Buildings* include three large lecture theatres, a large dissecting-room, laboratories for chemistry, biology, morbid anatomy and histology, and public health, as well as a spacious library (containing 14,500 volumes), a well-appointed museum of anatomy-physiology, comparative anatomy, materia medica botany, and pathological anatomy. The pathological museum is complete. A new block in Giltspur-street has recently been acquired and has been fitted up as lecture theatres and laboratories for physics, chemical physiology, experimental physiology, histology, and pharmacology.

---

[1] Of these schools that of the Royal Free Hospital is reserved for women; University College and King's College admit men and women, both of them limiting the number of women when clinical work is reached; the remainder admit men only. Further information from respective Deans of schools. Plans are being considered for starting a medical school for women at the West London Hospital. These are not yet ripe for publication.

The College has recently bought the site and buildings in Charterhouse-square (five minutes' walk from the Hospital), formerly occupied by The Merchant Taylor's School, and the whole of the preclinical departments will shortly be transferred there.

Special Classes for the Primary and Final F.R.C.S. Examinations are held twice yearly. *Instruction in Preliminary Science* is given to University of London students in chemistry, biology, and physics throughout the year. Facilities for research work are afforded in the Clinical Units and laboratories of pathological and other departments. *Vacation Anatomy Courses* are given in spring and summer.

Scholarships given in aid of Medical Study.—Six Entrance Scholarships and Exhibitions are awarded annually—viz.: (1) and (2) a Scholarship entitling the holder to free undergraduate medical education for a period of three years; and an Exhibition of £60 in any two of the following subjects: Human Anatomy and Embryology, Physiology, Pathology (including Bacteriology), Biochemistry; (3) a Scholarship of £100 in Chemistry, Physics, and Biology; (4) and (5) a Scholarship of £100 and the Jeaffreson Exhibition of £50 in Mathematics, Latin or Greek or French or German, a second language or Chemistry or Physics; (6) Helen Cave Memorial Scholarship, awarded after open competition to sons of Registered Medical Practitioners, value about £200, conditions obtainable from the Dean; (7) Shuter Scholarship of £50 in Anatomy and Physiology, which is awarded after competitive examination among Cambridge Graduates. The more important of the other Scholarships and prizes are as follows: Four Junior Scholarships—(8) No. 1, £30, Anatomy and Physiology; (9) No. 2, £20, Anatomy and Physiology; (10) No. 3, £25, Chemistry, Physics, and Biology; (11) No. 4, £15, Chemistry, Physics, and Biology; (12) Senior Scholarship, £50, Anatomy, Physiology, and Chemistry; (13) Kirkes Scholarship, £30 and medal, Clinical Medicine; (14) and (15) two Brackenbury Scholarships, £39 each, one in Medicine and one in Surgery; (16) Sir G. Burrows Prize, 10 guineas, Pathology; (17) Skynner Prize, 13 guineas, Regional and Morbid Anatomy; (18) Matthews Duncan Medal and Prize, £20, Midwifery and Gynæcology; (19) Luther Holden Research Scholarship in Surgery, awarded by election, £105; (20) Lawrence Research Scholarship and Gold Medal in Pathology, awarded by election, £115; and (21) Baly Scholarship in Clinical Medicine, £75, awarded by examination.

The recreation ground of 10 acres, for the use of the members of the Students' Union, is at Winchmore Hill. The Union's premises at the Hospital contain a large reading and smoking room, a committee and writing room, luncheon and dining hall, and a miniature rifle range. Athletic amenities are also available on the new site in Charterhouse-square.

Charing Cross Hospital

The Hospital, to which the School is attached, contains 300 beds. The School has just celebrated its centenary, accompanied by a public appeal for funds with the principal object of providing a students' hostel. There are special departments for mental diseases, midwifery, diseases of women, of children, of the skin, ear, throat, nose, and teeth, for orthopædic cases, X ray work, and for electrical treatment. In the medical school demonstratorships and assistant demonstratorships are open to students of the school. Eight house physicians, six house surgeons, two obstetric and gynæcological house surgeons, six house surgeons to the special departments, two resident anæsthetists, and four clinical pathologists are appointed annually. The following appointments are open to students after they have held resident appointments: resident medical officer, at a salary of £400 per annum; resident casualty officer, at £200 per annum; and five registrars to the medical, surgical, obstetrical, and ear, nose, and throat departments, at £150 per annum each.

Primary and Intermediate students receive their lectures and practical work at King's College, and final studies are taken in the school and hospital, where systematic lectures, demonstrations, and tutorial classes are arranged in general and special subjects.

In the Institute of Pathology, under a whole-time staff of scientific workers and in fully equipped laboratories, students receive their training in preventive medicine, pathology, and bacteriology. There are special facilities for research, and post-graduate teaching is available. The course in practical ophthalmology is given in the Royal Westminster Ophthalmic Hospital. Courses in general medicine, surgery, and pathology, with the requisite clinical work in the wards and out-patient departments, are provided for students reading for dental qualifications.

The pathological museum, containing over 4000 specimens and 3000 histological preparations, comprises (1) the section on general pathology, and (2) the Cuthbert Lockyer Collection of over 1150 gynæcological and obstetrical specimens. The library contains 3950 volumes including the latest editions of text-books.

Scholarships and Prizes are offered annually: (*a*) for students commencing medical studies—two scholarships, each of the value of £50; (*b*) for students commencing clinical studies—two "University" scholarships, each of the value of £120, in Pathology; one "University" scholarship value £120, and one "Open" scholarship, value £75, in Anatomy and Physiology. There are a number of Exhibitions, and the following prizes are offered: (1) "Llewellyn" Prize, £25, for highest distinction throughout the final course of studies; (2) "William Travers" Prize, £15; (3) "J. H. Morgan" Prize, £10; other prizes in money are the "Pereira," "T. H. Green," and "Stedman," while prizes in money are offered for proficiency in clinical medicine and surgery, and all the different subjects of the curriculum.

The Students' club, with smoking and luncheon rooms on the school premises, cloak room, telephone, &c., provides for the social comfort and convenience of the students. The club is controlled by a committee of students, and includes the Medical Society and the Dramatic Society. The *Gazette* is published quarterly. The sports ground, of 8 acres, at Colindale affords facilities for Rugby and Association football, cricket, hockey, and tennis (hard and lawn courts). In addition there are sections of the club devoted to athletics, boxing, swimming, golf, and badminton.

St. George's Hospital

This hospital has a service of 436 beds, of which 180 are allotted to surgical, 150 to medical cases, and 100 are at the Convalescent Hospital at Wimbledon. There are all the usual special clinical departments. One ward is set apart for diseases peculiar to women, and there is a maternity ward of 11 beds. One ward is set apart for the medical diseases of children. There are two ophthalmic wards.

Eight house physicians, eight house surgeons, and eight casualty officers are appointed annually. Special attention is directed to the following paid appointments, among others, which are open to students after they have held house office: resident assistant physician at £250 per annum; medical officer to the Atkinson-Morley Convalescent Hospital at £300 per annum; medical registrarship at £200 per annum; two surgical chief assistants at £225 per annum; assistant curatorship of the museum at £100; obstetric assistantship (resident) at £100; the post of resident anæsthetist at £100.

The teaching and laboratories are devoted to clinical subjects, and arrangements have been made with the authorities of King's College and University College for students who enter the first, second, or third year of the curriculum as students of St. George's to carry out the necessary courses of instruction at one of those Colleges. Students then complete their course, without payment of any entrance fee, in a school entirely devoted to clinical work.

Scholarships and Prizes.—At this school 11 entrance scholarships and exhibitions are given, the money value and the subjects of examination being as follows: (*a*) and (*b*) two William Brown Exhibitions, £120 and £80 respectively; (*c*) and (*d*) two Anne Selina Fernee Scholarships, £80 each; (*e*) Devitt-Pendlebury Scholarship, £40 (approx.); (*f*) and (*g*) two Anne Selina Fernee Exhibitions, £60 each, Anatomy and Physiology, except in the case of (c) and (*f*) subject of examination for which is General Pathology.

In addition to the above, Exhibitions each of the value of £40 and up to four in number may be awarded to candidates of approved merit in the Entrance Scholarships Examination. The others are as follows: (*h*) Allingham Scholarship in Surgery for Students qualified not more than two years, £87; (*i*) and (*j*) two Brackenbury Prizes, one in Medicine and one in Surgery, £33 each, open to students of not more than five years' standing; (*k*) H. C. Johnson Memorial Prize, £20, Practical Anatomy; (*l*) Pollock Prize, £24, Physiology, Physiological Chemistry, and Histology; (*m*) Clarke Prize, £5; (*n*) Thompson Medal, £9, Clinical Reports; (*o*) Brodie Prize, £8, Clinical Reports; (*p*) Webb Prize, open to perpetual pupils, £34, Bacteriology; (*q*) Sir Francis Laking Memorial Prize, £45, open to students having registrable qualifications.

The Library is fully stocked with the latest and best text-books. The Pathological Museum has recently undergone complete revision. In addition to its well-known specimens of great historical interest, it contains a complete range of pathological conditions, set out in such a way that the student can easily obtain the fullest information relating to any disease.

The St. George's Hospital Club, with smoking- and luncheon-rooms on the hospital premises and an athletic ground at Wimbledon, is an amalgamation of the Hunterian Society, the *Gazette*, and the Rugby football, cricket, lawn tennis, boxing, rifle, and golf clubs. Students have the advantage of a library of medical and scientific books which is kept up to date.

Guy's Hospital

The Medical School, which has been entirely rebuilt within recent years, provides ample accommodation with modern equipment for all the non-clinical subjects of the medical curriculum. The School is a constituent part of the University of London and offers a complete medical education of University standard throughout. The Hospital contains 646 beds. On commencing the clinical period, students are placed for three months under the charge of an experienced clinical tutor while they are given a preliminary course of instruction in methods of clinical examination. Thereafter they hold a series of appointments, each of three months' duration, in surgical, medical, and obstetrical and gynæcological wards.

The following special departments are attached to the hospital: Departments of ophthalmology, laryngology, gynæcology, diseases of children, diseases of the nervous system, psychological medicine, dermatology, otology, actino-therapeutics, anæsthetics, dentistry, orthopædics, vaccine, tuberculosis, genito-urinary, venereal diseases, and the Salomon's Welfare Centre (for maternity and children). There is a Venereal Clinic in accordance with the scheme of the Local Government Board and the London County Council.

House physicians, house surgeons, out-patient officers, assistant house surgeons, obstetric residents, house surgeons in the departments of ophthalmology, laryngology, and genito-urinary diseases, house physicians in the departments for neurology and dermatology and for diseases of children, and clinical assistants are appointed from among recently qualified students according to merit.

Scholarships.—Six Entrance Scholarships are awarded annually as follows: (*a*) one War Memorial Scholarship, of the value of £200, to be awarded alternately in Arts and Science (next award, April, 1936, in Arts); (*b*) one Open Arts Scholarship of £100 for students under 19 years of age, awarded annually in April; candidates are required to take English and any two of the following subjects: Latin, Greek, French, German, and Mathematics; (*c*) one Open Junior Science Scholarship for students under 20 years, £100; subjects any three of the following: Inorganic Chemistry, Physics, Biology, and Mathematics; (*d*) a confined Junior Science Scholarship of the value of £100 is offered for competition, annually April, to candidates who have attended the Preliminary Science Classes at this School; (*e*) University Entrance Scholarships. These are (1) a War Memorial Scholarship entitling the holder to free medical education for three years, awarded annually in June or July; (2) an open exhibition of the value of £60, awarded annually in June or July, for students who have completed their examinations in Anatomy and Physiology in a British School or University outside the London Metropolitan area; subjects, any two of the following: Human Anatomy and Embryology, Physiology, Pathology including Bacteriology, Biochemistry. The examination is held in common with the Medical School at St. Thomas's Hospital and the Medical College of St. Bartholomew's Hospital

The Wills Library contains 10,000 volumes of standard text-books and books of reference, the Museum contains upwards of 5000 specimens of pathological anatomy, supplemented by more than 2000 drawings.

Prizes.—The following prizes are awarded annually: (*a*) Treasurer's Medal and Prize for Clinical Medicine; (*b*) Treasurer's Medal and Prize for Clinical Surgery; (*c*) Golding-Bird Gold Medal and Scholarship (£20) for Obstetrics and Gynæcology; (*d*) Golding-Bird Gold Medal and Scholarship (£20) for Bacteriology; (*e*) Charles Oldham Prize in Ophthalmology (£30); (*f*) Beaney Prize for Pathology (£34); (*g*) Leonard Lubbock Prize for Clinical Pathology; (*h*) Wooldridge Memorial Prize for Physiology (£10); (*i*) Sands-Cox Scholarship in Physiology (£45)—awarded triennially; (*j*) Prizes in Anatomy and Physiology for General Proficiency of the value of £20, £15, and £10 respectively; (*k*) Michael Harris Prize for Dissections (£5).

Studentships.—The following Studentships are open to graduates from this School: (1) Gull Studentship in Pathology (approx. £250 per annum); (2) Arthur Durham Travelling Studentship (£100)—awarded triennially; (3) Beaney Studentship in Materia Medica (£60 per annum); (4) Anderson Demonstratorship in Clinical Chemistry (£175 per annum); (5) Griffiths Demonstratorship and Research Studentship in Pathology (£320 per annum); (6) Adrian Stokes Fellowship in Pathology and Bacteriology (£300)—awarded biennially.

Within the grounds of the hospital are situated the residential college, with accommodation for 35 students, the students' club, with reading, smoking, luncheon, and dining-rooms, a squash court, a fives court, and swimming bath. The athletic ground and club house is situated at Honor Oak Park, and can be reached in 15 minutes from the hospital.

King's College Hospital

The New Medical School at Denmark-hill, opened in July, 1933, contains the Museum, Research Laboratory, Research Rooms, Common Rooms, Lecture Rooms, Refectory, and two Squash Rackets Courts.

Provision is made for all the subjects of the medical curriculum. The Hospital was opened in 1913, and is one of the most modern and best equipped in England. In the education at the hospital a special feature has always been the individual attention given to each student. The studies are co-ordinated under the direction of senior members of the honorary staff, assisted by medical, surgical, obstetric, and pathological tutors. Ten women medical students are admitted annually.

The numerous appointments open to students are those of clinical assistant to the general and special departments; medical, surgical, obstetric, and pathological tutorships; resident casualty officers, house physicians, and house surgeons; resident anæsthetist; resident radiologist; bacteriologist; clinical pathologist; pathological, medical, surgical, obstetrical and other registrarships. Thirty-one resident medical and surgical officers are appointed each year.

Post-graduate Courses.—Two advanced medicine courses are held annually, and are suitable for preparation for M.D. and M.R.C.P. Examinations.

Scholarships.—Those in connexion with King's College have already been enumerated. Scholarships of the total value of £1530 are awarded annually. These include: (*a*) Medical Entrance Scholarships—Science, £75; Anatomy and Physiology, £75; Pathology, £75; (*b*) two Burney Yeo Entrance Scholarships, £105 each, open to students of Oxford and Cambridge on the recommendation of the Regius Professsors; (*c*) two Raymond Gooch Scholarships, £105 each, open to students of British Universities on certain conditions; (*d*) Epsom College Scholarship, value £100, offered annually to a student of Epsom College who has taken the first part of the courses for Medical Degrees at the Universities of Oxford, Cambridge, or London; (*e*) two Seaman Scholarships, each £50 a year for a period not exceeding five years, restricted to the sons of clergymen of the Church of England; (*f*) Senior Scholarship (Clinical Studies), £40. The holders of the Warneford and Sambrooke Scholarships take the subjects of the preliminary and intermediate examinations at King's College, and the final subjects at King's College Hospital.

Prizes.—Tanner Prize, £10, Obstetrics and Diseases of Women; Todd Prizes, first £8 and medal, second £4, for Clinical Medicine; Burridge Prize, £4 4*s.*, Forensic Medicine; Jocelyn Almond Prize, £5 5*s.*, Diseases of Children; Wallis Prize, £10, Dentistry; The Ferrier Prize in Neurology, Bronze Medal and £20; The Legg Prizes in Surgery and Surgical Pathology, Ware Prize for General Pathology, Cheyne Prize for Surgery. Special Prizes for Diseases of Children, Orthopædic and Urology. Thirteen Class Prizes of £3.

Clubs, Hostel, Athletic Ground.—The King's College Hospital Clubs and Societies Union consists of the Listerian and Musical Societies, the Students' Common Rooms, and the various athletic and sports clubs. The athletic ground, over six acres in extent, is on Dog Kennel Hill, about ten minutes' walk from the hospital. There are also tennis courts in the grounds of the hospital and of "The Platanes"—a hall of residence for students. The Library contains 7000 bound volumes in addition to the medical and scientific periodicals. There are good facilities for quiet reading and books are lent for use at home.

London Hospital

The hospital, with its Medical College and Dental School, contains 847 beds. Its neighbourhood to the extensive docks, factories, and workshops of the east of London is unrivalled, and presents an immense field for clinical instruction. There are special departments for the treatment of diseases of children, the eye, ear, nose and throat, skin and teeth. In addition there are departments devoted to gynæcology and obstetrics, orthopædics, cardiology, neuro-surgery, radiology, electro- and physico-therapeutic light therapy, radium, and vaccine therapy.

A Clinical Unit in medicine, under the charge of a whole-time director, provides for the more elaborate methods of diagnosis and treatment, and takes a leading part in the initiation and coördination of medical research. The director has an assistant director, two assistants, and two house physicians.

To each medical and surgical firm throughout the hospital there is attached a first assistant, who is responsible for instructing the clerks or dressers of the firm in elementary medicine and surgery, and who assists the honorary members of the firm in the preparation of their demonstrations. In the department of obstetrics and gynæcology there is a first assistant and two resident accoucheurs. In the department for children's diseases there is a first assistant, a house physician, and two clinical assistants. Special courses of lectures and demonstrations are arranged in medicine and surgery and their ancillary subjects. Opportunities for research are provided under the supervision of the staff.

Many appointments are open to students before and after qualification, and holders of resident appointments have free board. Special classes are held for the examinations of the University of London, for the Fellowship of the Royal College of Surgeons, for the Membership of the Royal College of Physicians, and for other higher examinations. Special entries for medical and surgical practice can be made.

The salaried appointments open to past students of the hospital are those of assistants to the medical unit; first assistants to the medical and surgical firms; assistants to the departments of obstetrics and gynæcology; clinical assistants in the medical, surgical, ophthalmic, aural, light and skin, orthopædic, and electrical departments, and in the institute of pathology and clinical laboratory. There are appointed annually 4 resident accoucheurs, 16 resident house physicians, and 19 resident house surgeons, 14 resident receiving-room officers, 8 resident emergency officers, 8 clinical assistants to the medical out-patient department, and 16 clinical assistants to the surgical out-patient department, also paid and unpaid clinical assistants in the various special departments.

Scholarships and Prizes.—Entrance Scholarships: Price Scholarship £100, and one Scholarship of £50, subjects of First Medical Examination at the University of London; Epsom College Scholarship, free education, subjects of First Medical Examination as above; Price Scholarship, open to students of Oxford and Cambridge Universities, £100, Human Anatomy and Physiology; two Open Scholarships, each of the value of £100, subjects, Human Morphology and Embryology, Physiology and Pharmacology, Biochemistry, Pathology, Bacteriology, and Morbid Anatomy. Prizes: Buxton Prize, £40, subject of Anatomy and Physiology; Prize in Clinical Obstetrics and Gynæcology, £20; Sutton Prize, £20, Pathology; Duckworth Nelson Prize, biennial, £10, Practical Medicine and Surgery; Letheby Prizes (2), £25, Chemistry and Chemical Pathology; four Dressers' Prizes, amounting to £20, zeal, efficiency, and knowledge of Elementary Clinical Surgery; Hutchinson Prize, triennial, £60. Clinical Surgery; Treves Prize, £20, Clinical Surgery; two Practical Anatomy Prizes, £6 and £4 respectively; Andrew Clark Prize, £14, Clinical Medicine and Pathology; T. A. M. Ross (Prox. Acc.) Prize, £10 10*s.*, Clinical Medicine and Pathology; James Anderson Prizes (4), £20, Elementary Clinical Medicine; Arnold Thompson Prize, £15, Diseases of Children; and Liddle Prize, triennial, £120.

Medical Research Funds.—Funds to the value of over £113,000 permit of financial assistance being given to students and graduates engaged in Medical Research.

A laboratory for the manufacture of certain preparations of Radium has recently been endowed.

A new Residential Hostel has been opened and provides accommodation for 50 students. The hostel includes a library, writing, common and dining room, and 2 squash racket courts. There is also a hostel for resident medical officers. The Union Athletic Ground, 13 acres, is within easy reach of the hospital.

St. Mary's Hospital

The Hospital and Medical School have on one side a poor district of 500,000 persons, one-tenth of whom, on an average, pass through the hospital annually. On the other side are the residential districts of Kensington and Bayswater, making it possible for the student to live in touch with his work.

The hospital contains 370 beds, and recent structural additions have added two new operating theatres. By a scheme of affiliation, for teaching purposes, of certain neighbouring hospitals the teaching facilities extend over 1000 beds. The medical school provides complete courses of instruction, and students can join at once on passing a preliminary examination in arts. Terms begin in October, January, and April.

Clinical Units in medicine and surgery were established in 1920. Under this system professors of medicine and surgery, with competent assistants, give their whole time to teaching and research. The system also provides additional salaried posts which are open to students after qualification.

The Hospital has lying-in beds to which considerable additions have been made during 1933, and in addition to the instruction thus obtained each student attends a short course at Queen Charlotte's Hospital, as part of his training in Midwifery, without additional fee.

Students specially interested in Pathology and Bacteriology have singular advantages at St. Mary's. The institute comprises seven special departments, the whole being under the personal direction of Sir Almroth Wright. Research Scholarships of £200 each are awarded annually to students working in the departments, and research beds have been instituted. Clerkships in pathology, bacteriology, and chemical pathology, lasting for a period of three months, are open to students of the fifth year and enable them to carry out the pathological and bacteriological investigations of the wards, and learn the necessary technique under supervision. Seventy-two of these posts are available annually. Numerous appointments are open to newly qualified members of the medical school, including seventeen salaried posts with salaries varying up to £750 per annum. A special post-graduate course is held during the first week-end in October, and is open to all general practitioners and other qualified men without fee.

Entrance Scholarships.—From three to five Entrance Scholarships, each representing free tuition, are awarded annually by nomination.

The medical school and Institute of Pathology have been rebuilt on a site adjoining the Hospital, and the buildings are now in use. The new school provides for the teaching of the entire curriculum. A library and speech hall occupies a prominent position upon the ground floor, and a students' restaurant opens on to a courtyard, where are a garage for 50 cars and a swimming bath. A squash rackets court and gymnasium with a boxing-ring open out of the students' common room.

The athletic ground (10 acres) is situated at Wembley and can be reached in 20 minutes by a constant service of trains.

Middlesex Hospital

The hospital and cancer wing contain over 534 beds, with special wards for cancer, maternity, gynæcological, otological, neurological, dermatological, and ophthalmological cases, and for diseases of children. Other special departments include those for diseases of the eye, ear, nose and throat, and skin; nervous diseases, orthopædic cases, diseases of the rectum, and venereal diseases. There is also an electrotherapeutic department and a department of radium therapy and research. The cancer wing, containing 90 beds and special investigation laboratories, offers unrivalled opportunities for the study of cancer, both in its clinical and pathological aspects. In the electrotherapeutic department, students obtain instruction in the treatment of lupus and cancer by the X ray method of treatment.

The following appointments are made at intervals annually: eight house physicians, eight house surgeons, two obstetric and gynæcological house surgeons, two casualty medical officers, two casualty surgical officers, one senior resident anæsthetist, two junior resident anæsthetists, four resident officers to the special departments, and two dental house surgeons. Nine registrars are appointed annually. Non-resident qualified clinical assistants are appointed to assist in the various out-patient departments. Clinical clerks and surgical dressers are also appointed in every department.

The medical school, which includes the Bland-Sutton Institute of Pathology, the Courtauld Institute of Biochemistry, the Barnato-Joel Laboratories, and the Ferens Institute of Otology, is fully equipped for the theoretical and practical teaching of all the subjects of the medical curriculum, and the University diplomas in radiology. Ample laboratory and classroom accommodation is provided. The teaching staff includes 6 professors, 2 university readers, 31 recognised teachers, 10 demonstrators, 4 tutors. The Bland-Sutton Institute of Pathology and the Courtauld Institute of Biochemistry are completely equipped for routine hospital investigations, teaching, and research work, and contain large pathological, bacteriological, and clinical laboratories, also smaller laboratories for individual research work. A well-equipped anatomical and pathological museum and reference library offer every facility.

Other features of interest are: the course in medical radiology and electrology, under the direction of the "Joel" Professor of Physics and Dr. J. H. Douglas Webster. Primary F.R.C.S. courses are held twice yearly.

Scholarships and Prizes.—Two Entrance Scholarships, value £100 each, and two University Scholarships, value £90 and £60, are awarded annually in September. The successful candidates are required to become general students of the school. A Freer Lucas Scholarship is awarded annually on the nomination of the Headmaster of Epsom College. There are also two Broderip Scholarships, value £60 and £40 respectively; the Lyell Gold Medal and Scholarship, value £55 5s.; the John Murray Medal and Scholarship, value £25 (awarded every third year); the Freeman Scholarship, value £30; the Hetley Clinical Prize, value £25; the Leopold Hudson Prize, value 11 guineas; and the Second Year's Exhibition, value 10 guineas. There are numerous class prizes.

The Students' Amalgamated Clubs include the following: Medical Society, Common Room Society, Musical Society, cricket, football, rowing, chess, lawn tennis, hockey, sailing, golf, and fencing. There are a restaurant and a gymnasium in the school buildings, and athletic grounds at N. Wembley. Squash rackets are also available.

St. Thomas's Hospital

This hospital consists of eight linked-up pavilions, the medical school building being separated from the hospital by a quadrangle; the school buildings comprise the department of anatomy with its lecture theatre, museums, and research laboratory, the Sherrington School of Physiology, and a newly rebuilt department of chemistry with physical and biological laboratories. The hospital contains 644 beds and, in addition, has 30 beds at the Pyrford Orthopædic Hospital and 22 beds at the St. Thomas's Babies Hostel; there are teaching facilities for a further 150 beds, while students profit by liaison with Lambeth Hospital, where demonstrations are arranged at regular intervals. There is a Clinical Unit in medicine under a whole-time director, with laboratories and reading-room in connexion.

A complete curriculum is provided for students, the hospital having departments for the treatment of all the specialties. Particular attention is given to antenatal instruction and the teaching of diseases of children. A tuberculosis department in the hospital forms part of the Lambeth anti-tuberculosis scheme. The V.D. department is part of the L.C.C. scheme. In each department much clinical material is available. Instruction in anæsthetics takes place during appointment as dresser. Private coaching facilities are available and classes for the Primary F.R.C.S. Eng. are held. Revision classes have also been instituted in anatomy and physiology in accordance with the medical curriculums of Oxford and Cambridge. The obstetric training of students is now supplemented by an arrangement with St. James Hospital, Balham, whereby throughout the year two students at a time are in residence and take part in the maternity work. A special maternity ward of the hospital gives the student scope for elementary training before he undertakes cases in the district. In addition to the usual routine as clerk and dresser, every student works for a period of three months at the Medical Unit of the hospital. The post-mortem room, rebuilt in 1932, has a large amphitheatre adapted for teaching purposes and for the intimate study of morbid pathology.

The following appointments are open to students: 25 clinical assistantships to the various special departments are appointed every three months. Eight resident casualty officers and anæsthetists, seven house physicians, and nine house surgeons are appointed every six months. Nine chief assistants unpaid are appointed to the special departments, while there are nine non-resident registrars, medical, surgical, obstetric, and ophthalmic. A resident anæsthetist, a resident assistant physician, and a resident assistant surgeon, appointed annually, receive a salary. The assistants in the medical and surgical units hold appointments with a minimum tenure of four years, and there are three assistants in the department of pathology holding annual appointments. These officers are salaried.

A resident assistant physician and a resident assistant surgeon, salary £225 each per annum, and a resident anæsthetist, salary £200 per annum, are appointed annually. Three medical and four surgical registrars at a salary of £250 rising to £300 hold their appointments on a tenure renewable to a maximum of four years. A pathological registrar to the department of obstetrics and gynæcology (at an annual salary of £250), an ophthalmic registrar (at an annual salary of £200), and an orthopædic registrar (unpaid) are appointed yearly. Eight resident casualty officers and anæsthetists are appointed every six months. Seven house physicians (including two obstetric house physicians and one house physician to the department of diseases of children), nine house surgeons (including two ophthalmic house surgeons, one orthopædic house surgeon, and two house surgeons to the ear, nose, and throat department) are appointed every six months. Clinical assistants in the special departments are appointed every three months, and hold office for six months if recommended for re-election. There are three assistants in the department of pathology; the senior receives £600 a year, and the two juniors £450 each.

Scholarships and Prizes.—At this school there are the following Entrance Scholarships—namely, one in Arts, equivalent to the tuition fees for the first two years of study; three in Natural Science, of the value of £150, £100, and £60 respectively; and the University Scholarship of £100 in any two of the following—Anatomy, Physiology, Pathology, Chemistry; also the "Hector Mackenzie" University Exhibition of the value of £60. The value of all entrance scholarships must be taken out in tuition fees. The money value and subjects of examination of the remainder are as follows: (*a*) William Tite Scholarship for second-year students, £25; (*b*) and (*c*) Musgrove Scholarship or (alternately) Peacock Scholarship each for third-year students and tenable for two years, £35 each; (*d*) Mead Medal, Medicine, Pathology, and Hygiene; (*e*) Wainwright Prize, Medicine; (*f*) Toller Prize, Medicine; (*g*) Cheselden Medal, Surgery and Anatomy; (*h*) Clutton Memorial Medal in Clinical Surgery, biennial; (*i*) Beaney Scholarship, £50, biennially, Surgery and Surgical Pathology; (*j*) Solly Medal and Prize, biennial, Reports of Cases; (*k*) Sutton Sams Prize, biennial, Report of Cases; (*l*) Bristowe Medal, Pathology and Morbid Anatomy; (*m*) Hadden Prize, Pathology and Morbid Anatomy; (*n*) Grainger Testimonial Prize, £31 10*s*., Anatomy and Physiology; (*o*) Louis Jenner Research Scholarship, tenable for two years, £60 annually, Pathology; Perkins Research Fellowship, £40–£100; Myers Prize in Psychological Medicine, £10 10*s*.

In the school buildings are a reading room and library, containing approximately 8000 volumes. There is here a selection of new editions of current text-books, and periodical literature suitable to the needs alike of students and research workers. The Shattock museum, which forms part of the buildings, contains 5000 preparations, illustrating all morbid lesions of importance, an illustrative type series, and many specimens of historical interest. In the west wing of the school are the pathological institute and photographic department.

Opposite the hospital is St. Thomas's House, the premises of the amalgamated clubs, providing all the usual amenities and having squash courts, a miniature rifle range, and ample garage accommodation. There is a hard tennis court in the quadrangle. A hostel in the same buildings will receive 50 resident students. Field games are provided for and there is a sports ground at Chiswick.

University College Hospital

The final subjects in the curriculum are taught at the medical school of the hospital, which has 540 beds, including 85 in the new obstetric hospital. Clinical Units in medicine, surgery, and obstetrics and gynæcology are now in operation. The whole-time directors of the Units are concerned with the organisation of the teaching generally, but the honorary staff are responsible for the largest share of the teaching in the wards and out-patient department of the hospital. The department of otology, rhinology, and laryngology (the Royal Ear Hospital) has been provided with a separate building in Huntley-street, adjacent to the obstetric hospital. It contains 41 beds, including eight private wards for patients of limited means. In the dental school in Great Portland-street there is afforded the opportunity for attending lectures and practical instruction in diseases of the mouth and teeth.

The hospital is equipped with all modern appliances for investigation. The new buildings of the obstetric hospital of 85 beds (rendered possible by the Rockefeller Benefaction), the new residents' house (with accommodation for 30 residents and students), the extension to the nurses' home, and new research laboratories for the medical school are now finished and in full occupation. Twelve women students are admitted annually.

Original research in all subjects can be pursued in the laboratories of the school under the professor of pathology, and students can receive grants under certain conditions from the Charles Graham Medical Research Fund.

Clerkships and dresserships to the physicians, surgeons, anæsthetist, and pathologist are allotted amongst the students of the hospital. Maternity students are appointed each month and reside in the Students' House connected with the medical school and hospital. Sixteen house physicians, ten house surgeons, ten obstetric assistants, four house surgeons to the Royal Ear Hospital are selected annually by examination from among the senior students who have a medical qualification. All house officers reside free in the hospital. In addition to these posts there are certain special appointments which are vacant from time to time and are filled by senior students of the hospital: resident medical officer, surgical registrar, medical registrar, obstetric registrar, Harker-Smith cancer registrar, ophthalmic registrar, registrar to the Royal Ear Hospital, radiological registrar, casualty medical officer and a casualty surgical officer, first assistant in the children's department; assistants in ear, nose and throat, ophthalmic, skin, and venereal diseases departments and in the department of psychological medicine, and house anæsthetist.

Assistants to Medical, Surgical, and Obstetric Units. These salaried appointments are for senior students who may desire to remain at Hospital after holding the ordinary resident appointments continuing clinical work or pursuing laboratory or other research. The salaries range from £250 up to £900 a year, resident quarters being provided only for the chief assistant to the Obstetric Unit. The total number of such assistantships varies from time to time, being generally about 12, and an aggregate sum of about £5000 annually is available for their salaries.

Scholarships and Prizes (those in connexion with University College have already been enumerated).—At this School the first two Scholarships (*a*) and (*b*) entitle the holder to a complete course at University College and University College Hospital Medical School; the second two (*c*) and (*d*) entitle to a final course at the Medical School. The money value and subjects of examination are as follows: (*a*) Entrance Scholarship, Bucknill, 60 guineas, Chemistry, Physics, Botany, and Zoology; (*b*) Epsom Free Medical Scholarship, subjects of Preliminary Scientific Examination and Nomination by Epsom College; (*c*) and (*d*) two Goldsmid Entrance Scholarships entitling the holder to the Final Course of Medical Study, two of the following subjects: Anatomy, Physiology, General Pathology, Biochemistry; (*e*) Goldsmid Entrance Exhibition, entitling the holder to a reduction by £80 in the fees due for the full course of Final Medical Studies, two of the following subjects: Anatomy, Physiology, General Pathology, Biochemistry; (*f*) Filliter Entrance Scholarship, entitling the holder to a reduction by £52 10*s.* in the fees due for the full course of Final Medical Studies. Students need take Pathology alone if they desire to enter for the Filliter Entrance Scholarship only; (*g*) Ferriere Scholarship, value £25; (*h*) Graham Scholarship in Pathology, £300 per annum for two years, awarded by the Senate of the University of London; (*i*) Atkinson Morley Scholarship, tenable for three years, £45 per annum, Surgery; (*j*) Atchison Scholarship, tenable for two years, £55 per annum, General Proficiency in Medical Studies; (*k*) Magrath Clinical Scholarship, about £160, Clinical Cases; (*l*) Percival Alleyn Scholarship, about £110, Surgery; (*m*) Filliter Exhibition, £30, Pathology; (*n*) Erichsen Prize, £21, Practical Surgery; (*o*) two Senior and two Junior Fellowes Clinical Medals for Clinical Medicine; (*p*) two Liston Gold Medals for Clinical Surgery; (*q*) Alexander Bruce Gold Medal for Pathology and Surgery; (*r*) Tuke Silver and Bronze Medals for Pathology; (*s*) Radcliffe Crocker Travelling Scholarship for Dermatology; and (*t*) Leslie Pearce Gould Travelling Scholarship for Surgery. A limited number of Bursaries are available from the Atchison Fund, awarded at the discretion of the Dean, to enable students whose means do not allow to take Resident Posts.

The Museum of Pathological Anatomy is open for study daily. The Anatomical Museum of the University of London, University College, is open to all students of University College Hospital and medical school on the recommendation of the school committee. The library, open daily to every student of the School, contains about 30,000 medical works, including all the current text-books and works of reference.

The Medical Society exists for the dual purpose (1) of promoting the study of medical and surgical science, and (2) of promoting social intercourse among its members. All male students of the medical school are required to become members, and meetings are held once a fortnight for appropriate discussion connected with the study of medicine. The Society includes various athletic clubs and superintends the gymnasium and squash racquet-courts in the medical school, and the athletic ground at Perivale.

In Gower-street there is a well-equipped residential hostel solely for the use of the medical students.

Westminster Hospital

The Hospital contains 241 beds, and has attached to it a Radium Clinic with 22 beds, elaborately equipped for all forms of radium therapy and research. There are separate departments for diseases of the eye, skin, teeth, ear, nose and throat, for orthopædic practice, for diseases of women, for diseases of children, for radiography, for venereal disease, and for massage, electrical, and light treatment. The anatomical, pathological, and materia medica museums are open to all students of the school.

The entire teaching of the hospital is devoted to the subjects of the Final Examinations. Arrangements are made for the tuition required for Preliminary and Intermediate subjects.

Paid appointments as medical, surgical, and obstetric registrars, casualty officers, house physicians, house surgeons, and anæsthetist, are available for students when they have passed their examinations.

There are excellent opportunities for research work in the recently endowed John Burford Carlill Laboratories. Grants to assist research workers are made annually from the John Burford Carlill Endowment.

Scholarships and Prizes.—The following Entrance Scholarships are offered for competition: Winter Session: Two Scholarships in Anatomy and Physiology, £75 each. Summer Session: Two Scholarships in Anatomy and Physiology, £75 each. A certain number of Scholarships have been allotted to Universities of England, Wales, and the Colonies, and to Public Schools. These Scholarships are awarded entirely on the nomination of the principal of the university or school. During the period of study the following prizes may be competed for: Sturges Prize in Clinical Medicine, Reports on Cases; Chadwick Clinical Surgery Prize, Reports on Cases; Chadwick Prize in books or instruments—Medicine and Surgery, including Pathology and Applied Anatomy and Physiology; Frederick Bird Medal and Prize, open to Fourth-year Students, medal and books or instruments—Midwifery, Diseases of Women, Medicine, Pathology, Forensic Medicine and Bacteriology, and Public Health and Toxicology; Abrahams Prize in Clinical Pathology, a paper and tests in practical work; Hanbury Prize in Diseases of Children, 10 guineas; Alfred Hughes Memorial Prize, open to Second-year Students, books or instruments—Anatomy; Huxley Memorial Prize, 3 guineas in books or cash, open to Second-year Students—Physiology; Carter Gold Medal and Prize for Botany, open to Students of not more than three years' attendance, gold medal and books; Jelf Medal awarded to Third-year Students; Daniell Scholarship, £40, Chemistry; Rabbeth Scholarships open to First-year Students; Class Examinations in the Preliminary Scientific Course. Inchley Prize in Pharmacology, open to Students who within two years of passing the first examination for medical degrees have completed the course in Pharmacology. Hare Prize in Zoology, £2 10*s.*, open to First-year Students.

The annual fee includes membership of the Sports Union Club with its various branches—i.e., football, cricket, tennis, boxing, and Guthrie Society. The athletic grounds are situated in Tooting and are reached in 20 minutes from the hospital.

London (Royal Free Hospital) School of Medicine for Women

The Royal Free Hospital contains 321 beds. The Hospital also has large casualty and out-patient departments. A new block has recently been completed to extend the special departments for orthopædic, light, and obstetric and gynæcological out-patients. Maternity districts are attached to the Obstetric Unit operating in the Gray's Inn-road and Essex-road areas. Students also attend the in-patient and out-patient practice of the Elizabeth Garrett Anderson Hospital, Cancer Hospital, Hospital for Sick Children, Great Ormond-street, National Hospital, Queen-square, South London Hospital, and Central London Ophthalmic Hospital. Students after qualification can hold posts at the Royal Free Hospital of house physicians, house surgeons, obstetric assistants, clinical assistants, assistant anæsthetist and pathologist, and medical, gynæcological, and surgical registrars; and the posts of demonstrators in all the departments at the Medical School.

A Clinical Unit in Obstetrics controls 68 beds. The Pathology Unit has been extended and spacious new quarters are now available.

Courses are arranged for the Primary Fellowship Examination of the College of Surgeons.

The School buildings have been entirely rebuilt in recent years, and there are spacious, well-equipped laboratories, which afford every facility for efficiency of teaching and practical work in all departments. Students' Chambers are provided in the neighbourhood of the school and the Warden can be consulted on the subject.

Scholarships and Prizes.—Among the larger of these awards are the following: (*a*) Isabel Thorne and A. M. Bird Scholarships of £30 a year for six years. (*b*) St. Dunstan's Medical Exhibition, £60 a year for three or five years. (*c*) Mrs. George M. Smith Scholarship, £50 a year for three or five years. (*d*) Bostock Scholarship, £90 a year for five years. (*e*) Mabel Sharman-Crawford Scholarship, £20 a year for four years. (*f*) Sir Owen Roberts Scholarship, £75 a year for four years. (*g*) Mabel Webb and A. M. Bird Research Scholarship, £200 for one year. (*h*) Fanny Butler Scholarship, £16 a year for four years. (*i*) Sarah Holborn Scholarship, £20 a year for three or five years. (*j*) Dr. Margaret Todd Scholarship, £37 10*s*. a year for four years. (*k*) Lieutenant Edmund Lewis and Lieutenant Alan Lewis Memorial Scholarship, £25 a year for four years. (*l*) Alfred Langton Scholarships, £35 a year for two years. (*m*) Flora Murray Bursary, awarded every year to a fifth-year student, £50. (*n*) A. M. Bird Clinical Scholarship, £30 a year for three years. (*o*) School Jubilee Bursary, tenable for three years, £50 a year. (*p*) John Byron Bursary, £20 for two years. (*q*) Helen Prideaux Prize and Julia Ann H. Cock Prize, to be spent in assisting the newly qualified holder to further study, £60 each. (*r*) A. M. Bird Post-graduate Scholarship in Pathology, £200 for one year. (*s*) Dr. Edith Pechey Phipson Post-graduate Scholarship of the value of £100, open to all medical women, preferably coming from India or going to work in India. The Dorothy Chick Gift, £20, and other prizes value £84 are awarded annually. The Students' Union arranges the social, athletic, and other clubs and societies.

Inquiries may be addressed to the Warden and Secretary of the Medical School, 8, Hunter-street, London, W.C.

British Post-Graduate Medical School

This school, which will be open to post-graduate students during the academic year 1934–35 at a date still to be determined, is the outcome of joint action by H.M. Government, the University of London, and the London County Council. The School will be run in connexion with the London County Council Hospital at Hammersmith, which has at present some 400 beds, a number which is likely to be increased at a later date. Parliament has voted £100,000 for its new buildings and equipment, and the London County Council is spending a similar sum on additional hospital buildings and equipment in order to improve the supply of clinical materials for teaching.

The School, of which the buildings are now substantially completed, is situated in the grounds of the Hammersmith Hospital at Ducane-road. These grounds cover 14 acres and provide ample room for further building. Ducane-road runs parallel to Western-avenue, to the south of a large area of open ground known as Wormwood Scrubs, which can never be built over. On the west lies the prison, and the extensive plot on the east belonging to St. Clement Danes Grammar School will also remain open.

The Board of Governors of the Post-Graduate School, as prescribed in its Charter, is made up of representatives of various interested bodies, and at present consists of the following 17 members under the chairmanship of Sir Austen Chamberlain, K.G., M.P.:—

Names.	*Nominated by—*
F. C. Goodenough.	Secretary of State for Dominion Affairs.
Lt.-Col. H. R. Dutton, C.I.E., F.R.C.S., I.M.S. (ret.).	Secretary of State for India.
Sir Thomas Stanton, K.C.M.G., M.D.	Secretary of State for the Colonies.
Sir Austen Chamberlain, K.G., M.P.	Minister of Health.
Sir George Newman, K.C.B., M.D.	Minister of Health.
Miss Florence Barrie Lambert, C.B.E., M.B., D.P.H.	London County Council.
L. Silkin.	London County Council.
H. L. Eason, C.B., C.M.G., M.S.	Senate of the University of London.
Prof. G. E. Gask, C.M.G., D.S.O., F.R.C.S.	Senate of the University of London.
Lord Dawson of Penn, G.C.V.O., M.D., P.R.C.P.	Royal College of Physicians of London.
Sir Holburt Waring, C.B.E., P.R.C.S.	Royal College of Surgeons of England.
R. C. B. Wall, M.D., F.R.C.P.	Society of Apothecaries of London.
T. Watts Eden, M.D., F.R.C.P.	Royal Society of Medicine.
Sir Robert Bolam, O.B.E., M.D., F.R.C.P.	British Medical Association.
Sir Frederick N. Kay Menzies, K.B.E., M.D., D.P.H.	Coöpted.
Miss L. Martindale, C.B.E., M.D., B.S. Lond., F.C.O.G.	
H. J. Paterson, C.B.E., F.R.C.S.	

The School has been provisionally recognised as a school of the University of London, and all appointments of Professors and Readers will be made by that body.

It is under consideration to provide facilities for at least three different classes of post-graduate student: (1) students from the Empire and abroad who at present have scarcely any opportunity of sharing in practical work in this country; (2) those who have qualified at one or other of the British undergraduate medical schools and feel a desire for further scientific training; (3) practitioners, especially those from the country, requiring short and highly concentrated refresher courses to keep them in touch with new developments in medicine and surgery.

The new block in which it is proposed to house the medical school consists of three floors around a central courtyard. On the ground floor is the clinical theatre, with seating room for 100 students, directly abutting on the main east-west corridor of the hospital, with a room for a cinema operator on the one side and examination rooms for patients on the other. On the north side of this floor is a very complete pathological department centring around a top-lighted post-mortem room with four tables, attached to which is abundant cold storage. The adjacent mortuary opens on a yard with a separate entrance to the street and completely cut off from the rest of the hospital. Alongside are rooms for histology and photography, and a service lift to take material up to the museum and preparation laboratories on the floor above. On the east side are chemical laboratories with workshops, stores, and centrifuge room; on the west side are the committee room and the offices of the dean and clerical staff. On the first floor are the library and museum, as well as the lecture theatre which lies over and duplicates the clinical theatre below. Here are the laboratories for the professors and a number of other laboratories large and small, with a small refreshment room, an earnest of the restaurant which is one of the desiderata in the next extension. On the second floor is a large animal section with preparation, operating, and post-mortem and infectious rooms, abundant pens and cage accommodation. All this is opening on a flat roof and completely shut off from the rest of the building. On the third floor also are microscopic and other laboratories, with hot rooms and autoclaves.

The following appointments to the School have so far been made and further appointments are receiving consideration : Dean, Dr. M. H. MacKeith ; Professor of Medicine, Dr. F. R. Fraser ; Professor of Obstetrics and Gynæcology, Dr. James Young ; Professor of Pathology, Dr. E. H. Kettle. It is intended that visiting experts shall be invited to conduct special courses from time to time, and that, while ample opportunity for refresher courses is to be provided, advanced workers will find their needs considered.

At the hospital a new surgical and maternity block has been provided and a large out-patient department —this last a novel feature for one of the London County Council hospitals. It is intended to arrange that patients from any of the London County Council's hospitals may be sent to Hammersmith for the purpose of diagnosis and the specialised treatment available there.

The responsibility for the care of patients will continue to rest with the Council, and while the proper duty of the School is teaching the two functions are in practice inseparable, at least with regard to the more senior posts. The School will depend for its main income on a grant from the University Grants Committee administered through London University (which has two representatives on the Governing Body), but will also receive a payment from the Council in respect of services rendered to the hospital, and, in addition, fees will be charged to students attending courses.

UNIVERSITY OF DURHAM

There are two degrees in Medicine, *M.B.* and *M.O.* ; two in Surgery, *M.S.* and *D.S.* The University also gives degrees or diplomas in *Dental Surgery, Hygiene and Public Health*, and *Psychiatry*.

For the degrees of *Bachelor of Medicine* and *Bachelor of Surgery* there are four professional examinations. The subjects of the First Examination are—Elementary Biology and Chemistry in relation to medicine. The subjects of the Second Examination are— Anatomy and Physiology. The subjects of the Third Examination are—Pathology and Bacteriology, Materia Medica, Pharmacology and Pharmacy, Medical Jurisprudence, and Public Health. The subjects of the Fourth Examination are—Medicine, including Therapeutics, Clinical Medicine, Surgery, Clinical Surgery, Operative Surgery, Midwifery and Gynæcology, Psychological Medicine, Diseases of the Skin, of the Throat, Nose, and Ear, and of Children, and Ophthalmology. The University requires that at least three years be spent in residence in the University. In certain cases candidates may obtain exemption from the First and Second examinations, but the later professional examinations must be passed in the University.

For the degrees of *Doctor of Medicine* and *Master of Surgery* a candidate must not be less than 24 years of age. He must have obtained the bachelor degrees of the University, and been engaged for two years subsequently to the date of admission to these degrees in research work, or in attendance on the practice of a recognised hospital, or in the naval or military services, or in medical or surgical practice. The candidate for the M.D. degree may present an essay or undergo a special examination in the subjects of Medical Anatomy, Medical Pathology, and the Principles and Practice of Medicine. The subjects of examination for the M.S. are—Principles and Practice of Surgery, Surgical Pathology, Surgical Anatomy, Surgical Operations, Clinical Surgery.

Doctor of Surgery.—Candidates must be registered medical practitioners, and not less than 25 years of age, and must devote three years, subsequently to obtaining a registrable qualification, to the study of Surgery, one at least to be spent in the University. The course of study of the candidate must be submitted to the Professor of Surgery and approved by the Board of the Faculty. One year shall be devoted mainly to work in the departments of Anatomy, Physiology, Pathology, and Bacteriology, and the candidate must submit evidence of having so worked. Not less than six months of another year must be spent as resident surgeon in a recognised teaching hospital, and the rest of the year in the study of surgery in a recognised medical centre. Not less than six months of one of the three years must be spent in surgical study abroad.

Candidates must give six weeks' notice of entry for all examinations to the Secretary of Examinations, University of Durham College of Medicine. The M.D. (essay) must be sent in before April 1st.

Scholarships and Prizes.—The following are awarded : University of Durham Entrance Scholarship, £25 a year for four years ; Pears' Entrance Scholarship, £40 a year for three years (awarded every third year) ; Heath Entrance Scholarship (from Kepier Grammar School), £60 (renewable) ; Province of Durham Masonic (Entrance) Scholarship, £60 (renewable) ; Heath Scholarship for Surgery, £200, available every second year ; Rutherford Morison Surgical Scholarship, £180, available every third year. Approved applicants may obtain special grants for surgical research from the Stephen Scott Research Fund.

The following Scholarships are tenable for one year, namely : Tulloch Scholarship for Elementary Biology and Organic Chemistry, £20 ; Dickinson Scholarship for Medicine, Surgery, Midwifery, and Pathology, £20 ; Charlton Scholarship for Medicine, £25 ; Gibb Scholarship for Pathology, £28 ; Luke Armstrong Scholarship for Comparative Pathology, £25 ; Stephen Scott Scholarships for Anatomy and Physiology, two of £50 each ; Philipson Scholarships for highest marks in Final M.B., B.S. Examinations, two of £45 each ; Goyder Memorial Scholarship for Clinical Medicine and Clinical Surgery, interest on £325 ; Hamilton Drummond Memorial Scholarship, in aid of research in Clinical Surgery, about £50 ; Gibson Prize for Midwifery and Diseases of Women and Children, £10 ; Turnbull Prize and Silver Medal for Surface Anatomy ; and Outterson Wood Prize for Psychological Medicine, £10 ; Sewell Memorial Prize and Silver Medal for Clinical Pathology.

Newcastle-upon-Tyne : College of Medicine

Hospital practice and post-graduate work are carried out at the Royal Victoria Infirmary, a general hospital containing 700 beds, and there are facilities for the study of the various special subjects. Post-graduate work can be pursued at the Newcastle General Hospital.

Practical midwifery can be studied at the Princess Mary Maternity Hospital, which contains 90 beds, with an annual indoor and outdoor attendance on 3000 cases.

Psychological medicine can be studied at the Newcastle Mental Hospital, and infectious diseases at the City Hospital, under the M.O.H. of the city.

The bacteriological laboratory is adjacent to Armstrong College.

Post-graduate Instruction.—1. General courses in Clinical Medicine, Surgery, and Pathology at the Royal Victoria Infirmary, meeting once weekly for ten weeks. One course is held from October to December and one from April to June. 2. Special courses of clinical instruction, meeting once weekly for ten weeks, in the following subjects: Gynæcology; Diseases of the Eye; Diseases of the Throat, Nose, and Ear; Diseases of the Skin; Venereal Diseases; Neurology; Diseases of Children; Electrotherapeutics and Radiology; special courses in Midwifery are held at the Princess Mary Maternity Hospital. 3. An intensive course of 14 days' duration in the Summer Vacation. 4. In addition to the regular post-graduate courses practitioners may attend the ordinary medical and surgical practice of the Royal Victoria Infirmary, also at the Princess Mary Maternity Hospital for specified periods, and for clinical instruction at Newcastle General Hospital.

There is a well-furnished Students' Union for the students of the Newcastle Division of the University, and special accommodation has been provided for women students.

The clinical work is done mainly at the

Royal Victoria Infirmary

The Infirmary has over 700 beds. Clinical lectures are delivered by the physicians and surgeons weekly and ward demonstrations are given daily. Tutorial classes are given by the assistant physicians, assistant surgeons, the medical and surgical registrars, and the assistant to the gynæcological department, and demonstrations are given in the several out-patient departments daily. Pathological demonstrations are given by the pathologist daily or as opportunity occurs. In addition to medical and surgical in-patient and out-patient departments the following special departments are fully equipped for teaching: ophthalmic, throat, nose, and ear, skin, and venereal disease, gynæcological, orthopædic, and electrical. The hospital building contains the following laboratories: 1. Special pathological laboratories attached to the post-mortem rooms. 2. Bacteriological laboratory in which all clinical bacteriological investigations are carried out. 3. There is in addition a clinical laboratory attached to each ward and to the out-patient department. There are five operating theatres in use in the hospital. The winter session of 1934 opens on Oct. 2nd, and the summer session of 1935 on April 17th. Applications for detailed information should be made to the Sub-Dean, Dr. Horsley Drummond, at the hospital.

Appointments of assistants in the pathological and other special departments and of clinical clerks and dressers are made periodically. Resident appointments are also made every six months; and each year medical and surgical registrars (who also act as tutors) are appointed from candidates who have previously held resident appointments at any recognised hospital. These latter posts afford an excellent opportunity for post-graduate study, not only at the Infirmary, but also in the departments of anatomy, physiology, pathology, and bacteriology of the college.

UNIVERSITY OF BIRMINGHAM

The University of Birmingham grants the degrees of *M.B.*, *Ch.B.*, *M.D.*, *Ch.M.* There is also the degree of *Ph.D.* (for *Research Study*), and a degree and a diploma in *Public Health*. The Senate may recognise attendance at other Universities as qualifying for these degrees and these examinations passed at Universities as exempting from the examinations in Physics, Chemistry, Biology, and Organic Chemistry; but at least three years must be spent in attendance upon classes in the University. The final year may be spent at any other medical school recognised by the University.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—The student must have passed the Matriculation Examination of the Joint Board or an examination accepted in lieu thereof. Before commencing the study of Anatomy and Physiology, examinations in Chemistry and Physics and Biology must be passed (First M.B., Ch.B.), or examinations in lieu thereof. All communications respecting the Matriculation Examination, and examinations accepted in lieu thereof, must be sent to the Secretary, Joint Matriculation Board, 315, Oxford-road, Manchester. Second Examination.—Part I., Organic Chemistry; Part II., Anatomy and Physiology. Third Examination.—General Pathology and Bacteriology. Fourth Examination (at the end of the fifth year).—Forensic Medicine and Toxicology; Public Health; and Materia Medica, Pharmacology, and Therapeutics. Two years' hospital work must have been accomplished. Final Examination.—Medicine, Surgery, Midwifery and Diseases of Women, Mental Diseases, and Ophthalmology. Attendance at a general hospital for a year after the passing of the fourth examination will be required, also attendance at a fever hospital three months, maternity hospital three months, and mental hospital three months. Vaccination instruction must be taken and courses of Ophthalmology, Venereal and Skin Diseases, and Diseases of Ear, Nose, and Throat, Medical and Surgical Anatomy, and Operative Surgery. Distinctions may be awarded in the subjects (severally) of the Second, Third, Fourth, and Final; and First- and Second-Class Honours in the Final Examination.

Degrees of Doctor of Medicine and Master of Surgery. One year after having passed the final M.B., Ch.B. examination the candidate can present himself for these higher degrees. They present a thesis on some medical or surgical subject, and pass a general examination in Principles and Practice of Medicine for the M.D. and one in Principles and Practice of Surgery, including operations on the cadaver, for the Ch.M., or, at the discretion of the examiners, in a special branch of Medicine or Surgery respectively. A thesis of exceptional merit may exempt from any part of these examinations, in which Honours may be awarded.

Degree of Ph.D.—Candidates must possess a medical degree of a British, Colonial, or other university approved of by the Senate of the University, and have been engaged as a rule in advanced study for two years, either in a laboratory of the University or in one or more of the hospitals associated with the University. But under approved conditions after the first year research may be carried on elsewhere, when, on completing the course, candidates present a thesis and submit themselves for oral and possibly written examination.

Scholarships and Prizes.—The following are awarded:—Entrance Scholarships: (*a*) Frank Fletcher and Catherine Fletcher Scholarships of £100 per annum each, for five years. Two or more offered annually; open to men and women students under certain prescribed conditions as to residence, &c.; (*b*) Sydenham Scholarship of £42, tenable for three years, award of Council to orphan sons of medical practitioners; (*c*) Sands Cox Scholarship of £21 per annum during two years, awarded to the candidate, not being more than 19 years of age, taking the highest marks at the Higher School Certificate Examination of the Joint Matriculation Board; (*d*) Dental Scholarship of £46 17*s.* 6*d.*, Open Competitive Examination in subjects learned during apprenticeship; (*e*) Myers Travelling Studentship of £300, tenable for one year, offered in alternate years, awarded by vote of committee to M.B., Ch.B. candidates, tenable at some University or Hospital not in Great Britain or Ireland; (*f*) two Ingleby Scholarships of £10 each awarded to the candidates at Final Examination obtaining highest marks in the subjects of Midwifery and Diseases of Women; (*g*), (*h*), (*i*), and (*j*) Four Queen's Scholarships of £10 10*s.* each, awarded to the candidate taking the first place in the Second, Third, Fourth, and Final Examinations respectively, provided that the candidate's work is sufficiently distinguished; (*k*) Priestley Smith Prize in Ophthalmology, value about £6 10*s.*, is awarded annually to the student passing the Final M.B., Ch.B. Examination on first entry who shows the best knowledge of Ophthalmology, provided the Examiners deem him worthy of this distinction; (*l*) George Henry Marshall Scholarship of £10, awarded annually, for the encouragement of Research Work in Ophthalmology; and (*m*) Russell Memorial Prize, a prize of books, value about £2, awarded annually to the Student who, not being of more than six years' standing as a student of the School of Medicine of the University, shall pass the best examination in the subject of Nervous Diseases. The "Arthur Foxwell Memorial Medal" (Gold Medal) is awarded annually to the candidate taking the highest place in Clinical Medicine and passing the Final M.B., Ch.B. Examination in June; the "Sampson Gamgee Memorial Medal" (Gold Medal for Surgery) is awarded annually to the best candidates passing Final M.B., Ch.B. Examination in June in Surgery (paper, oral, and clinical); Peter Thompson Prize for Anatomy (Third Year); and John Barritt Melson Gold Medal for Physiology (Third Year). The University Clinical Board awards Gold and Silver Medals on examinations in Medicine, Surgery, and Midwifery, respectively, in fourth and fifth years, open to all students.

Post-graduate Instruction.—A "William Withering Lectureship" has been established. Courses of lectures are given annually for post-graduates on subjects chosen from year to year. Post-graduate courses of clinical demonstrations for general practitioners are arranged annually by the University Clinical Board (April to July) at the Birmingham General, Queen's, and Children's Hospitals.

The students receive clinical instruction by attending the amalgamated practice of the General Hospital, Queen's Hospital, Maternity Hospital, Children's Hospital, Birmingham and Midland Eye Hospital, Mental Hospital, and Fevers Hospital, under the direction of the University Clinical Board. Appointments are open to students varying from £40 to £200 a year.

Queen's Hospital

There are 330 beds. Ward rounds and out-patient clinic classes are held daily, and regular tutorial classes throughout the session. Post-graduate courses arranged by the University are conducted every year. There are special departments in gynæcology, diseases of the eye, of the ear, nose, and throat, dentistry, radiology, pathology, bacteriology, biochemistry, physiotherapy, electrocardiography, and there is a psychiatric clinic associated officially with the Birmingham Mental Hospitals. There are also large wards for midwifery and postnatal cases, a nursery for instruction in infant welfare, an extensive midwifery district, and residential facilities for students. There are 23 resident appointments (inclusive of registrars) available each year for recently qualified students.

Birmingham General Hospital

There are 487 beds. Special wards for children, gynæcological, ear and throat, venereal, and radium cases; special beds for eye and skin cases. Laboratories for bacteriology, biochemistry, cancer research, and morbid histology. Separate rooms adjoin the medical and surgical wards for clinical pathology. Six operating theatres (one for out-patients and one for casualty department, which is a separate department), are all of them fitted on modern lines. In addition to clinical teaching given in the wards and out-patient department by the honorary staff, medical and surgical tutorial classes are held for senior and junior students. Clinical instruction in all the special departments, which include those for radium, electrotherapy, electrocardiographic investigation, and venereal diseases. Post-graduate classes are held in every branch of medicine and surgery. The Jaffray Branch Hospital contains 61 beds.

UNIVERSITY OF LIVERPOOL

The degrees in the Faculty of Medicine are Bachelor of Medicine and Bachelor of Surgery (*M.B.* and *Ch.B.*), Doctor of Medicine (*M.D.*), Doctor in Philosophy (*Ph.D.*), Master of Surgery (*Ch.M.*), Master of Hygiene (*M.H.*), and Master of Orthopædic Surgery (*M.Ch.Orth.*). There is a diploma in *Medical Radiology and Electrology.*

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates for the degrees of Bachelor of Medicine and of Surgery must have attained the age of 22 years on the day of graduation. At least two of the six years of medical study must have been passed in the University, and one year at least must have been passed in the University subsequently to the date of passing the First Examination. The other three years may be passed at any college or medical school recognised for this purpose by the University. Candidates must pass three examinations entitled respectively: the First Examination, the Second Examination, and the Final Examination. The subjects of the First Examination are: (1) Chemistry; (2) Biology (Zoology and Botany); (3) Physics. The subjects of the Second Examination are: (1) Anatomy; (2) Physiology (including Biochemistry and Histology). The subjects for the Final Examination are: (1) (*a*) Pathology, (*b*) Pharmacology and General Therapeutics; (2) (*a*) Forensic Medicine and Toxicology, (*b*) Public Health; (3) (*a*) Obstetrics and Diseases of Women, (*b*) Surgery, Systematic, Clinical, Operative, and Practical, including Ophthalmology, (*c*) Medicine, Systematic and Clinical, including Therapeutics, Mental Diseases, and Diseases of Children. Candidates may take Parts (1), (2), and (3) separately, provided that they do not present themselves for Part (3) until they have completed the sixth year of medical study and have passed the examination in Parts (1) and (2).

Degrees of Doctor of Medicine and Master of Surgery. No candidate will be admitted to the degree of Doctor of Medicine or Master of Surgery unless he has received the Degrees of Bachelor of Medicine and Bachelor of Surgery (Liverpool), and at least two years have elapsed since he passed the examinations for those degrees. Candidates may also take the degree of Doctor of Medicine by examination after five years from taking Liverpool M.B., Ch.B. in (*a*) Medicine, and (*b*) a selected branch of Medicine. Candidates for the degree of Doctor of Medicine, who elect to present a thesis, are required (*a*) to present a thesis, acceptable to the Faculty, and certified to be the candidate's own work, together with (if the candidate desires) copies of published original papers upon Medical Science; (*b*) to present themselves for an oral examination on the subject of the thesis.

The subjects of examination for the Degree of Master of Surgery are: Surgery, Clinical Surgery, Operative Surgery, Surgical Pathology and Bacteriology, and Surgical Anatomy.

Degree of Master of Orthopædic Surgery.—May be conferred on graduates in Medicine of Liverpool or other approved University and graduates of a Faculty other than Medicine of Liverpool or other approved University who are Fellows of the Royal College of Surgeons of England, Edinburgh, or Ireland, or of the American College of Physicians.

The University also awards Diplomas in Medical Radiology and Electrology, Public Health, Tropical Medicine, and Tropical Hygiene.

Scholarships, Fellowships, and Prizes.—The following are awarded: (*a*) Robert Gee Entrance Scholarship (Men), annually, of £42 10*s.*, tenable for four years; (*b*) Junior Lyon Jones Scholarship, of £19 per annum, tenable for two years, on results of First M.B. Examination; (*c*) Senior Lyon Jones Scholarship, of £19, Competitive Examination on results of Professional Examination in Anatomy and Physiology; (*d*) Derby Exhibition of £15, Competitive Examination in Clinical Surgery; and (*e*) Clinical School Exhibition of £15 in Clinical Medicine; (*f*) University Scholarship of £50 for one year, awarded on results of the Final (Part I.) Examination for the degrees; (*g*) Holt Fellowships, Physiology and Pathology, of £150 each, for one year; (*h*) Gee Fellowship, Anatomy, of £100, for one year; (*i*) John Rankin Fellowships in Anatomy, two, each of the value of £120, tenable for two years; (*j*) Johnston Colonial Fellowship, Biochemistry, of £100, for one year; (*k*) John W. Garrett International Fellowship, Bacteriology, of £100, for one year; (*l*) Thelwall Thomas Fellowship, Surgical Pathology, of £150, for one year; (*m*) Ethel Boyce Fellowship in Gynæcology, of £100, for one year; (*n*) Mary Birrell Davies Memorial Fund Scholarship, of the value of £60, tenable for four years, offered for competition in alternate years; open only to women students who will have attained the age of 19 on the first day of October in the year of the award; (*o*) Rankin Exhibition in Practical Anatomy, of £23, for one year; (*p*) Lady Jones Research Fellowship in Orthopædic Surgery, £200; (*q*) Samuels Memorial Scholarships, three at £27; (*r*) Ridgway Research Scholarship (£94); (*s*) T. J. Hughes Research Scholarship (£72); numerous prizes and medals.

The Medical School.—All the laboratories and classrooms are situated close together, communicating with one another, and are made up of four large blocks of buildings which form one side of the College quadrangle. There are the Johnston Laboratories for Biochemistry; the Medical School for Anatomy, Surgery, Toxicology, and Ophthalmology; and the Thompson-Yates Laboratories for Physiology and Pathology. There is also a separate building for Tropical Medicine and Public Health. Medical research has also been endowed with several new laboratories in which students can pursue research work after graduation.

Clinical Studies.—The Clinical School of the University consists of four general hospitals—the LIVERPOOL ROYAL INFIRMARY, the DAVID LEWIS NORTHERN HOSPITAL, the LIVERPOOL ROYAL SOUTHERN HOSPITAL, and the LIVERPOOL STANLEY HOSPITAL; and of five special hospitals—the Eye and Ear Infirmary, the Women's Hospital, Liverpool, Liverpool Maternity Hospital, the Royal Liverpool Children's Hospital, and St. Paul's Eye Hospital. These hospitals contain in all a total of about 1500 beds. The organisation of these hospitals to form one teaching institution provides the medical student and the medical practitioner with an extensive field for clinical education and study. All the hospitals are within easy access of the University. There are a large number of appointments to house physicianships and surgeonships both at the general and special hospitals which are open to qualified students of the school.

Public Health Department.—This is located in a separate building, in which full courses of instruction are given to students for the Diplomas and Degrees of the University and of other Examining Boards.

Prospectuses and further information may be had on application to the Dean of the Faculty of Medicine, University of Liverpool.

UNIVERSITY OF MANCHESTER

Four degrees in Medicine and Surgery are conferred by the Victoria University of Manchester—viz., Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), and Master of Surgery (Ch.M.). A Diploma in Psychological Medicine, a Diploma in Public Health, a Diploma in Bacteriology, and a Diploma in Pathology are awarded by examination to registered medical practitioners.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Before admission to the degrees of M.B. and Ch.B. candidates are required to present certificates that they will have attained the age of 21 years on the day of graduation, and that they have pursued the courses of study required by the University Regulations during a period of not less than five and a half years subsequently to the date of their registration by the General Medical Council, two of such years having been passed in the University subsequently to the date of passing the first M.B. Examination.

The First Examination: (1) Chemistry and Physics; (2) (*a*) Botany, (*b*) Zoology. Candidates must have attended the prescribed courses both of lectures and of laboratory work in each of the above-named subjects. The Examination is divided into two parts: Part 1, Inorganic and Elementary Organic Chemistry and Physics; Part 2, (*a*) Botany, (*b*) Zoology. The candidates sit for these parts separately. The Second Examination: (1) Anatomy and Histology; (2) Physiology, including Physiological Chemistry. Both parts must be passed simultaneously. The Third Examination: (1) Pharmacology and Materia Medica; (2) Pathology and Bacteriology. The Final Examination: (1) Medicine, Systematic and Clinical (including Mental Diseases and Diseases of Children); (2) Surgery, Systematic, Clinical, and Practical; (3) Obstetrics and Gynæcology (including Clinical and Practical); (4) Forensic Medicine; (5). Hygiene and Preventive Medicine. The Final Examination is divided into two parts: Part I., Forensic Medicine, Hygiene and Preventive Medicine; Part II., Medicine, Surgery, Obstetrics and Gynæcology (Systematic, Clinical, and Oral). The two parts of the Final Examination must each be passed as a whole. Candidates for the Second Part must have completed the sixth year of medical study.

Degree of Doctor of Medicine.—Candidates are not eligible for the degree of Doctor of Medicine unless they have previously obtained the degrees of Bachelor of Medicine and Bachelor of Surgery of this University, and at least one year has elapsed since they passed the examination for those degrees. Candidates may elect either (1) to present an original dissertation; or (2) to undergo an examination. The dissertation must embody the results of personal observation, or original research, either in some department of medicine or of some science directly relative to medicine. The examination, which will be written and practical, is in the Principles and Practice of Medicine, in Pathology, and in some other subject to be selected by the candidate.

Degree of Master of Surgery.—Candidates are not eligible for the degree of Master of Surgery unless they have previously obtained the degrees of Bachelor of Medicine and Bachelor of Surgery of this University, and at least one year had elapsed since they passed the examination for those degrees. The degree is conferred in the following branches: Surgery (Branch I.), Gynæcology (Branch II.), Ophthalmology (Branch III.), Laryngology, Otology, and Rhinology (Branch IV.).

Degrees of B.Sc. and M.Sc.—The ordinary degree of B.Sc. in the Schools of Anatomy and Physiology may be obtained by students in Medicine who in their third year of study for the degree of M.B., Ch.B., complete the additional courses in these subjects prescribed for this degree. Candidates for the Honours degree of B.Sc. in Anatomy or Physiology, who are students in Medicine, are required to attend courses in advanced Anatomy and Physiology for four terms after passing the Second Examination for the degrees of M.B., Ch.B. Graduates in science may proceed to the degree of M.Sc. by presentation of an approved thesis.

Diplomas: 1. The following are available for candidates holding a registrable qualification in medicine, surgery, and midwifery; examinations are in two parts in each diploma and are written, oral, and practical. Candidates may present themselves for Parts I. and II. separately or at the same time provided that no candidate be admitted to Part II. unless he has already passed in Part I. No candidate's name will be published until he has satisfied the examiners in both parts of the examination:—

(*a*) *Diploma in Psychological Medicine.*—Part-time course: extending over three University terms, two of which must be spent at the University. Six months' residence must be spent at a recognised Hospital for Mental Diseases.

(*b*) *Diploma in Public Health.*—The course extends over twelve calendar months at least: Part I. of the examination is held in June and October, and Part II. in March and October. Instruction for at least one of the parts must be taken out at the University.

2. *In Veterinary State Medicine.*—Length of course, three University terms. Candidates must be members of the Royal College of Veterinary Surgeons.

3. *In Bacteriology.*—For candidates who have graduated either in science or medicine, or obtained other approved qualification. Length of course, one academic year. A satisfactory thesis on an approved subject must be presented.

4. *In Pathology.*—For candidates who have obtained a registrable medical qualification or other qualification approved by the Senate. Length of course, one academic year. A satisfactory thesis on an approved subject must be presented.

Scholarships, Fellowships, and Prizes.—The following are offered in connexion with medical study at the Victoria University:—Scholarships: Dreschfeld Entrance (triennial), £20; John Russell Medical Entrance, £45; Sam Gamble Entrance for Women; Graduate Entrance (fees up to 160 guineas); two Dauntesey Medical Junior, £50 each; Dauntesey Medical Senior, £50; Professor Tom Jones Exhibition in Anatomy, £25; Dickenson Trust Scholarships in Anatomy and Pathology; Platt Physiological, £90; Graduate Research Scholarship, £70; Dickenson Trust Travelling Scholarships in Medicine and Surgery; Ashby Memorial in Diseases of Children (triennial), £100; Holt Post-Graduate Medical Scholarship for Women, £60; Elected Research Studentships. Fellowships: Leech Research, £70; Professor Tom Jones, Surgical, £105; Morrison Watson in Anatomy, £150; John Henry Agnew in Diseases of Children, £120; Delépine in Preventive Medicine (biennial), £300; Pilkington Fellowship in Cancer Research, £300; Knight Fellowship in Psychological Medicine; Honorary Research Fellowships. Prizes: Sidney Renshaw in Physiology—Junior £10, Senior £20; Wild Prize in Pharmacology, £10; Turner Medical, two prizes each of 10 guineas; Dumville Surgical, £15; John Henry Agnew in Diseases of Children, £30. There are many general entrance scholarships, in addition to those already mentioned, open for competition, the examinations for which are held in the month of May. Full particulars can be obtained from the Registrar.

The Medical School.—This school, largely extended in 1920, is provided with dissecting-rooms, X ray rooms, physiological laboratories, private laboratories, and work-rooms, besides lecture-rooms, museums, and general and departmental libraries. A special laboratory is equipped for experimental work on the central nervous system. In the pathological laboratories (now removed to special buildings close to the Royal Infirmary) ample provision is made for the teaching of pathology and bacteriology and for the prosecution of original research. The Helen Swindells Laboratory is specially equipped as part of a new department for investigation in cancer. Ample facilities for investigation are provided in Anatomy, Physiology, and Materia Medica; new Pharmacological Laboratories were recently added. In the public health department, which is lodged in a separate institute in York-place, near the Royal Infirmary, suitable laboratory accommodation is provided for the study of sanitary chemistry, physics, and practical bacteriology in the departments of chemistry and physics and in that of pathology.

Clinical Studies.—The clinical and practical departments of medical study are taught partly in the medical school of the University and partly in the Royal Infirmary and St. Mary's Hospitals for Women and Children, a fever hospital, mental hospitals, a convalescent home, and other special hospitals

A residential Hostel for final year students will be opened shortly in proximity to the University, where accommodation will be available also for a few graduates.

The Manchester Royal Infirmary, near the University, has accommodation for 640 beds (including 54 beds at the Central Branch). Associated with the Infirmary are: (1) the Convalescent Hospital at Cheadle, containing 132 beds; and (2) the Central Branch in the City, which has accommodation for 54 patients. The Associated Hospitals thus contain 772 beds and are under the same management. The medical side consists of four units, each unit having a testing-room for the scientific investigation of morbid products and a class-room. The surgical beds are arranged in five units, each unit having its own operation theatre, with anæsthetising, recovery, sterilising, testing, and apparatus rooms, and its own class-room attached. One of the surgical units is assigned to orthopædic and neurosurgical cases. The gynæcological, aural, and out-patient departments each have their own operating theatre. Bacteriological investigations are carried out in a special clinical laboratory. A department for the study of heart disease, with an electric cardiograph and other instruments for research, diagnosis, and teaching purposes is attached to the medical wards. There is also a laboratory for clinical research. The X ray department has nine separate X ray outfits for different purposes, and one large room is put aside specially for X ray demonstrations and teaching purposes. A large massage school is also connected with this department. Women students are admitted on the same terms as men. Two Entrance Scholarships in Medicine of the value of £160 each are offered annually by the Council of the Manchester University and the Medical Board of the Manchester Royal Infirmary for proficiency in Arts and Science subjects respectively. All the usual appointments may be held by those who have attended the practice of the Infirmary.

The Royal Manchester Children's Hospital at Pendlebury contains 190 beds and 30 in the Convalescent Home, Lytham St. Anne's. Clinical instruction is given by the medical staff at the Hospital and Dispensary, Gartside-street, Manchester. There is a massage and electrotherapeutic department, also an artificial sunlight department. Clinical assistants are appointed for periods of six months. There is an orthopædic department, out-patients for which are seen at Gartside-street, and a ward at Pendlebury is devoted to those cases needing operative treatment.

Ancoats Hospital, Manchester, is a general hospital of 120 beds and a Convalescent branch which is situated at Great Warford, Alderley Edge, Cheshire, and has 35 beds.

The medical side consists of three units under the care of three honorary physicians with three out-patient clinics of consultative nature. A cardiographic department is under the care of one of the physicians. Much work is done in gastro-enterology, neurology, and diseases of the blood. The surgical units are four in number, each under the care of an honorary surgeon; the orthopædic department, which deals with all fractures and bone injuries, is very large. One surgical unit is devoted to abdominal surgery, and one is devoted to oto-rhino-laryngology, while a urological department is under the care of one of the honorary surgeons. All these units have a largely attended out-patient department. Clinical teaching is given both to under-graduate and post-graduate Students in all the out-patient clinics which are free to them, and in the wards, while special courses of post-graduate lectures are given as part of the Manchester University post-graduate scheme. Clinical assistantships are available for post-graduates.

There are six resident appointments which are open to men and women graduates. There are also four registrar appointments, part-time: medical, surgical, orthopædic and laryngological made annually.

UNIVERSITY OF LEEDS

Four degrees in Medicine and Surgery are conferred—viz.: Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), Master of Surgery (Ch.M.), also Degrees and Diplomas in Dental Surgery and Diplomas in Public Health and in Psychological Medicine. Courses and Degrees in the Faculty are open to men and women alike.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates for these degrees are required to present certificates showing that they will have attained the age of 21 years on the day of graduation, and have attended courses approved by the University extending over not less than five years, two of such years at least having been passed in the University, one of which must be subsequent to the date of passing the First Examination. Candidates must also satisfy the examiners in the several subjects of the following examinations, entitled respectively: the Matriculation Examination, or such other examination as may have been recognised by the Joint Matriculation Board in its stead; the First Examination; the Second Examination; and the Final Examination. The First Examination consists of: Part I., Physics and Inorganic Chemistry; Part II., Organic and Physical Chemistry; Part III., Botany; Part IV., Zoology. Candidates will be allowed to pass the parts separately. The Second Examination consists of: Part I., Materia Medica and Practical Pharmacy; Part II., Anatomy and Physiology. Candidates will be allowed to pass either part separately. The Final Examination consists of: Part I., Pharmacology, Pathology, and Bacteriology; Part II., Medicine, Surgery, Obstetrics and Gynæcology; Part III., Forensic Medicine, Public Health, and Therapeutics. Part I. may be taken at the end of the second clinical year, and Parts II. and III. may be taken at the end of the third clinical year, but not before the completion of the fifth year of medical study. If taken separately Part III. may not be passed before Part II.

Degree of Doctor of Medicine and Master of Surgery. Candidates are not eligible for the degree of Doctor of Medicine or Master of Surgery unless they have previously received the degrees of Bachelor of Medicine and Bachelor of Surgery of the University (or of Victoria prior to December, 1904) and at least two years' Hospital Practice or four years' other professional practice for the former and one year has elapsed for the latter since they passed the examination for those degrees. Candidates for the degree of Doctor of Medicine may present a dissertation and, if the dissertation is considered to be of exceptional merit, will not be required to pass an examination. The first term commences on Oct. 1st. Prospectus can be obtained from the Academic Sub-Dean.

Post-graduate work.—Practitioners wishing to attend Infirmary practice during short periods, or post-graduate classes held by members of the clinical staff, may do so an application to the Clinical Sub-Dean, from whom particulars may be obtained.

The Scholarships and Prizes, in order of importance, are: (1) medical scholarship, value £130; (2) Infirmary scholarship, value £75; (3) the Littlewood prize, value about £50; (4) West Riding Panel Practitioners, prize value, £25; and (5) the William Hey gold medal. The last is generally awarded to a young graduate who figures in the other prizes and sentimentally may be considered of first importance.

Clinical Studies.—The clinical studies are pursued mainly at the LEEDS GENERAL INFIRMARY AND WOMEN'S HOSPITAL, which has accommodation for 694 in-patients, including 88 beds at branch hospitals in the country. Clinical teaching takes place daily in the wards, in medicine and surgery. There are medical, surgical, ophthalmic, aural, electrotherapeutic, and radiographic departments, in each of which special instruction is imparted to students. Gynæcological and children's departments, together with laryngeal, venereal, and skin clinics, are in operation, and there is a special ward for cases of nutritional disorders of children.

In addition to work in the General Infirmary, clinical instruction in obstetrics is given in the Leeds Maternity Hospital and in mental and infectious diseases in the Wakefield (W.R.) Mental Hospital and Leeds City Fever Hospital respectively.

The General Infirmary.—This hospital has accommodation for 694 beds which are allotted, 300 to general medical and surgical cases, adults and children, the remainder being given up to ophthalmic, aural, orthopædic, and a few gynæcological cases. In that total is included the patients in the semi-convalescent branch hospitals, the Ida and Robert Arthington, containing 96 beds. The University and hospital paid appointments in connexion with the Infirmary and other bodies are numerous. Connected also with the Infirmary is the Women's Hospital of 66 beds for the treatment of gynæcological and obstetric diseases; students when eligible attend the practice of this hospital, to which there are four resident appointments attached whose holders receive honorariums.

Leeds Maternity Hospital contains 126 beds for cases of labour, while there is other accommodation attached for the treatment of morbid pregnancies. There is an X ray department, and large extern districts are centred upon the institution. The hospital is affiliated to the University for purposes of clinical training, and every student takes an obstetric clerkship and attends in the intern and extern departments. During the second and third months personal contact with not less than 20 cases of labour is required, the students being resident in the neighbouring hostel.

West Riding Mental Hospital.—The well-known hospital at Wakefield accommodates 2400 patients, a separate building, containing 360 beds, being provided for the treatment of acute insanity, while mentally deficient children are accommodated in separate homes in juxtaposition. Clinical clerkships in the wards and laboratories can be filled by qualified practitioners or, on application to the medical director, by senior students.

UNIVERSITY OF SHEFFIELD

The Degrees in the Faculty of Medicine are Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.), Doctor of Medicine (M.D.), and Master of Surgery (Ch.M.), Bachelor of Dental Surgery (B.D.S.), and Master of Dental Surgery (M.D.S.). There is also a Diploma of Licentiate in Dental Surgery. The courses and degrees in the Faculty of Medicine are open to men and women alike. Candidates must matriculate in the University or pass such other examination as may be recognised for this purpose by the University and sanctioned by the Joint Matriculation Board, and must pass also the further examination in Chemistry and Physics.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—A candidate must have attained the age of 22 years on the day of graduation, and have pursued the courses of study required by the University regulations during a period of not less than five and a half years subsequently to the date of his matriculation, three of such years at least having been passed in the Faculty of Medicine of the University one at least being subsequent to the passing of the Second Examination. The subjects of the First Examination are Chemistry, Physics, and Biology. Candidates must, in addition to matriculation, pass a preliminary examination in Physics and Chemistry before taking the First Examination, for which they must have attended courses of instruction (lectures and laboratory work) in Chemistry, Physics, and Biology for one year each. Students who before entry have attained a standard in Chemistry and Physics approved by the Faculty of Medicine have the opportunity of working for the degree of B.Sc.

(with honours) in Physiology concurrently with their work for the degree of M.B., Ch.B. The Second Examination: Candidates must have attended courses of instruction in Physiology (first part) for one year, and in Anatomy for five terms. The Third Examination: Candidates must have attended courses of instruction in Pathology for five terms, in Pharmacology for four terms (and one term in Pharmacy), in Applied Anatomy for four terms, and in Physiology (second part) for six terms. The Final Examination: The subjects are, Part I., Forensic Medicine and Public Health. Candidates must have attended courses for one term in each subject; Part II., Medicine (including Mental Diseases, Diseases of Children, and Vaccination), Special Pathology (including Morbid Anatomy and Clinical Pathology), and Therapeutics; Part III., Surgery (including the administration of Anæsthetics, Diseases of the Ear, Nose, and Throat, Ophthalmology, and Surgical Pathology), and Obstetrics and Gynæcology, including Antenatal and Postnatal practice and Infant Hygiene. Candidates for Parts II. and III. must have completed a minimum of five and a half years of approved study.

Degree of Doctor of Medicine.—Candidates for the degree of Doctor of Medicine must have passed the examination for the degrees of M.B., Ch.B. at least three years previously, must present a thesis embodying observations in some subject approved by the professor of medicine, and must pass an examination in the Principles and Practice of Medicine.

Degree of Master of Surgery.—Candidates must have taken the M.B., Ch.B. at least three years previously, and must since have held for not less than twelve months a surgical appointment in a public hospital.

The subjects of examination are Systematic, Clinical, and Operative Surgery, Surgical Anatomy, Surgical Pathology and Bacteriology.

Scholarships and Prizes.—The following scholarships are offered: Four Town Trustees scholarships offered annually, each of the value of £50 per annum for three years. Medical: offered annually, covers cost of tuition for a degree course in the Faculty of Medicine. Six Edgar Allen, offered annually, each of the value of £100 per annum for three years. Post-graduate: Frederick Clifford scholarship, value £50 per annum, tenable for two years. Mechanics' Institute scholarship, value £50 for one year with free admission to those University courses taken by the holder in connexion with his work, renewable for a second year. Town Trustees fellowship, value £75 for one year. Medals and Prizes: Kaye scholarship; Thomas Woodcock Prize; Gold Medal in Clinical Medicine and Surgery; John Hall Gold Medal in Pathology; Holroyd Gold Medal in Anæsthetics; the Walter S. Kay Gold Medal in Mental Diseases; bronze medals. Particulars of all the above may be obtained from the Registrar.

The Medical School.—The Medical Department occupies the entire north wing of the University quadrangle. The various athletic and other students' societies are under the management of the Union Representative Council, elected annually. There are large and comfortable common rooms both for men and women students, and two Students' Unions, one for men and one for women. A refectory is open daily at the University where students may obtain meals and refreshments at moderate prices. The University journal *The Arrows*, edited by a committee of staff and students, is published each term, and the medical school also publishes a journal. A well-equipped Union building is in course of erection. There is good hostel accommodation for women students and similar amenities will soon be provided for men.

Clinical Studies.—The University is within easy reach of the various hospitals with which it is connected for clinical purposes, and, as will be seen, the aggregate number of beds is very large. The SHEFFIELD ROYAL INFIRMARY (500 beds) provides all the opportunities of a large general hospital with special departments for Skin and Ear. The SHEFFIELD ROYAL HOSPITAL (340 beds) has special out-patient departments for Diseases of the Throat, Ear, Skin, Orthopædics, and Mental Diseases. The two institutions are amalgamated for the purposes of clinical practice, medical, surgical, and special. There are special departments for the treatment of Diseases of the Eye, with wards assigned to them, at both hospitals, and excellent junior appointments. The JESSOP HOSPITAL FOR DISEASES OF WOMEN, with 143 beds, has also a Maternity department, with about 110 in-patients per annum and about 3000 out-patient cases attended. The CHILDREN'S HOSPITAL has 92 beds. Special courses on Fevers are held at the CITY FEVER HOSPITALS (988 beds) and on Mental Diseases at the SOUTH YORKSHIRE MENTAL HOSPITAL (2000 beds). Every facility is afforded in the various laboratories for the prosecution of advanced studies and research.

Post-graduate Courses.—Post-graduate courses of clinical instruction are held annually in the various hospitals connected with the School.

UNIVERSITY OF BRISTOL

In the Faculty of Medicine there are the following degrees: Bachelor of Medicine and Bachelor of Surgery (M.B. and Ch.B.), Doctor of Medicine (M.D.), Master of Surgery (Ch.M.), Bachelor of Dental Surgery (B.D.S.), and Master of Dental Surgery (M.D.S). There are also the following diplomas: Diploma in Public Health (D.P.H.), Diploma in Dental Surgery (L.D.S.), and Diploma in Veterinary State Medicine.

All candidates for degrees in Medicine, Surgery, and Dentistry are required to pass, at Matriculation standard, an examination called the School Certificate Examination, or to pass such examination as may be regarded as equivalent by the Senate. All courses, degrees, and diplomas are open to men and women.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates shall be not less than 21 years of age and shall have pursued the courses prescribed by University Regulations during not less than five years after passing the first examination in Chemistry and Physics and entering on the professional curriculum at the University, or an institution recognised as equivalent, of which three shall have been passed in the University, and two of these three subsequent to passing the second examination. All candidates for the degrees of M.B., Ch.B. are required to satisfy the examiners in the several subjects of three examinations. The First Examination: The subjects of examination are: Chemistry (Inorganic), Physics, and Biology, the courses pursued being those for the time being approved for the intermediate part of the B.Sc. curriculum. This part of the curriculum shall extend over one year. (Candidates who have passed the Higher School Certificate approved by the Board of Education in these subjects will not be required to sit for the first examination and will be regarded as having completed one year of study.) The Second Examination: The subjects of examination are: Organic Chemistry (Part I.) and Anatomy and Physiology (Part II.). The Final Examination: The subjects of examination are: Materia Medica and Pharmacy, Pharmacology and Therapeutics, General Pathology, Morbid Anatomy, and Bacteriology (Part I.); Special Pathology, Forensic Medicine and Toxicology, Public Health, Obstetrics (including Diseases of Women), Surgery (Systematic, Clinical, Practical, and Operative, including Ophthalmology and Oto-rhino-laryngology), Medicine (Systematic, Clinical, and Practical, including Mental Diseases) (Part II.). The subjects included in Part II. may be taken in two groups—viz., Group I., Surgery and Obstetrics; Group II., Medicine, Public Health, Special Pathology, Forensic Medicine, and Toxicology. Candidates may pass Parts I. and II. together, or separately, and the two groups of Part II. may be taken together or separately, but no student can obtain honours who elects to take the two groups of Part II. separately. Forensic Medicine and Toxicology may be taken with Part I., or with Group II. of Part II.

Degree of Doctor of Medicine.—Candidates shall be Bachelors of the University of not less than two years' standing as such and may elect either (1) to pass an examination in General Medicine, or (2) to pass an examination in State Medicine, or (3) to present a Dissertation. The candidate who elects to pass the examination in State Medicine must hold a Diploma in Public Health of some University or College, and the candidate who elects to present a Dissertation may be examined in the subject thereof.

Degree of Master of Surgery.—The degree may be taken in General Surgery or in Special Subjects. Candidates shall be Bachelors of the University who have practised for two years in an approved hospital (including the holding of an approved appointment for six months) and one of the two years shall have been spent in a hospital with a medical school attached. They shall present a Dissertation and pass an examination. For General Surgery, the examination shall include a written examination in Surgery, a written examination in Surgical Anatomy and Surgical Pathology, a Clinical examination, an oral examination and an examination in Operative Surgery. For special subjects—that is, Ophthalmology or Oto-rhino-laryngology or Gynæcology—the examination shall include a written examination in the Anatomy, Physiology, and Pathology of the region of the body concerned (including in the case of Ophthalmology, Physiological Optics) and a written examination in General Surgery together with a written, oral, and clinical examination in the particular branch of Surgery concerned, as well as an examination in Operative Surgery of the region concerned.

Scholarships and Prizes.—The following are awarded: The Ashworth Hallett Scholarship, value £40, open to women only; two Martyn Memorial Pathological Scholarships of £10 each; the Tibbits Memorial Prize, value 7 guineas, for proficiency in practical surgery; the Committee's Gold and Silver Medals for fifth or sixth year students for general proficiency; the Augustin Prichard Prize, value about 6 guineas, for proficiency in anatomy; the Henry Clark Prize, value 11 guineas, for proficiency in gynæcology; the Crosby Leonard Prize, value 6 guineas, for proficiency in surgery; the Suple Surgical Prize, a gold medal and 7 guineas; the Suple Medical Prize, a gold medal and 7 guineas; the Henry Marshall Prize, value £12, for dressers; the H. M. Clarke Scholarship, value £15, for proficiency in surgery; the Sanders Scholarship, value £22 10*s.*, for general proficiency; the Barrett-Roué Scholarship for proficiency in diseases of the eye, ear, nose, and throat or skin, value £17; Lady Haberfield Scholarship, value about 25 guineas; the Paul Bush Gold Medal in alternate years to best Resident Medical Officer at Royal Infirmary; Markham Skerritt Memorial Prize, awarded every three years to that member of University, not a member of Medical Board, who, in opinion of that Board, has published the best original work during the three years.

Bristol City Senior Scholarships and those offered by the Counties of Gloucestershire, Somerset, Wilts, and Dorset and the City of Bath are tenable in the University. There are also a Miriam Badock Scholarship of the value of £120, H. H. Wills Science Scholarships, open to boys proceeding from Clifton College; and the Harold Greenwood Memorial Scholarship, of the value of £20, open to boys who have received instruction at State-provided schools in Clevedon (or elsewhere in Somerset) and subsequently at secondary schools in Somerset or Bristol. The Beaverbrook Fellowship and some of the Fellowships awarded by the Colston Research Society for research in the University are allotted to the Faculty of Medicine. University Graduate Scholarships are open to graduates of not more than one year's standing. The Michael Hiatt Baker Scholarship of the value of £200 is open to graduates from New Zealand for research in the University.

Clinical Studies.—The Allied hospitals (BRISTOL ROYAL INFIRMARY and BRISTOL GENERAL HOSPITAL) have between them more than 700 beds and extensive out-patient departments, special clinics for Diseases of Women and Children, including antenatal and postnatal work, also for eye, ear, nose and throat, and skin diseases, in addition to large and well-equipped departments for Dental work and large outdoor Maternity Departments. The Bristol Royal Infirmary has now been selected by the National Radium Commission as a Radium Centre.

At each of these institutions there are well-arranged pathological museums, post-mortem rooms, and laboratories for morbid anatomy. There are also laboratories for work in clinical pathology, bacteriology, and biochemistry, in which special instruction is given in these subjects. Departments are provided and well-equipped for radiology, radiotherapy, actinotherapy, electrotherapy, and massage, with all forms of physiotherapy.

The students of the school also attend the practice of the Royal Hospital for Sick Children and Women, containing 120 beds, and that of the Bristol Eye Hospital with 40 beds, the Bristol Mental Hospital, Southmead Hospital, and Ham Green Fever Hospital. Other institutions, including Stoke Park Colony for mental defectives and the Winford Orthopædic Hospital, are also available for their special purposes.

There are numerous salaried junior appointments for residents who are graduates.

Post-graduate Study.—Qualified medical practitioners may be appointed as clinical assistants for a period of one or more months. They may act as assistants, if times permit, in more than one department and in any of the hospitals during their period of study. They will be entitled to the use of the clinical laboratories and medical library, and have the right to attend in all departments, including operations, post-graduate and ordinary clinical demonstrations, and post-mortem examinations. Demonstration courses are held at various times when applied for by groups of practitioners.

All inquiries and applications for admission should be addressed to the Director of Post-graduate Studies (Clinical Section), Department of Medicine, University of Bristol, who can be seen on any day by appointment.

Further information as to scholarships, curricula, and fees can be obtained from the Dean of the Faculty of Medicine or the Registrar of the University.

UNIVERSITY OF WALES

THE WELSH NATIONAL SCHOOL OF MEDICINE

The University grants degrees in Medicine and Surgery—Bachelor in Medicine and Bachelor in Surgery (M.B., B.Ch.), Doctor in Medicine (M.D.), and Master in Surgery (M.Ch.)—and Diplomas in Public Health and Tuberculous Diseases.

Degrees of Bachelor in Medicine and Bachelor in Surgery.—Candidates are required to pursue a course of study of not less than six academic years subsequent to their matriculation in the University, and of these years at least three must have been passed in one of the constituent colleges situated at Aberystwyth, Bangor University College of South Wales and Monmouthshire, Cardiff and Swansea. They must hold an arts or science degree of the University of Wales, or of some other University approved for the purpose, but certain of the courses pursued for a B.Sc. or a B.A. degree may be counted as required for the Medical degrees.

The courses for the M.B., B.Ch. are divided into two sections. The first includes the preliminary subjects: (*a*) Physics, Chemistry, Botany, and Zoology; and (*b*) Organic Chemistry, Human Anatomy, and Physiology. Study of the preliminary subjects and of Organic Chemistry must extend over at least one academic year; study of Physiology and Human

Anatomy must extend over at least two academic years; the first section of the course must occupy not less than three years. The second section includes courses in (*a*) Pathology and Bacteriology, Materia Medica and Pharmacology, (*b*) Hygiene and Forensic Medicine, (*c*) Medicine, Surgery, and Obstetrics and Gynæcology. These courses cannot be commenced until the examinations relating to the preliminary and ancillary courses have been passed. Examinations in all the subjects are held in June of each year, and in Pharmacology, Pathology, Medicine, Surgery, Obstetrics, and Gynæcology, in December also.

Degrees of Doctor in Medicine and Master in Surgery. Bachelors of not less than two years' standing may become candidates for the degrees of Doctor in Medicine (M.D.) and/or Master in Surgery (M.Ch.).

Post-graduate Study.—Certain courses of Post-graduate study are given during the year, and facilities may be offered to graduates in medicine and other duly qualified persons to carry out research work in the different departments of the Medical School.

Clinical Institutions.—Clinical teaching is carried out in the Cardiff Royal Infirmary (490 beds); the Llandough Hospital (City of Cardiff) (340 beds); the City Lodge Hospital (City of Cardiff) (420 beds); the Cardiff City Mental Hospital (790 beds); the Cardiff City Sanatorium (Fevers) (300 beds); the Prince of Wales' Hospital (Orthopædic) (136 beds); the Cefn Mably and Glan Ely Hospitals (Tuberculosis) (298 beds). These Institutions are modern and well equipped, and provide facilities for both In-patient and Out-patient Clinical Instruction. The Cardiff Royal Infirmary is the main teaching hospital. It serves a district having a population of more than half a million, and during the year 1933 6325 patients were admitted to the wards, and 38,010 patients treated in the Out-patient Departments.

Scholarships, Free Studentships, Prizes, and Medals. Entrance Scholarships, County Free Studentships and Scholarships are available for Medical Students in the first three years of their scheme of study. Particulars of these are contained in a special Prospectus, which can be obtained on application. An Isaac Roberts Scholarship in Science, of the value of £50 per annum, tenable for three years, is awarded triennially on the results of the Entrance Scholarship Examination of the Cardiff College. The Samuel Brothers' Scholarship, value £12 to £15, is awarded annually on the results of the work of the first year of the Medical Course at Cardiff College. The Dr. Price Prize, value £50, is awarded annually on the results of the work of the first year of the Medical Course at the Cardiff College. The Dr. Howell Rees Scholarship, value £17 10*s*., is awarded triennially, and is held in the Welsh National School of Medicine; it is awarded on the result of the examinations in Anatomy and Physiology. Numerous other prizes are awarded for proficiency in different subjects.

Research Scholarships.—A Catherine Buckton Scholarship of £60 for one year is offered periodically by the Council of Aberdare Hall (one of the Halls of Residence for Women Students) to a woman who shall undertake to do Post-graduate work. The Mrs. John Nixon Research Scholarship of £150 per annum is available for the promotion of research in Medicine and Medical Pathology. The Lord Merthyr Research Scholarship, value £200 per annum, is available for the promotion of research in Cancer. A Cecil Prosser Research Scholarship, value £250 per annum, is available for the promotion of research in Tuberculosis. The Ewen Maclean Research Scholarship, value £150 per annum, is available for the promotion of research into the factors which constitute and the conditions which vary resistance to disease, especially as regards midwifery.

Regulations regarding the diplomas in Public Health and Tuberculosis are detailed elsewhere.

All inquiries should be addressed to the Secretary, Welsh National School of Medicine, The Parade, Cardiff.

ENGLISH MEDICAL CORPORATIONS GRANTING DIPLOMAS

CONJOINT EXAMINING BOARD

All the schools described under the heading of the Universities to which they are attached are recognised as suitable places of instruction by the corporations granting medical diplomas. On p. 418 will be found the Metropolitan Hospitals, where general and special studies can be pursued. On p. 424 is a list of the centres outside London affording educational facilities. The courses of study at the principal colonial medical schools are also recognised as qualifying for the examinations of these corporations.

Students of the Royal Colleges pass a Preliminary Examination in General Education recognised by the Board, and a *Pre-Medical Examination* in Chemistry, Physics, and Elementary Biology conducted by the Conjoint Examining Board before commencing the five years curriculum of professional study or some other examination recognised by the Board—namely, the examination in Chemistry, Physics, and Biology for the degree in Medicine of any University recognised by the Board; the Higher School Certificates of Oxford and Cambridge Universities, and the Oxford and Cambridge Schools Examination Board; the Higher Certificates of London, Bristol, Durham Universities, the Joint Matriculation Board of the Northern Universities, and the Central Welsh Board Higher Certificate. A candidate must enter for Chemistry and Physics together, and he will not be allowed to pass in one without obtaining at the same time at least half the number of marks required to pass in the other subject. No study of anatomy and physiology is recognised before this examination is passed. Not more than two terms of professional study (Anatomy and Physiology) will be recognised before Elementary Biology is passed. He will be admitted to the examination on producing evidence of having passed the required preliminary Examination in General Education. The examination is partly written, partly oral, and partly practical. A candidate rejected in one or both subjects of the examination will not be admitted to re-examination until after the lapse of a period of not less than three months.

There are two Professional examinations called the *First* and *Final Examinations*. The courses of study for these examinations may be commenced before the Pre-Medical examination in Biology or some equivalent examination has been passed, provided that three terms of study are completed after the examination has been passed.

The subjects of the First Professional Examination are: Section I. (*a*) Anatomy, including Histology and Embryology; (*b*) Physiology, including Biochemistry. Section II. Pharmacology and Materia Medica. A candidate must have attended at a recognised Medical School courses of instruction in Anatomy, including Embryology, during five terms, during which he must have dissected the whole body, courses of instruction in Physiology, including Biochemistry during five terms, courses of instruction in Pharmacology and Materia Medica. A candidate may present himself for the two Sections together or separately, but he must take parts (*a*) and (*b*) of Section I. together until he has passed in one or both parts, but a candidate will not be allowed to pass in one part unless he obtains at the same time at least half the number of marks required to pass in the other part.

Section II. of the examination may be passed at any time before the candidate enters for the Final Professional Examination, provided that the courses for Section I. have been completed. A candidate who produces satisfactory evidence of having passed an examination in the subjects of Section I. or of either part of Section I. and of Section II. in the examination for the degree in Medicine conducted at a University recognised by the Board will be exempted from further examination in such subjects.

Final Professional Examination.—The subjects of the Final Professional Examination are: Section I. Pathology (including Morbid Anatomy, Morbid Histology, and Clinical Pathology) and Bacteriology. Section II. Part I. Medicine, including Medical Anatomy, Forensic Medicine, and Public Health. Part II. Surgery, including Surgical Anatomy and the use of Surgical Appliances. Part III. Midwifery and Gynæcology. The examination is partly written, partly practical, partly clinical, and partly oral. A candidate may take Sections I. and II. and the three parts of Section II. of the Final Examination separately or may take the whole examination together. He will be required to produce the certificates required by the regulations before being admitted to the respective parts of the examination. Members of recognised universities outside the British Possessions are admissible to the examinations of the diplomas of L.R.C.P. and M.R.C.S. under special conditions. Graduates in medicine and surgery are required to pass the first examination and to complete 24 months hospital practice before admission to any part of the final examination. Undergraduates are required to complete the full curriculum of 33 months for the final examination after having passed the first examination. For further information see the current regulations of the Conjoint Examination Board in England.

Members of certain recognised Indian, Colonial, and Foreign universities who have passed examinations for the Degree of Doctor or Bachelor of Medicine or Surgery in the subjects of the First Examination may present themselves for the Final Examination under special conditions. The Board also grants Diplomas in Public Health, in Psychological Medicine, in Ophthalmic Medicine and Surgery, in Tropical Medicine and Hygiene, in Laryngology and Otology, in Gynæcology and Obstetrics, and in Medical Radiology. Candidates must hold a Medical qualification registrable in the United Kingdom or be Graduates in Medicine of a recognised Indian, Colonial, or Foreign University.

Particulars may be obtained from the Secretary of the Examining Board, Examination Hall, Queen-square, London, W.C.1.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

THE MEMBERSHIP AND FELLOWSHIP

The College confers two separate diplomas—the *Fellowship*, a purely honorary distinction, and the *Membership*, obtained by examination.

Membership.—The age for admission to this diploma, it will be noticed, has been changed from 25 to 23 years. The alteration in the by-law of the College is designed to enable men who have just finished house appointments to sit for an examination for which their recent clinical experience has exactly fitted them. The candidate must either have obtained the licence of the College, or a degree of Doctor or Bachelor of Medicine at a University which is registrable by the General Medical Council and is recognised by the Censors Board. The examination is directed partly to pathology and partly to the practice of medicine. Credit is also given to candidates who show a knowledge of Latin, Greek, French, or German. Further information may be obtained from the Registrar at the College.

Fellowship.—Fellows are selected annually from the ranks of Members by the Council of the College.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

THE FELLOWSHIP

The Royal College of Surgeons of England confers its diploma of Fellow upon a few distinguished persons in an honorary capacity. Two Members of long standing may also be elected to the Fellowship annually. But the bulk of the Fellows obtain the diploma as the result of examination.

Fellowship.—The examination for the Fellowship is divided into two parts—viz., the First Examination and the Second Examination. The subjects of the First Examination are Anatomy and Physiology and those of the Second Examination are Surgery, including Surgical Anatomy and Pathology. The examinations are partly written and partly viva voce, and include the examination of patients and the performance of operations on the dead body. The First Examination is held in June and December and the Second Examination in May and November.

A Member of the College is admissible to the First Examination at any time after receiving his Diploma of Membership. A candidate who is not a Member is admissible after passing the First Professional Examinations of the English Conjoint Board in Anatomy and Physiology, or the equivalent examination in his University, on the production of certificates of attendance upon prescribed courses.

A Member of the College is admissible to the Second Examination at any time after having passed the First Examination on producing evidence of having been engaged not less than six years in the study (or study and practice) of the profession.

A candidate who is not a Member of the College must possess the registrable surgical and medical degrees of universities recognised by the Council and must have been engaged in the study (or study and practice) of the profession for not less than four years subsequent to the date of obtaining the recognised qualification, one year of which shall have been spent in attendance on the Surgical Practice of a recognised hospital. The diploma of Fellow is not conferred upon successful candidates until they have attained the age of 25 years.

From Jan. 1st, 1935, conditions of admission to the Second Examination will be as follows: A candidate who has passed the First Examination and who is *either* (*a*) a Member of the College who can produce satisfactory evidence of having been engaged in the study (or study and practice) of the profession for not less than six years, or (*b*) a Graduate of four years' standing in Medicine and Surgery in a University recognised by the Council for the purpose, is admissible to the Second or Final Examination on producing evidence that he has held for not less than six months the post of Resident House Surgeon, or other responsible post in charge of general surgical patients in the wards of a general hospital recognised by the Council for the purpose.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS [1]

The College was founded and incorporated in September, 1929. The objects of the College are set forth in the Memorandum of Association. The first, and most important object, is "To encourage the study and practice of Obstetrics and Gynæcology, subjects which should be inseparably interwoven."

The College consists of Fellows and Members. Candidates for the Membership of the College whose names must be entered on the British Register of Medical Practitioners or on the Register of Medical Practitioners of a British Dominion or Dependency, or of the Irish Free State, or on such other Register recognised by the General Medical Council, have to show evidence of having held resident appointments in general medicine or surgery, as well as in Obstetrics and Gynæcology, before entering for the examination. The Fellowship of the College is granted to those Members who are judged by the College to have advanced the science and art of Obstetrics and Gynæcology. The Fellowship and Membership of the College include practically every teacher of Obstetrics and Gynæcology in Great Britain, and many distinguished exponents in the British Dominions.

---

[1] The British College is placed with the English Corporations, but its advantages are open, as are those of the English Colleges to all who can comply with the regulations.

The Fellowship or Membership of the College is now a necessary qualification for election to the staff of several obstetric and gynæcological hospitals, and it is hoped that in time it will be essential for election to the staff of all such hospitals. Consequently, all intending to specialise in these subjects should endeavour to obtain the Membership as soon as possible.

The College also grants a Diploma, which is intended for practitioners who have had special experience in obstetrical work and wish to produce evidence of efficiency in this subject when applying for Consultant or other posts in regard to Maternity services under voluntary, County, or Municipal control.

The Regulations for the Membership and Diploma may be obtained from the Honorary Secretary, British College of Obstetricians and Gynæcologists, 58, Queen Anne-street, London, W.1.

SOCIETY OF APOTHECARIES OF LONDON

The Pre-Medical and Primary Examinations are held quarterly. The Pre-Medical includes Chemistry, Physics, and Elementary Biology. The Primary includes Anatomy, Physiology and Histology, Materia Medica, and Pharmacy. The latter examination cannot be passed before the completion of five terms' Physiology and Practical Anatomy with Demonstrations, and the first two subjects cannot be taken separately except in the event of the candidate having previously passed in one, and obtained at least half the marks required to pass in the other.

The Final Examination for the Licence (L.M.S.S.A. Lond.) is held monthly, except in September. (*a*) Principles and Practice of Surgery, including Surgical Pathology, Surgical Anatomy, Operative Manipulation, Instruments and Appliances. (*b*) Principles and Practice of Medicine, including Therapeutics, Pharmacology, Medical and General Pathology, Bacteriology, and Morbid Histology. (*c*) Midwifery, Gynæcology, Diseases of New-born Children, and the Use of Obstetric Instruments. (*d*) Forensic Medicine, Hygiene, Mental Diseases, and the Theory and Practice of Vaccination. The examination is partly written, partly practical, partly clinical, and partly oral. Sections *a*, *b*, *c*, and *d* may be taken at separate examinations, but there is no exemption from any part of the Final Examination.

The minimum period of medical study extends over five years (57 months), and three academic years (33 months) must elapse after a candidate has passed the examination in Anatomy and Physiology before he can complete the *Final Examination*. The course of study for the Final Examination includes attendance on the Surgical and Medical Practice with Post-mortem Examinations, at a hospital connected with a medical school for a period of three winter and three summer sessions, including a course of Practical Midwifery, with attendance on 20 Midwifery cases. The offices of dresser and clinical clerk must have been filled at a hospital or institution recognised by the Society.

All candidates making their first entry for the Final Examination after Jan. 1st, 1935, will be required to pass the present Section D (Forensic Medicine, Hygiene, and Mental Diseases) with Section B (Medicine, General Pathology, and Bacteriology). The Sections which may be taken separately will therefore be; A, Surgery; B + D, Medicine, etc.; C, Midwifery. The form and scope of the Examination will otherwise be unchanged.

The certificates prescribed by the Regulations must be produced before admission to the respective sections of the Final Examination.

Master of Midwifery.—The examinations for this Diploma are held in May and November. Candidates will be admitted to the examination who have been registered practitioners for at least three years and who have held a resident appointment in an institution recognised by the Society for six months or more, and who for three months in each case have attended an antenatal clinic and an infant welfare centre, also recognised by the Society. Medical officers employed by a public health authority, and having special duties connected with Maternity and Child Welfare, will be admitted to the Examination on production of evidence to that effect. The examination will be conducted by written papers and by clinical and oral tests.

Candidates for the examination must send in their certificates to the Registrar, who will supply any other information.

METROPOLITAN CENTRES AFFORDING EDUCATIONAL FACILITIES

Certain organisations and institutions provide for the needs of the medical student in his curriculum and for the post-graduate student requiring special forms of instruction and opportunities for clinical observation. Many of the institutions are recognised by the English Conjoint Examining Board as a place of study for the fifth year of the curriculum.

Special Diplomas in public health, tropical, psychological, and ophthalmic medicine, medical radiology and electrology, laryngology, otology, and tuberculosis are now granted in proof of intensive work along the different lines indicated. Of these, the Diploma in Public Health, being regulated by the General Medical Council, is registrable. Appointments to and promotion in the various Services are largely dependent on the possession of a particular diploma, and each syllabus of the special courses available at the institutions which follow, either with or without association with the Fellowship of Medicine, is planned to afford the necessary instruction.

The Special Diplomas are dealt with fully on p. 454, where the Bethlem Royal Hospital, the Maudsley Hospital, and the Diploma in Psychological Medicine are referred to. Similarly the Hospitals of the Metropolitan Asylums Board provide post-graduate as well as under-graduate facilities, while the hospitals of the Seamen's Hospital Society both supply the instruction necessary for the Diploma in Tropical Medicine and Hygiene, and coöperate in the activities of the Fellowship of Medicine and Post-Graduate Medical Association.

The Fellowship of Medicine and Post-Graduate Medical Association

Some 50 general and special London hospitals work in conjunction with this Association, which has its office at Room 28 in the House of the Royal Society of Medicine, 1, Wimpole-street, London, W. 1. Arrangements are made for courses in medicine and in surgery and the specialties, occupying the whole or part of each day for periods of one to four weeks. Daily clinical teaching arranged. Special evening clinical courses for the M.R.C.P. and F.R.C.S. (Final) Examinations are organised at intervals. Courses, demonstrations, and lectures arranged by the Fellowship of Medicine are open only to members of the Fellowship. The membership fee is £1 1*s*. per annum, which includes the subscription to the monthly *Post-Graduate Medical Journal*. The provisional list of Special Courses impending will shortly be available. Full information regarding the courses of study and fees can be obtained from the Secretary.

Infectious Hospitals of the London County Council

Classes of instruction in fevers for under-graduate medical students are given at the various hospitals. In addition, classes of instruction for the Diploma in Public Health, which comply with the rules of the General Medical Council for that diploma, are given at two of these hospitals—viz., the North-Western Hospital and the Brook Hospital. Full particulars relating to the classes at the hospitals may be obtained on application to the Medical Officer of Health, London County Council, Public Health Department (Special Hospitals), County Hall, Westminster Bridge, S.E.1.

Seamen's Hospital Society

The Society possesses six establishments: the Dreadnought Hospital at Greenwich, 250 beds; the Albert Dock Hospital, E.16, 53 beds; the Hospital for Tropical Diseases, Endsleigh-gardens, W.C.1, 76 beds; Tilbury Hospital, Tilbury Docks, Essex, 94 beds; King George's Sanatorium for Sailors, Bramshott, Hants, 80 beds; and the Angas Home, Cudham, 36 beds. Courses of operative surgery and surgical pathology are arranged by the London School of Clinical Medicine at the Dreadnought Hospital. Post-graduate Courses for Ship Surgeons are organised by the Society, Part II. (Tropical Medicine and Hygiene) being held at the London School of Hygiene and Tropical Medicine, commencing April 11th, and Part III. (Refresher Course in clinical subjects) at the Dreadnought Hospital, Greenwich, commencing in October.

The clinical teaching of the London School of Hygiene and Tropical Medicine is given at the Society's Hospital for Tropical Diseases, Endsleigh-gardens, W.C.1.

GENERAL

Royal Northern Group of Hospitals

The Royal Northern Hospital, Holloway, London, N.7, is the main institution of the Royal Northern Group of Hospitals, which includes the St. David's Wing for private patients, the Royal Chest Hospital, City-road, E.C., Grovelands Hospital (Recovery Branch), Southgate, the Maternity Nursing Association, and the Reckitt Convalescent Home, Clacton-on-Sea. The total number of beds in the group is 466. Besides the honorary staff, there are six anæsthetists, two pathologists, medical and surgical registrars, resident medical officer, two resident house physicians, three resident house surgeons, two resident casualty officers, one resident obstetric surgeon, and one resident anæsthetist. The large rectangular and circular wards, each of which contains 25 beds, the maternity ward and children's ward for children up to 5 years of age, the observation wards in the new Casualty Department, the six operation theatres, and out-patient department are designed with a view to offer the greatest facilities for clinical work. The Special Departments include the following: Orthopædic, genito-urinary, and neurological, physiotherapeutic, pathological, tuberculosis, venereal diseases, and X ray (recently remodelled). Patients are removed to the Recovery Branch by ambulance a few days after operation. Demonstrations are given daily in the wards and out-patient departments. Clinical assistants (qualified), clinical clerks, and pathological clerks are appointed in the general and special departments, and may receive certificates at the end of their terms of office. A new maternity department has been opened and the light department has been re-equipped. A complete hospital for paying patients has just been completed.

Post-graduate lectures and demonstrations are arranged from time to time, as advertised in the medical press.

Prince of Wales's General Hospital

This hospital, situated in Tottenham, is in the midst of a densely populated neighbourhood, and contains medical, surgical, gynæcological, and children's wards, having 238 beds. There are special departments for gynæcological cases, diseases of the eye, ear, throat, and nose, skin diseases, medical electricity, radiography, and dentistry. Operations are performed every afternoon of the week (except Saturday) at 2.30 P.M. Clinical instruction is given in the wards and out-patient departments, laboratories, and lecture hall in connexion with the North-East London Post-Graduate College attached. There are six resident medical officers, and clinical assistants are appointed under certain conditions. Special intensive post-graduate courses are also held at intervals throughout the year.

West London Hospital

This hospital has 220 beds. Attached to the hospital is the West London Post-Graduate College. The practice of the hospital is reserved exclusively for qualified men. Instruction is given in the medical and surgical out-patient rooms and demonstrations are given in the wards. Clinical assistantships are obtainable in the various general and special out-patient departments. The accommodation for post-graduates consists of a lecture room, together with reading, writing, and class rooms. The hospital has a fully equipped pathological laboratory. The certificate of the hospital is accepted by the Admiralty, War Office, Colonial Office, and India Office in cases of study leave, and by the Conjoint Board of Examiners.

National Temperance Hospital

The hospital (Hampstead-road, N.W.) contains 152 beds. The medical and surgical practice of the hospital is open to students and practitioners. Operations: Monday, 1.30 P.M.; Tuesday, 2.30 P.M.; Wednesday, 2 P.M.; Thursday, 8 A.M.; Friday, 11 A.M. Out-patient Departments for special diseases have been opened: Diseases of the Stomach and Disorders of Digestion, Dermatology, Ophthalmology, Oto-rhino-laryngology, and Chest.

Hampstead General and North-West London Hospital

In-patient Department: Haverstock Hill, N.W.; Out-patient Department: Bayham-street, Camden Town (138 beds—viz., 109 free, 8 isolation and observation, and 21 paying or contributory). Serves Hampstead and the populous districts of Kentish Town and Camden Town. The out-patient and casualty departments are at Bayham-street, Camden Town. Hampstead casualties are received at Haverstock Hill. In addition, consultative clinics are held at Haverstock Hill, where patients are seen upon presenting letter from their doctors. There is a post-graduate School free to the medical practitioners of the district. The hospital is also associated with the Fellowship of Medicine.

Metropolitan Hospital

This hospital has 150 beds, 17 of which are reserved for children. The adult accommodation includes special wards for the reception of Hebrew patients, and there is a Kosher kitchen and Jewish cook. Operations are held in the afternoons daily, except Saturdays and Sundays. The out-patient department is a large one, and has facilities for the treatment of all diseases; Jewish patients can attend special sessions. Special departments comprising: Neurological, Ophthalmic, Rectal Diseases, Diseases of Women, Genito-urinary, Diseases of the Throat and Ear, Eye and Skin, Electrotherapeutics, Dental, and V.D. Attached to the hospital is a Tuberculosis Dispensary for patients from the boroughs of Hackney and Stoke Newington.

Queen Mary's Hospital for the East End

This hospital has developed from the West Ham and Eastern General Hospital. It has 219 beds and ministers to a very poor public. Founded as a dispensary in 1861, and developing into a hospital in 1890, steady extensions have been made during this century. A Royal Charter was obtained in 1917, and the hospital has become a valuable charity with a full medical staff of physicians and surgeons, and specialists for gynæcology, obstetrics, ophthalmological surgery, radiology, dermatology, and dental surgery. The Fellowship of Medicine makes frequent use of the opportunities.

NEUROLOGY

National Hospital, Queen-square

The hospital, with the Convalescent Home at East Finchley and branch at Clapham Park, contains 265 beds and cots. The out-patient physicians attend every Monday, Tuesday, Wednesday, Thursday, and Friday at 2 P.M., and the physicians daily. Clinical clerks are appointed under physicians and clinical assistants to out-patient physicians. Post-graduate Courses of Lectures and Demonstrations are held twice every year, usually commencing in January and October, and lasting about ten weeks. Special courses in Neurological Ophthalmology, Neuropathology, and the Anatomy and Physiology of the Nervous System are given. The Pathological Laboratory is available for special work under the Pathologist.

West End Hospital for Nervous Diseases

This institution is recognised by the University of London and by the Conjoint Board as a school of instruction in Neurology for the M.D. degree, Branch III., and for the D.P.M. The Out-patient Department is in Welbeck-street, W.; the In-patient Department is at Gloucester-gate, Regent's Park, and contains 78 beds. Completely equipped with pathological and other special departments, the hospital offers every facility for instruction in Neurological subjects. In conjunction with Bethlem Royal Hospital it offers courses of instruction for the D.P.M. The hospital coöperates with the Fellowship of Medicine in the programmes of special post-graduate teaching organised by the Association. A concentrated week's course for general practitioners will be held this year from Oct. 29th to Nov. 3rd. The practice of the hospital is open to students and practitioners by arrangement. Appointments as Hon. Clinical Assistants in the Out-patient Department are open to registered medical practitioners. Senior and Junior Resident House Physicians are appointed for a period of six months in the first place with remuneration at the rate of £150 and £100 per annum, respectively. The Savill Memorial Prize (value £15) and Medal are offered biennially for competition among post-graduate students who have attended the practice of the hospital or any special course.

Hospital for Epilepsy and Paralysis

This hospital in Maida Vale, W., contains 88 beds, including 20 private wards and 6 pay beds. Both in-patient and out-patient departments are open free to students, as well as to medical graduates. The out-patient department is open every week-day except Saturday at 2 P.M.

HEART AND LUNGS

Royal Chest Hospital

The Royal Chest Hospital, City-road, E.C., associated with the Royal Northern Group of Hospitals, has accommodation for 84 in-patients and a large out-patient department, open daily. Special departments include Thoracic Surgery, Laryngology, Radiology, Electrocardiograph, Massage and Physical Exercises, and an Ultra-violet Light clinic. Clinical Assistants are appointed to work with the physicians in the out-patient department. The Tuberculosis Dispensary for Islington South is attached to the hospital.

Brompton Hospital for Consumption and Diseases of the Chest

The hospital contains 344 beds, of which 30 are allocated to the Surgical side and 98 to Paying Patients. A further 150 beds are provided at the Sanatorium at Frimley, which also contains beds for paying patients. The beds for paying patients at the hospital are so divided up as to provide Wards of two and five beds each at a small inclusive fee, and single bedrooms in which the fees are non-inclusive. A first assistant resident medical officer, whose duties include those of assistant to the surgeons, is appointed annually; a second assistant resident medical officer, who assists in the artificial pneumothorax clinic, is also appointed annually. There are six resident house physicians, whose duties include attendance at the out-patients' and special departments, and one of these serves as assistant to the tuberculosis officer for Chelsea; these officers are appointed for a term of six months each. Post-graduates are admitted to the practice of the hospital. Clinical assistants are appointed to the in-patient and out-patient physicians, the surgeons and the special departments of the hospital. Clinical demonstrations in the Wards, the out-patient and special departments are given throughout the year, and two special post-graduate courses of one week each, and three week-end courses are held annually. Special courses are also held in the Pathological Department. The medical practice of the hospital is recognised by the Conjoint Board, the University of London, the Apothecaries Society, and the Army and Navy and Indian Medical Boards. Four special courses for students of eight demonstrations each are held during the year before each final Conjoint Board Examination.

City of London Hospital for Diseases of the Heart and Lungs

(186 beds). Special Departments: Surgical, Laryngological, Bronchoscopical, Radiological, Pathological, Electrocardiographic. Assistants are appointed to the Clinics, and a limited number of research workers to the Pathological Department. The in-patients staff visit generally in the afternoon; out-patients at 2 P.M. Graduates are admitted on payment of fees which entitle them to attendance at clinics, post-mortem demonstrations, and operations. Special demonstration and lecture courses are provided, and a club room. Graduates desiring Assistantships in any department should address applications to the Head of that department. A Tuberculosis Dispensary (Boroughs of Bethnal Green and part Hackney) is established at the Hospital.

National Hospital for Diseases of the Heart

The practice of the hospital, with 44 beds, is open daily to post-graduates and others. Systematic courses of instruction, with lectures and clinical demonstrations, are arranged during the winter and summer sessions; in addition an intensive course, of a fortnight's duration, takes place in January, June, July, and October of each year. The hospital is fully equipped with all the modern instruments for the investigation of the diseases of the cardiovascular system, and facilities exist for those requiring practical instruction in electrocardiography, X rays, and other graphic methods. Clinical Assistants in the out-patient department are appointed from time to time.

DISEASES OF WOMEN AND CHILDREN

Hospital for Sick Children

The Hospital is situated in Great Ormond-street, W.C., contains 252 beds, and has an Out-patients' Department attended by some 30,000 new cases each year. There are Asthma, Dental, and Rheumatic Clinics. The practice is open to students of both sexes who have completed four years' medical study and also to qualified medical men and women. Members of the Medical Staff are recognised by the University of London as teachers in Diseases of Children. Clinical instruction is given daily by Members of the Honorary Medical Staff. Clinical Clerks are appointed once a month. These appointments are open to students of recognised medical schools. Arrangements have been made with the London School of Medicine for Women for the routine admission of their students for Clerkships in the wards. Time spent in clerking and dressing is recognised by the Universities of London, Oxford, and Cambridge as part of the final curriculum. Facilities are afforded to post-graduates for obtaining theoretical and practical instruction in Clinical Pathology, Bacteriology, and Medical Biochemistry in the Laboratories. In addition, special courses lasting a fortnight and consisting of about 60 lectures, &c., of one hour each, are held twice yearly, usually in May and October.

Queen Charlotte's Maternity Hospital and Midwifery Training School

This hospital, formerly Queen Charlotte's Lying-in Hospital, is situated in Marylebone-road, N.W. The hospital receives over 2700 patients annually, besides having a large out-patient department. Medical students and qualified practitioners are received at all times of the year. They have unusual opportunities of seeing obstetric complications and operative midwifery on account of the very large number of primiparous cases—nearly one-half of the total admissions. Clinical instruction is given on the more important cases which present themselves. They also receive valuable instruction in the Antenatal and Child Welfare Departments, where over 4000 patients attend yearly. Special Lecture-demonstrations are given by members of the staff. Certificates of attendance at this hospital are recognised by all the Universities, Colleges, and licensing bodies. Pupil midwives and maternity nurses are received and specially trained. A Residential College provides accommodation for students and qualified practitioners (both men and women), and is opposite the hospital, with which it is in telephonic communication.

Arrangements have been made for Medical Students to receive the preliminary instruction in Practical Midwifery recommended by the General Medical Council.

The Isolation Block (30 beds) for Puerperal Fever and Puerperal Pyrexia, which has been built on the new site at Ravenscourt Park, Hammersmith, was opened for the reception of patients in September, 1930, and the Research Laboratories, which have been erected adjoining this block, are now in full working order. Students may attend the clinics conducted by the staff at the Isolation Block.

City of London Maternity Hospital and Midwifery Training School

This hospital (City-road, E.C.) receives nearly 1700 in-patients annually, in addition to attending mothers in their homes. Monthly or fortnightly residential courses are provided for two Medical Students at a time and facilities are offered to Post-graduates to see the work of the Antenatal Clinics on three mornings weekly. Pupil Midwives and Maternity Nurses receive the recognised course of training, assisted by a Sister Tutor.

Royal Waterloo Hospital for Children and Women

This hospital has recently undergone considerable extensions and has now 130 beds, while the latest buildings include a Nurses' Home, a new Operating Theatre, and private pay beds. It has a full staff of surgeons, physicians, and gynæcologists, and also special departments. Amongst the many new additions to the equipment of the hospital is an Electrocardiograph apparatus. A new Orthopædic Department is in use, and the Physiotherapeutic and Electrical Department has been extended and re-equipped. There are facilities for post-graduates to attend the general and special clinics in medicine and surgery for in-patients, and for out-patients, including a genito-urinary clinic, a clinic for varicose veins, a L.C.C. Clinic for children suffering from rheumatic fever and chorea, and the X ray department for gastro-intestinal diagnosis. Particulars of post-graduate courses, which are held from time to time, can be obtained from the Secretary of the Hospital.

Victoria Hospital for Children

This hospital in Tite-street, Chelsea, S.W., contains 138 beds and a large out-patient department; the home at Broadstairs has 50 beds. There are two private wards where patients may be under the care of any medical practitioner holding an appointment on the staff of a recognised hospital, and the question of payment for his fees is arranged between him and the child's parents.

Queen's Hospital for Children

This hospital, for the sick children of the poor up to 14 years of age, was formerly known as the North-Eastern Hospital for Children. There are 160 beds in London (Hackney-road, E.2) and 44 at the seaside branch, Little Folks Home, Bexhill. Special departments in Ear, Nose, Throat, Skin, and Eye, and Dentistry. Rheumatic Clinic in coöperation with L.C.C. schools twice weekly. A radiologist attends four times weekly. There are massage and light departments, and a special whooping-cough physician. The practice of the hospital is open to students by arrangement with the medical staff, and post-graduate instruction in children's diseases, lectures and demonstrations are given at times notified by the Fellowship of Medicine.

Paddington Green Children's Hospital

This is a hospital of 51 beds, with a large out-patient department and a full staff, with Eye, Ear, Skin, Light, and Dental departments. The facilities which it offers for observation of clinical practice are used by the Fellowship of Medicine.

Hospital for Women, Soho

This hospital in Soho-square, W., contains 81 beds. The teaching is available for post-graduates only in limited numbers. Operations take place on Tuesdays, Wednesdays, and Thursdays at 2 P.M. and on Wednesdays and Fridays at 9.30 A.M. The X ray department is supplied with the latest installation both for diagnosis and treatment, and experience can also be gained in the treatment of malignant disease by means of radium. Incorporated is the London School of Gynæcology, comprising attendance in out-patient department, operating theatre, clinical lectures, and X ray treatment.

Samaritan Hospital for Women

Contains 70 beds. Qualified practitioners are admitted as clinical (gynæcological) assistants to both the in- and out-patient departments. Full particulars may be obtained from the Secretary to the Medical Committee at the hospital, Marylebone-road, N.W.

Princess Elizabeth of York Hospital for Children

There are 140 beds. Clinical instruction in Pædiatrics is given to fifth-year Students at the hospital in Glamis-road, Shadwell, E. Two clinical clerkships for qualified or unqualified students are open every three months. Clinical assistants are from time to time appointed in the out-patient department. There is an Orthopædic Clinic on Wednesdays and a Rheumatism Clinic on Fridays. Special instruction in Infant Feeding. Post-graduate Clinical Demonstration on the third Wednesday in each month at 3.30 P.M.

Chelsea Hospital for Women

This hospital has 104 beds; 18 for patients paying £5 5*s.* a week and moderate fees to the surgeons for operations. There is a convalescent home of 32 beds at St. Leonards. In the out-patient department the patients are seen at a nominal payment or with subscribers' letters. The hospital caters for post-graduate teaching. In the out-patients' department clinical assistantships can be obtained which entitle the holder to attend and examine patients under the instruction of the visiting surgeons. The operating theatre is open to visitors, and all operations are demonstrated and discussed by the surgeons. The Pathological Department contains one of the finest gynæcological museums in the country. Special intensive courses, with lectures and special demonstrations, are held three times a year through the organisation of the Fellowship of Medicine.

Evelina Hospital and Belgrave Hospital

The Evelina Hospital, Southwark (80 cots), and the Belgrave Hospital (76 cots), Clapham-road, also give facilities for out-patient practice.

CANCER

Cancer Hospital (Free)

The hospital, situated in Fulham-road, S.W., contains 135 beds for poor persons afflicted, who are admitted free. The Out-patient Department is open every week-day, except Saturday, at 2 P.M., also Wednesday morning at 10 and Saturday morning at 11. A course of study in Physics and Radiology, qualifying for the Diploma in Medical Radiology, is given. The hospital is a recognised teaching school of the University of London, in Medical Radiology, Experimental Pathology, and Pathological Chemistry. Senior and Junior Resident House Surgeons are appointed for a period of six months at a salary at the rate of £100 per annum.

Mount Vernon Hospital

The hospital contains 130 beds for surgical cancer cases. Clinical Demonstrations are given by the visiting Surgical Staff at the hospital at Northwood. Clinical assistants are appointed to surgeons in the wards. Diagnostic and follow-up departments, 14, Riding House-street, W. Further information can be obtained from the Secretary, 32, Fitzroy-square, W.

Marie Curie Hospital

This hospital, which is officered by medical women, is a radium centre for the treatment of women suffering from cancer and allied diseases. The In-patient Department contains 39 beds, of which eight are for private patients. There is a daily Out-patient Clinic to which cases are sent for diagnosis and at which the cases already treated by radium are kept under observation. A department for deep X ray therapy was opened in January, 1934. The practice of the hospital is open to graduate visitors, and one graduate wishing to study the subject of radiology is accepted for full-time service for four to six months.

OPHTHALMOLOGY

Royal London Ophthalmic Hospital

The attendance at Moorfields Eye Hospital (Moorfields, 1804–1899), City-road, E.C. (152 beds) is now very large. Operations are performed each day from 10 A.M. to 1 P.M. and four surgeons attend daily. Students are admitted to the practice of the hospital and special courses of instruction are given, which extend over a period of five months, by members of the surgical staff and certain outside lecturers, beginning in October and March. The instructions and classes are arranged to meet the requirements for the various diplomas in Ophthalmology, both for the preliminary examinations in Anatomy, Physiology, and Optics, and those subjects required in the second part. Students of the hospital are eligible as house surgeons or clinical and junior assistants. House surgeons are appointed every six months, clinical and junior assistants every three months. During the past few years certain improvements have been made. A floor of private wards has been opened and the capacity of the hospital increased, and at the moment the out-patients' department is being rebuilt, together with the Medical School, including the Pathological and Bacteriological Departments. When these are finished the arrangements for instruction will be very much improved.

Royal Westminster Ophthalmic Hospital

This hospital, in Broad-street, Holborn, W.C. (86 beds, including 14 rooms for paying patients), has removed from its original site at Charing Cross to much larger premises, well adapted for teaching purposes. The clinics are held in the afternoons from 1.30 P.M. Operations are performed daily in the theatre at 3 P.M. Lectures and practical classes in the various branches of Ophthalmology, including Operative Surgery, Bacteriology, and Pathology, are held during the winter and summer sessions at 5 P.M. The practice of the hospital is open to both men and women practitioners, and medical students. Post-graduate students at the hospital are eligible for appointment as house surgeon, assistant house surgeon, refraction officer (seven appointments paid), and senior and junior assistants.

Royal Eye Hospital

There are 46 beds at this hospital, which is situated in St. George's-circus, Southwark, S.E., and an annual attendance of 68,000 patients. The staff attend daily, Mondays to Fridays at 2 P.M., and on Saturdays at 9.30 A.M., when clinical instruction is given. Special classes held in May and October are planned to meet the requirements of students preparing for the D.O.M.S. and similar examinations, and cover Anatomy, Physiology, Optics, Clinical Ophthalmology, Operative Surgery, and Pathology. Clinical Classes in medical ophthalmology are held for candidates for the M.R.C.P. examinations. A Course suitable for general practitioners is held in April under the auspices of the Fellowship of Medicine. Apart from the Honorary Staff of six Surgeons, there are also a Pathologist, a Bacteriologist, two resident House Surgeons, 12 Chief Clinical Assistants, 24 Clinical Assistants, 14 L.C.C. Refraction Officers, 10 Hospital Refractionists, and an officer in charge of the Squint Training Clinic. Reference departments for general medicine, neurology, dental treatment, ear, nose, and throat investigations, orthoptic training, and radiology, including ultra-violet therapy are available. The pathological and bacteriological departments are available to ophthalmic surgeons and institutions desiring reports on specimens, cases of interest being dealt with without charge. A Research Scholarship in Ophthalmology to the value of 100 guineas per annum is awarded yearly.

Central London Ophthalmic Hospital

This hospital, in Judd-street, St. Pancras, W.C., has 51 beds, and clinical teaching is given daily. The Pathological and Bacteriological Laboratories have been rendered available for the use of any ophthalmic surgeons who desire to send specimens for examination. A small fee is charged for a report. An Orthoptic Department for the treatment of cases of squint has been established, and pupils are taken for training in this work. Voluntary ophthalmic clinics are held on Mondays and Thursdays at 4.30 P.M. Ten private rooms are available for private patients. A clinical Demonstration is held by members of the staff at the Central London Ophthalmic Hospital at 5 P.M. on the first Tuesday of every month. Doctors and students of medicine are admitted free.

GENITO-URINARY AND VENEREAL DISEASES

London Lock Hospital and Home

There are 74 beds for men, women, and children. Male out-patients are seen at 91, Dean-street, Oxford-street, W.1, at any time from 10 A.M. until 10 P.M. daily (Sunday, noon–10 P.M.). Intravenous injections are given at every clinic. Irrigations for males are given daily from 9 A.M. to 11 P.M. Female out-patients and children are seen daily at 283, Harrow-road, Paddington, W.9, from 9 A.M. until 8 P.M. Irrigations for females are given at any time. The hospital is linked up with the Fellowship of Medicine; special courses of lectures are held in May and November each year, and application for tickets should be made direct to the Secretary of the Fellowship. Only a limited number of practitioners and students are permitted to attend the practice of the Female Lock Hospital, and application should be made to the Dean at the Male Lock Hospital between the hours of 11 A.M. and 5 P.M.

St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum

At St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum, City-road, E.C. (founded 1835), for men and women, there are 63 general beds and 9 private beds. Operations are performed on Mondays, Tuesdays, Wednesdays, and Thursdays at 2.30 P.M. and Saturdays at 11 A.M. Medical practitioners and students are invited to the operations and to the clinical instruction in the wards and in the out-patient department. Three weekly courses are held during the year in coöperation with the Fellowship of Medicine.

St. Peter's Hospital for Stone

The hospital in Covent Garden is thoroughly up to date in all departments, and research is still carried out with radium specially loaned for the purpose by the British Empire Cancer Campaign. Medical practitioners and students are invited to attend the practice of the Hospital in the out-patient department, excepting that the only clinic open to medical women is that held at 9.30 A.M. Fridays for women and children. The operating theatre is open to medical visitors as follows: Mondays, Tuesdays, Thursdays 2 P.M., Fridays 2.30 P.M. Special courses of lectures and demonstrations are held in May and November by arrangement with the Fellowship of Medicine.

All Saints' Hospital

The in-patient department of the All Saints' Hospital for Genito-Urinary Diseases is at Austral-street, West-square, St. George's-road, S.E., contains 55 beds, including those in 4 private wards and cubicles, and the terms of admission are free or by payment according to means. The out-patient department provides clinical instruction through the Fellowship of Medicine, in addition to which demonstrations in cystoscopy and other branches of genito-urinary work are available for all medical practitioners at the Out-patient department on Monday, Tuesday, Wednesday, Thursday, Friday, and Saturday afternoons at 2 P.M., without fee.

ORTHOPÆDICS

Royal National Orthopædic Hospital

This institution, situated in Great Portland-street (480 beds), is a good example of the fusion of scattered activities for the creation of an effective whole. The three orthopædic hospitals of the metropolis were combined for the formation of this central institution at the instance of King Edward's Hospital Fund, with the result that the grants from this Fund and the income from subscriptions can now be used to far better purpose and with economy. The hospital has also been approved by the Ministry of Health for the treatment of surgical tuberculosis, the connexion between orthopædics and the therapeutics required in many forms of tuberculosis having become obvious. Country branch at Brockley Hill, Stanmore (280 beds). Both branches of the hospital are residential schools for physically defective children, certified by the Board of Education. A post-graduate course of 14 days is held about March each year. The out-patient department (entrance in Bolsover-street) is open every week-day, except Saturday, at 1.30 P.M. The Evening Clinic on Tuesdays from 6 P.M. to 8 P.M.

EAR, NOSE, AND THROAT

Central London Throat, Nose and Ear Hospital

This hospital in Gray's Inn-road (74 beds) is open daily to all qualified medical practitioners on presentation of their visiting cards. Demonstrations of the cases and clinical instruction are given daily by the chief surgeon of each clinic. Lectures each Friday at 4 P.M. An intensive Course of Lectures (especially suitable to D.L.O. students), with Anatomy and Physiology Class, Operative Surgery Class, Peroral Endoscopy Class, and Pathology Class is given twice yearly—in May and October. Preparatory courses in methods of Examination and Diagnosis at frequent intervals. Consultations on interesting cases take place on the fourth Wednesday in each month at 4 P.M. Clinical Assistants are appointed and are expected to hold office for at least three months. They are required to attend twice weekly at 1.30 o'clock for the afternoon, and at 4.30 o'clock for the evening clinics. New wing, with complete out-patient department and additional wards, was opened in August, 1929, and a Recovery Home at Ealing with 26 beds was opened in July, 1933.

Golden-square Throat, Nose, and Ear Hospital

The hospital (93 beds), which has absorbed the London Throat Hospital, is situated in Golden-square. Clinical instruction in the diagnosis and treatment of disease is given daily in the out-patient department from 2 to 4 P.M., and on Tuesdays and Thursdays from 6.30 to 7.30 P.M. There is an annual out-patient attendance of over 55,000. Minor operations are performed on Mondays, Wednesdays, and Fridays at 9.30 A.M. The hospital now contains 101 beds, of which 15 are for private patients. There is also semi-private accommodation at 4 guineas a week inclusive. Practitioners and medical students are admitted to the practice of the hospital, and clinical assistants are appointed periodically.

Metropolitan Ear, Nose, and Throat Hospital

The hospital is in Fitzroy-square and contains 21 beds. The Out-patient Department is opened daily at 2.30 P.M., Saturdays 1.30 P.M., to all medical practitioners and senior students for acquiring clinical instruction and technical knowledge. Operations upon in-patients are performed on Tuesdays, Wednesdays, Thursdays, and Fridays at 10 A.M. Clinical Assistants are appointed as vacancies occur.

SKIN

London School of Dermatology

The London School of Dermatology, St. John's Hospital for Diseases of the Skin, has an in-patient department (40 beds) at 262, Uxbridge-road, W., and out-patient Clinics are held daily at 2 and 6 P.M. (Saturdays 2 P.M. only), when demonstrations are given on the cases presenting themselves. The Chesterfield Lectures, constituting a systematic course in dermatology, are given on Tuesdays and Thursdays at 5 P.M., from October to March, by the hon. medical staff of St. John's Hospital and the physicians in charge of the Dermatological Departments of the London Teaching Hospitals. The lectures are free to those attending the practice of the hospital and to registered medical students. At the end of the course an examination is held for the Chesterfield Medal in Dermatology, and is open to all medical practitioners. A summer course of lectures is also held during the month of May each year. The electrical department is open daily from 2 to 4 P.M., except on Wednesdays and Saturdays. Laboratory Courses in the Pathology and Bacteriology of the Skin can be arranged.

London Skin Hospital and Hospital for Diseases of the Skin

The London Skin Hospital (Fitzroy-square) and the Hospital for Diseases of the Skin (Blackfriars-road) admit graduates to their practice, which is among out-patients. London Skin Hospital, daily at 2 P.M. and 5.30 P.M.: Hospital for Diseases of the Skin, daily at 2 P.M., and Fridays, 5.30 P.M.

CENTRES OUTSIDE LONDON AFFORDING EDUCATIONAL FACILITIES

Nearly every hospital of a general character in the country having more than 150 beds falls within this category, and certain of them have already been noticed in connexion with the universities to which their clinical practice is attached. The hospitals vary much in size and scope.

The following alphabetical list includes the provincial hospitals which are recognised by the English Conjoint Board for a part of the required training in medical and surgical practice through clerkships and dresserships.

Bath Royal United Hospital

This hospital contains 284 beds of modern construction, 72 of which are for paying patients only; possesses X Ray, Massage, Bacteriological Departments, a Pathological Laboratory, Obstetric and Gynæcological, Ear, Nose, and Throat, and Skin and Neurological Departments. Secretary-Superintendent: Mr. J. Lawrence Mears. V.D. Clinics are held on Tuesdays (for women), and on Fridays and Saturdays (for men), at 5 P.M.

Bedford County Hospital

This hospital at Bedford has 124 beds, including 15 beds in the paying and 13 beds in the maternity wards; Ear, Nose, and Throat Departments, and X Ray and Pathological Departments. There is in connexion with the institution a convalescent home (20 beds) at Aspley Heath, near Woburn Sands. The hospital is approved by the English Conjoint Board for the examinations. Secretary: Mr. B. Wadmore.

Berkshire Royal Hospital

This hospital at Reading, which contains 274 beds includes an Out-patient Department, a Casualty Department, an X Ray and Radiotherapeutic Department, Electrotherapeutic and Massage Department, an Orthopædic Department, a V.D. Clinic, a Laboratory, an Eye Theatre, Eye Wards, a Maternity Ward, a Paying Patients Unit, and a Private Nursing Staff, and two motor ambulances. The hospital is approved as a Training School for Nurses and by the Ministry of Health for V.D. Treatment. The Blagrave Branch, Calcot, contains in addition to the above 63 beds for cases of disease of bones and joints and those requiring open-air treatment.

Bradford Royal Infirmary

This hospital at Bradford contains 223 beds and, in addition, has 50 recovery beds at the Woodlands Convalescent Home, Rawdon. The acting staff consists of 4 Honorary Physicians, 4 Honorary Surgeons, 1 Honorary Radiologist, 1 Honorary Laryngologist, 1 Honorary Ophthalmic Surgeon, 1 Honorary Dental Surgeon, 1 Honorary Assistant Dental Surgeon, 2 Honorary Assistant Physicians, 2 Honorary Assistant Surgeons, 6 Anæsthetists, 1 Pathologist, 1 Physician-in-charge of Radium Therapy Department, 1 Resident Surgical Officer, 1 House Physician, and 4 House Surgeons. There are special clinics for Orthopædic cases, for Electro-therapeutic and Sunlight Treatment, and for Radium Therapy and Laryngological cases. A new hospital of 336 beds is in construction, and a self-contained block for 70 paying patients has been opened adjoining the new Infirmary. Secretary-Superintendent: Mr. J. J. Barron.

Coventry and Warwickshire Hospital

There are 307 beds available at the Main Hospital at Coventry (established 1840), and 40 beds at the Alcock Convalescent Hospital, Keresley (three and a half miles distance), which is used as an annexe. At the Main Hospital there are separate Medical, Surgical, Maternity, Children's, and Accident Wards, also separate Ophthalmic Block complete with its own Theatre. There are separate departments for Clinics for Ear, Nose, and Throat Diseases, X Ray, Electrical, and Sunlight Clinics, also V.D. Clinic. There is also an up-to-date Pathological Laboratory and Cardiograph Department.

Derbyshire Royal Infirmary

This general hospital at Derby (360 beds) was rebuilt in 1892–94. In recent years there have been numerous alterations and additions to keep pace with modern requirements. The hospital is built on the pavilion system and provides, in addition to the usual Medical and Surgical blocks, a separate Ophthalmic block of 40 beds, a separate Children's block of 34 beds (Medical and Surgical), Gynæcological Wards, and an Ear, Throat, and Nose Department. There is a large and well-equipped Out-patient Department, also separate Orthopædic, X Ray, Electrical, Pathological, and Venereal Diseases Departments. The salaried Medical Staff consists of a non-resident Staff of 1 Surgeon-in-charge of X Ray and Electrical Departments, 1 Surgeon-in-charge of Venereal Diseases Department, 5 Anæsthetists, and a Resident Staff of 4 House Surgeons, 1 House Physician, and 1 Assistant House Surgeon and Casualty Officer. Registered Medical Students are admitted to witness the medical and surgical practice on payment of fees. Superintendent and Secretary: Mr. Walter Banks, F.C.I.S.

Devon and Exeter Royal Hospital

The hospital at Exeter contains 230 beds (including special children's wards) and has a good library, museum-post-mortem room, and pathological laboratory. Attendance on the practice of this hospital qualifies for all the examining boards. There is also a Private Nursing Staff attached to the hospital. Sun balconies were added in 1933 to this wing. The "Victory" wing is for the treatment of discharged disabled soldiers and sailors. The Electrical Department now forms one of the most important sections of the hospital. At the department for the treatment of genito-urinary diseases there are three sessions per week, two for men at 3 P.M. and 7 P.M., and one for women at 3 P.M. Doctors in practice may use the museum and library.

Devon (South) and East Cornwall Hospital

This hospital at Plymouth has 240 beds. Special departments include Pathological, X Ray, Deep Therapy, Cardiographic, Ultra-violet Rays, Electro-therapeutic, Orthopædic, Gynæcological, and Aural; also medical and surgical out-patients. Pensioners are received as in-patients, and are also treated as out-patients. The hospital has been approved by the National Radium Commission as a Regional Centre for the South-West.

Gloucestershire Royal Infirmary and Eye Institution

This hospital at Gloucester has 216 beds. Secretary: F. J. Symons. An Electrical and Massage Department has been established and Venereal Clinic opened. Also Ear, Nose, and Throat Department, X Ray, Electrocardiograph, and Ultra-violet Ray Departments, Orthopædic Department, Dental Department, Pathological Laboratory, and Neurological Clinic. Sixteen beds for paying patients in new block.

Hampshire Royal County Hospital, Winchester

This hospital, which was founded in 1736, contains 158 beds. There is a private nursing staff attached. The building and amenities are completely up to date; there are an efficient Out-patient Department, a Pathological Laboratory, and an Electrical and Massage Department. A new Children's Block has been opened.

Hull Royal Infirmary

This hospital contains 267 beds, plus 100 beds at the branch hospital at Sutton-on-Hull, and has undergone steady additions and improvements, including up-to-date Ophthalmic, Radiological, Nose, Throat, and Ear, Dental, V.D., Violet Rays, and Pathological Departments, and a Clinic for Functional Nervous Diseases was opened in 1931, under the Mental Treatment Act, 1930. Recent extensions include a new Operating Theatre, Nurses' Home, and extensions to the old X Ray, Electrical, and Out-patient Departments. The Resident Staff consists of 1 Resident Surgical Officer, 2 House Physicians, 3 House Surgeons, 1 Surgeon to Special Departments, 1 Casualty Officer. Sutton Branch: 1 House Surgeon and 1 House Physician. An annexe at Withernsea has accommodation for 30 patients. The senior house physician's appointment, and that of the house physician at the Branch hospital, are recognised by the University of London for the M.D., Branch I. (General Medicine) examination. It also recognises the posts of senior house surgeon, second house surgeon, and house surgeon of the Branch hospital, for the M.S., Branch I. (General Surgery) examination. The post of house surgeon to the Special Departments is recognised by the Conjoint Board of the Royal Colleges for the examinations for the Diplomas in Ophthalmic Medicine and Surgery, and Laryngology and Otology. The hospital is also recognised by the Royal Colleges for the F.R.C.S. examinations.

Kent and Canterbury General Hospital

The hospital at Canterbury contains 137 beds. Pupils of the staff are admitted to the practice of the hospital. Operations daily. Special departments include Ophthalmic, Ear, Nose and Throat, Venereal, Orthopædic, Electrical, Actinotherapeutic, X Ray, and Bacteriological. Accommodation for paying patients is available. The hospital is recognised by the University of London for the purpose of the M.D. and M.S. examinations.

Leicester Royal Infirmary

At the Leicester Royal Infirmary there are 483 beds (children's 75 and venereal diseases 15); 80 additional beds are retained at local convalescent homes for the reception of pre-convalescent cases. A rebuilding scheme has been carried out and is still being developed, providing modern operating theatres, three new wings, a self-contained out-patients' department, pathological laboratories and post-mortem rooms, and special departments. The Children's Hospital was reconstructed and enlarged, and a Nurses' Home is now in process of enlargement to accommodate 220 nurses at a cost of £55,000. There are 13 resident salaried medical officers—viz., four house surgeons, two casualty officers, three house physicians, three anæsthetists, one dresser. The posts are filled half-yearly—April and October—and afford exceptional opportunities for post-graduate experience. Senior students are appointed as dressers and are given an honorarium (applications to the House Governor and Secretary). A post-graduate course of lectures is arranged annually by the Leicester Medical Society, and clinical classes are held for graduates preparing for M.D. and M.R.C.P.

Norfolk and Norwich Hospital

This hospital at Norwich has at present 392 beds. There is a convalescent home with accommodation for 35 patients at Cromer. The Resident Medical Staff consists of one House Physician, three House Surgeons, one House Surgeon to the Ear, Nose, Throat, and Eye Department, and one Casualty Officer. There is also a Private Patients' Home which has at present 20 beds. Students are admitted to the practice of the hospital for a fee of £5 5s. for six months. House Governor and Secretary: Mr. Frank Inch.

Northampton General Hospital

In 1926 a new isolation block of 30 beds was opened. The number of beds is 253. There is an up-to-date Pathological Laboratory; also X Ray and Therapeutic Department and V.D. Clinic. Two new operating theatres have been built, and a new ophthalmic in-patient department has recently been completed. Further particulars may be obtained from the Secretary-Superintendent. A new Deep X Ray Therapy Department is in course of construction.

Nottingham General Hospital

There are at this hospital 386 beds available for medical and surgical patients, and 110 beds are in the detached branch, known as "The Cedars" Branch of the General Hospital. The honorary staff includes 3 Physicians, 2 Assistant Physicians, 4 Surgeons, 2 Assistant Surgeons, 2 Aural Surgeons, Surgeons in charge of Radium-therapy and Orthopædics, a Physician in charge of the Skin and Ultra-violet Light Departments, a Radiologist, Anæsthetists, and Surgeon-Dentist. The special departments are the Ear, Nose, and Throat, Skin, Dental, Massage, X Ray, Deep X Ray Therapy, Orthopædic, Electrotherapeutic, Ultra-violet Light. The Resident Medical Staff consists of 2 House Physicians, 4 House Surgeons, 1 Aural House Surgeon, and 2 Casualty Officers. The hospital is a recognised training school for nurses.

Portsmouth Royal Hospital

The hospital contains 205 beds. There are Medical, Surgical, X Ray, Massage, Gynæcological, Orthopædic, and Urological Out-patients' Departments. Further particulars may be obtained from the Secretary.

Preston and County of Lancaster Queen Victoria Royal Infirmary

This is a General Hospital with 365 beds, including 72 at two Homes of Recovery. In addition to the Medical and Surgical Wards, there are special wards for Eye, Ear, Nose, and Throat conditions and Venereal Diseases, also a Maternity Department (recognised by the Central Midwives Board). The special departments include Bacteriological, Pathological, Biochemical, X Ray, including Superficial Deep Therapy, Electrocardiograph, Light (including Finsen installation), Neurological, Electrotherapeutical, Ophthalmic, Aural, Orthopædic, Dental, Venereal Diseases (including daily intermediate treatment). Radium treatment is given at the hospital in conjunction with the Manchester Radium Institute. The Visiting Staff consists of 5 Surgeons (4 in consulting practice), 3 Physicians, 3 Radiologists, 2 Eye and Aural, 1 Pathologist, 3 Anæsthetists, 1 Medical Officer to Electrotherapeutic Department, and the Resident Staff—R.S.O., 3 House Surgeons, 1 Casualty Officer, 1 House Physician.

Royal Sussex County Hospital

This hospital at Brighton has 246 beds and affords ample facilities for students, possessing a large out-patient department, including Ophthalmic, Dental, Dermatological, Ear, Nose, and Throat, X Ray, and Electrotherapeutic sections, and a well-appointed clinical research and bacteriological department. The *hospital does not take* resident pupils, but out-pupils may attend the practice of the hospital for any period not exceeding two years, on payment in advance of a fee, not exceeding 20 guineas, as the Board of Management shall direct.

Salisbury General Infirmary

This hospital at Salisbury contains 161 beds. Maternity and Antenatal Ophthalmic Wards; and Ear, Nose, and Throat Wards; maternity and child welfare clinic.

Salop Royal Infirmary

This hospital at Shrewsbury has 156 beds. The New Wing for the reception of Women and Children is capable of accommodating some 40 patients.

South Hants and Southampton Royal Hospital

This hospital at Southampton contains 275 beds with every facility for clinical instruction. There have been many alterations and additions in recent years and further extensions are at present in process. The Staff consists of: 4 Honorary Physicians, 4 Honorary Surgeons, 3 Honorary Anæsthetists, 2 Honorary Radiologists, 2 Honorary Ear, Nose, and Throat Surgeons, 1 Honorary Dermatologist, 3 Honorary Dental Surgeons, 1 Pathologist, 1 Physician in charge of Radium Department, and 6 Resident Officers. Special Departments: Ear, Nose, and Throat, Ophthalmic, Dermatological, Electrocardiograph, X Ray, Massage, and Electricity, Ultra-violet Ray, Radium (Regional Radium Centre), Pathological Institute, and large Out-patient Department.

Staffordshire General Infirmary

This hospital was established at Stafford in 1766, and has over 100 beds. It is a Training School for Nurses. Paying patients are accepted.

Staffordshire (North) Royal Infirmary

The New Infirmary opened in 1869 at Hartshill, Stoke-on-Trent, built on the pavilion plan, has accommodation for 389 patients, including Children's wards, and a Private Patients' Department of 33 beds. The Infirmary is a Regional Radium Centre (National Radium Commission), and has the following departments: Bacteriological, Pathological, Biochemical, Ophthalmic, X Ray, Electrotherapeutical (including Ultra-violet Ray Lamps), Electrocardiograph, Aural, Orthopædic, Dental, Plastic, and Venereal Diseases Clinics, including daily Intermediate Treatments. Recent extensions comprise a new ward block, new X Ray and Orthopædic Departments, with connecting corridors to the existing Infirmary, large extensions to the nurses' home, new boiler house, new chimney stack, new laundry, new surgery and casualty department, and a new pay beds department.

West of England Eye Infirmary

Students of the Exeter hospital can attend the practice of the Eye Infirmary (55 beds). A ward is set aside for newly born babies suffering from infectious eye diseases. Mothers with babies are accommodated.

Wolverhampton—the Royal Hospital

There are 290 beds. Special Departments: Children, Gynæcology, Maternity, Ear, Throat, and Nose Diseases, Electrotherapeutic and X Rays, Orthopædics, Artificial Sunlight, Venereal Disease, Pathological and Biochemical Laboratories, Dentistry, Radium, Skin Diseases, Psychiatric Clinic, and Electrocardiograph. There is an excellent medical library. The Resident Staff consists of Resident Assistant Surgeon, Resident Assistant Pathologist, one House Physician, and five House Surgeons. Women's Department, one Resident Obstetric Officer and one House Surgeon. Pupils are allowed to witness the whole of the practice of the hospital, and to be present at operations, and have every opportunity of acquiring a practical knowledge of their profession. The hospital is recognised by the various Examining Bodies for a part of the requisite attendance on Medical and Surgical Practice. A course of Practical Pharmacy is given by the Pharmacist. Fees on application. Applications should be made to the Honorary Secretary of the Medical Committee.

Worcester Royal Infirmary

The hospital has 142 beds. An obstetric department and side wards to be opened this year will increase the accommodation by 16 beds. In 1932 a new wing was added consisting of two operating theatres and a complementary suite of rooms, an Orthopædic and Electro-massage Department, a Pathological Laboratory, and Ear, Nose, and Throat Ward, a Mortuary, Post-mortem Room, Viewing Chapel, and Inquest Room. A new Nurses' Home was also opened in 1932, providing accommodation for Matron, 10 Sisters, and 50 Nurses. The Resident Medical Staff has been increased to three, and a house in the Infirmary grounds has been furnished and equipped for them. All hot water and steam services are run on oil fuel. There is a Department for Venereal Diseases, and Surgical Tuberculosis cases are treated. There is also a Mental Out-patient Clinic.

York County Hospital

This hospital at York contains 197 beds. There are balconies for outdoor treatment, X Ray Department, Orthopædic, Dental, Electrotherapeutic and Massage Departments, actinotherapy installation, and clinical laboratories. There are clinics for Functional Nervous Disorders, Venereal Diseases, and Electrocardiography. The out-patient department is now being rebuilt together with a new Women's Surgical ward.

MEDICAL EXAMINING BODIES AND SCHOOLS IN SCOTLAND

UNIVERSITY OF ABERDEEN

The University of Aberdeen grants four degrees in Medicine and Surgery—viz., *M.D.*, *Ch.M.*, *M.B.*, and *Ch.B.* The Degree of Doctor of Philosophy (*Ph.D.*) is also granted in the Faculty of Medicine.

Degrees of M.B. and Ch.B.—Candidates, before entering on the curriculum, must have passed the Preliminary Examination or hold a qualification recognised as exempting from such examination.

The curriculum for the degrees extends over a period of five years, during which attendance is required in the following subjects: Biology, Physics, Chemistry (Systematic and Practical), Anatomy (Systematic and Practical), Physiology (Systematic and Practical), Materia Medica and Therapeutics, Practical Pharmacy, Pathology (Systematic and Practical), Forensic Medicine, Public Health, Surgery, Medicine, and Midwifery.

Candidates must attend for at least three years the medical and surgical practice of a recognised hospital, they must have attended courses of at least nine months in clinical medicine and clinical surgery, and have acted as clerk in the medical and dresser in the surgical wards of a hospital. Attendance is required on the practice of a dispensary or the out-practice of a hospital and also on courses in Mental Diseases, Fevers, Ophthalmology, Post-mortem Examinations, Venereal Diseases, Tuberculosis, Radiology, X Ray Therapeutics and Electrical Treatment, and Clinical Chemistry, and other special subjects. The candidate is also required to have been properly instructed in Vaccination and to have attended at least 20 Midwifery cases.

Degrees of M.D. and Ch.M.—Candidates for either of these degrees must already hold the degrees of M.B. and Ch.B. of Aberdeen. A Thesis (in duplicate) has to be presented and an examination has to be passed in Clinical Medicine (or in some special Department of Medical Science) or Clinical Surgery, as the case may be.

Degree of Ph.D.—For this degree candidates must pursue a course of special study or research during a period of nine academical terms as Research Students in the University of Aberdeen or in any College or Institution that may be affiliated thereto. A Thesis (in duplicate) must be presented for approval.

A Diploma in Public Health is granted by the University to graduates in Medicine of a University in the United Kingdom, after a special examination.

Scholarships and Prizes.—In the Faculty of Medicine of the University of Aberdeen there are the following Bursaries, Scholarships, and Prizes:—Bursaries:

about 80 Bursaries (competition and presentation) ranging in value from £30 to £50 per annum, most of them being tenable from three to five years. Scholarships: five Post-graduate Scholarships, ranging in value up to £250 per annum. Numerous Prizes and Gold Medals reward proficiency in special departments.

Clinical Studies are carried on mainly at the ABERDEEN ROYAL INFIRMARY. There are 366 beds. The main clinical work of the students is done in the infirmary with its general and special facilities, including a department of clinical chemistry. A dietetic department has recently been established under the direction of a qualified Dietitian. A post-graduate course in medicine is given during the summer term.

The ABERDEEN ROYAL MENTAL HOSPITAL contains about 900 beds, and a class of mental diseases meets at the University of Aberdeen, and clinical instruction is given at the hospital during three months in summer. Wellwood Nursing Home, Pitfodels, Cults, Aberdeenshire, for the treatment of early cases of nervous and mental disorders, has 20 beds.

Students have the opportunity of attending the following institutions: City Fever Hospital, Sick Children's Hospital, General Dispensary, Lying-in and Vaccine Institutions, and the Ophthalmic Institution.

UNIVERSITY OF EDINBURGH

Four Degrees in Medicine and Surgery are conferred by the University of Edinburgh—viz., *M.B.*, *Ch.B.*, *M.D.*, and *Ch.M.* The degree of *Ch.B.* shall not be conferred on any person who does not at the same time obtain the degree of *M.B.*, and the degree of *M.B.* shall not be conferred on any person who does not at the same time obtain the degree of *Ch.B.* No one is admitted to the degrees who has not been engaged in study for five years.

Candidates for the degrees of M.B. and Ch.B. must have attended for at least three academic years the medical and surgical practice either of the Royal Infirmary, Edinburgh, or of a general hospital elsewhere which accommodates not fewer than 80 patients and possesses a distinct staff of physicians and surgeons. They must have attended courses of instruction in Clinical Surgery and Clinical Medicine each of nine months, and courses of instruction in all the subsidiary subjects. They must have attended a course in Clinical and Practical Midwifery and have personally conducted 12 cases at least.

With respect to the places and institutions at which the studies of the candidates may be prosecuted the following regulations have effect: Three of the five years of medical study must be spent in the University of Edinburgh. The remaining two years may be spent in any University of the United Kingdom, or in any Indian, Colonial, or Foreign University or medical school recognised for the purpose by the University Court. Women are admitted to graduation in medicine under the same conditions as men.

Bachelors of Medicine and *Bachelors of Surgery* may proceed to the degrees of *Doctor of Medicine* and *Master of Surgery* after they have spent one year in the medical or surgical wards respectively of a hospital, or the Military or Naval Medical Services, or in scientific work bearing directly on their profession, or two years in practice. In each case an examination must be passed and a thesis submitted.

Clinical instruction is carried on mainly at the EDINBURGH ROYAL INFIRMARY. At this institution there are 1011 beds, including 42 cots for children. The clinical work of the Edinburgh student is done at the Royal Infirmary. Courses of Clinical Medicine and Surgery are given by the physicians and surgeons to male and female students. Special instruction is given on Diseases of Women, Diseases of the Skin, Diseases of the Eye, Ear, Nose, and Throat, and the Teeth. Separate wards are devoted to Venereal Diseases, Diseases of Women, Diseases of the Eye, the Ear, Throat, and Nose, and the Skin, and also to cases of Incidental Delirium or Insanity. There is also a large and complete Radiological Department in which is given theoretical and practical instruction for the University Diploma in Radiology, &c. In addition to the Out-patient Departments connected with the Surgical and Medical Houses, there are separate Out-patient rooms attached to the Special Departments. Post-morten examinations are conducted in the anatomical theatre by the pathologist and his assistants, who also give practical instruction in Pathological Anatomy amd Histology.

The appointments are: 1. Resident physicians and surgeons are appointed and live in the house free of charge. The appointment is for six months, but may be renewed at the end of that period by special recommendation. 2. Non-resident house physicians and surgeons and clinical assistants are appointed for six months. The appointment may be renewed for a like period by special recommendation. 3. Clerks and dressers are appointed by the physicians and surgeons. These appointments are open to all students and junior practitioners holding hospital tickets. 4. Assistants in the Pathological Department.

Among other hospitals where the students obtain clinical instruction are the MUNICIPAL HOSPITALS, the ROYAL HOSPITAL FOR SICK CHILDREN, the EDINBURGH ROYAL HOSPITAL FOR MENTAL DISORDERS, and the CITY HOSPITAL FOR INFECTIOUS DISEASES. The Hospital for Sick Children at Sciennes-road, Edinburgh, has 120 beds, fitted with every modern improvement. A fully equipped out-patient department (medical and surgical) is conducted daily.

Post-graduate Instruction.—In the departments of the Faculty of Medicine provision is made for research by students of graduate standing. In the University laboratories facilities will be provided for approved candidates for the Degree of Ph.D.

In connexion with the University and Royal Colleges Post-graduate Instruction is given each year, chiefly in the Summer Vacation (July–September). Special Courses are arranged for, and particulars may be had on application to the Hon. Secretary, Post-graduate Courses in Medicine.

The University of Edinburgh is especially rich in scholarships and prizes in medical subjects. Full particulars concerning these, as well as concerning the fees at different stages, can be obtained from the Dean of the Medical Faculty.

UNIVERSITY OF GLASGOW

The University of Glasgow is both a teaching and a degree-granting body, but admits to graduation only candidates whose preliminary examination and course of study conform to its own regulations. Within certain limits instruction given by recognised medical schools and teachers may be accepted, but not less than one-half of the subjects other than clinical must be taken in this or some other recognised university, and at least two years of the course must be taken in Glasgow University. Seven degrees, open both to men and women, are conferred: *M.B.* and *Ch.B.* (always conjointly), *M.D.* and *Ch.M.*; *B.Sc.* in Public Health; *D.Sc.* in Public Health; *B.Sc.* in Pharmacy; and *Ph.D.* in the Faculty of Medicine. A Diploma in Public Health (*D.P.H.*) is also granted.

All information as regards the extent and standard of the Preliminary Examination may be obtained by application to the Secretary, Scottish Universities Entrance Board, 81, North-street, St. Andrews.

For the degrees of M.B. and Ch.B. a curriculum of five years is required. The candidate must attend a course or courses of instruction in each of the following subjects of study, extending over not less than the number of terms specified in each case, and including such class examinations as may be prescribed in connexion with the several courses: Chemistry (including Organic Chemistry), with Practical Chemistry, three terms;

Physics (with practical work), one term; Botany (with practical work), one term; Zoology (with practical work), one term; Anatomy and Practical Anatomy, five terms; Physiology and Practical Physiology, three terms; Materia Medica and Therapeutics (together or separately), each subject, one term; Pathology and Practical Pathology, three terms: Medical Jurisprudence and Public Health (together or separately), each subject, one term; Midwifery and Diseases peculiar to Women and to Infants, two terms; Surgery, two terms; Medicine, two terms. Candidates must attend for at least three years the Medical and Surgical Practice of a recognised hospital accommodating at least 80 patients and having a distinct staff of physicians and surgeons. At least nine months' hospital attendance is required on both Clinical Surgery and Clinical Medicine with nine months more of general hospital *practice; the student must have acted for six months* as clerk in medical and dresser in surgical wards, and must have had six months' outdoor practice; he must also have attended a course of Mental Diseases and of Practical Pharmacy (25 meetings), must have been properly instructed in Vaccination at a public vaccination station, and must have attended at least 20 cases of labour and the Practice of a Lying-in Hospital. The University also requires further study in various special subjects: Ophthalmology, Diseases of the Ear, Throat, and Nose, Venereal Diseases, Tuberculosis, Fevers, Vaccination. The final year consists of three intensive terms of study: one devoted to Midwifery and Diseases of Women, one to Surgery, and one to Medicine.

There are four Professional Examinations, the first comprising Botany, Zoology, Physics, and Chemistry; the second comprising Anatomy and Physiology; the third comprising Materia Medica and Therapeutics and Pathology; and the fourth or final, comprising Medical Jurisprudence and Public Health, Surgery and Clinical Surgery, Practice of Medicine and Clinical Medicine, and Midwifery and the Diseases peculiar to Women and to Infants.

The degrees of M.D. (Doctor of Medicine) and Ch.M. (Master of Surgery) are granted to candidates, not under 24 years of age, who have previously obtained the double bachelorship, on submitting an approved thesis and completing examinations in Clinical Medicine for M.D., and in Surgical Anatomy, operations on the dead body, and Clinical Surgery for Ch.M. The higher degree of Doctor of Philosophy (Ph.D.) is also conferred in the Faculty of Medicine. Candidates must already have obtained a degree (or equivalent diploma) from an approved University or College, and must prosecute a course of special study or research for two or three years and give evidence of satisfactory progress. A thesis must be presented for approval by the Senate on the recommendation of a Special Committee. The candidate may be required to undergo an oral or other examination on the subject matter of the thesis.

Post-graduate Medical Teaching is available under the auspices of Glasgow Post-Graduate Medical Association, which is representative of practically all the Teaching Institutions in Glasgow. Weekly demonstrations for practitioners are given throughout the winter and spring, and comprehensive courses of instruction during the summer and autumn. There is a General Medical and Surgical Course during the last two weeks of August and the first two weeks of September. This is a whole-time course and includes most of the subjects of interest to the general practitioner. Arrangements have been made whereby a limited number of graduates may become attached to wards or out-patient departments nominally as clinical assistants for definite periods throughout the year.

There are many Bursaries, Scholarships, and Prizes in connexion with the Medical Course.

Clinical Studies are carried on mainly at the ROYAL INFIRMARY—824 beds, including the Ophthalmic Institution. Other centres for clinical instruction are the Western Infirmary (600 beds) the Victoria Infirmary, and other general hospitals in the city. Facilities for the study of special branches are afforded by the Royal Hospital for Sick Children (350 cots), the Royal Mental Hospital, Hawkshead Asylum, the City Fever Hospital, the Royal Maternity Hospital, the Samaritan Hospital, the Eye Infirmary, and the Bridge of Weir Sanatorium.

Anderson College of Medicine

Courses are given at Dumbarton-road, Glasgow, W., which qualify for all the licensing boards and for the Universities of Oxford, Cambridge, London, Durham, Edinburgh, and Glasgow (the latter two under certain conditions). Extensive accommodation is provided for practical anatomy, chemistry, botany, zoology, physiology, pharmacy, and operative surgery. Women students are admitted on the same terms as men, and the Carnegie Trust extends its benefactions to *students of the College. Candidates for the L.D.S.* can obtain the full medical curriculum; the courses special to dentistry are conducted at the Dental Hospital, Glasgow.

The following are additional centres of instruction:—

Glasgow Western Infirmary

This hospital of 650 beds adjoins the University. Special wards are set apart for diseases of women, throat, nose, and ear, and for affections of the skin. In the out-patient department there are special clinics for diseases of women and for diseases of the throat, ear, nose, teeth, skin, venereal disease, and electrotherapeutics. This is the radium centre for Glasgow and the West of Scotland. The clinical courses are given by the physicians and surgeons, each of whom conducts a separate class, and students require to enter their names at the beginning of the session for the class which they propose to attend. Special instruction is given to junior students by tutors or assistants, and clinical clerks and dressers are selected from the members of the class. In the pathological and bacteriological departments the courses are both systematic and practical, and extend through the winter and following summer; these are likewise recognised by the University for graduation. In addition post-graduate courses are held. Eighteen resident assistants are appointed annually from those who have completed their course. In the Clinical Laboratory students receive laboratory instruction from the lecturer on clinical methods. A new Ophthalmological Department is being erected where special courses will be held.

Victoria Infirmary

This institution, situated at Langside, and having its office at 40, St. Vincent-place, Glasgow, has 427 beds, and is the third of the extensive general hospitals in Glasgow to afford opportunity for clinical instruction to students. In addition to a full general staff there is a clinical research laboratory with pathologists and bacteriologists attached; radiological instructor, and a full assortment of specialists. The Bellahouston Dispensary, also with a clinical staff, is conducted in connexion with the Victoria Infirmary. A wing for paying patients opened three years ago with 32 beds is now being extended to contain 80 beds. The extension should be completed by the end of 1934.

Royal Hospital for Sick Children, Glasgow

This institution consists of: (1) a hospital at Yorkhill containing 275 cots, built on an elevated and central site close to the University; (2) an out-patient department in West Graham-street; and (3) a country branch at Drumchapel, Dumbartonshire, containing 80 cots. There are one professorship and four lectureships in the University of Glasgow in connexion with the hospital, one professorship and one lectureship on the medical diseases of infancy and childhood, one lectureship on surgery and orthopædics in relation to infancy and childhood, one lectureship on biochemistry in relation to infancy and childhood, and one research lectureship on the pathology of the diseases of infancy and childhood. The lectures are both systematic and clinical, but particularly and chiefly the latter. In addition, special facilities are given for post-graduate study. Resident house physicians and surgeons are appointed every six months, in April and October.

Glasgow Royal Maternity and Women's Hospital

The average number of patients in the hospital at Rottenrow is 164. There are also over 4000 mothers attended per annum in their own homes. The work of the antenatal wards with their 50 beds is supplemented by large antenatal clinics where over 5000 new patients are seen in the course of the year. Well-equipped research laboratories were opened in 1926. A pædiatrician gives daily attendance and the practice of the hospital affords a good field for post-graduate study.

Glasgow Royal Samaritan Hospital for Women

The hospital has 160 beds and offers excellent facilities for clinical instruction in the diseases peculiar to women. Lectures and clinical demonstrations are given by members of the surgical staff to students and to post-graduates; and the hospital is represented on the Board of the Glasgow Post-Graduate Medical Association formed for coördinating post-graduate medical teaching in all the hospitals. The Royal Samaritan Lectureship in Gynæcology is a University lectureship associated with the hospital.

Glasgow Lock Hospital

The hospital at 41, Rottenrow, Glasgow, contains 84 beds and 16 cots for the treatment of females suffering from Venereal Diseases. There is also a Labour Ward, and a well-equipped Dispensary for out-patient attendances. There is a bacteriological laboratory, equipped with modern appliances, where continuous research work is done. Large University classes are held on the subject of female venereal disease. Post-graduate classes are also held. Recently the hospital has been completely renovated and modernised.

Glasgow Eye Infirmary

The wards and dispensary at Berkeley-street and Charlotte-street are recognised by the University for the purpose of instruction in ophthalmology for graduation in medicine at the University. A venereal centre has been established, and a branch dispensary has been opened in Clydebank. Post-graduate classes are held.

Glasgow Ear, Nose and Throat Hospital

The hospital contains 57 beds. At out-patient and indoor departments at 306, St. Vincent-street, clinical instruction is given. A research department has been installed, and post-graduate courses are held during the year.

Queen Margaret College

Queen Margaret College (Women's Department of the University) is an integral part of the University of Glasgow. The classes are taught by professors of the University and other lecturers appointed by the University Court, and it is governed by the University Court and Senate. The curricula, regulations, and fees are the same as those of the male students, and the University degrees are open to women on the same conditions as to men. The school of medicine is a special feature of the College, and gives full preparation for the medical degrees of the University. The women students attend classes in the various University Buildings at Gilmorehill, the Royal Infirmary, the Western Infirmary, and the Victoria Infirmary. Facilities for clinical work are given in the Royal, Western, and Victoria Infirmaries, in the Maternity, Royal Sick Children's, and other hospitals. The Arthur Scholarship is open every third year to students of first year; other Bursaries are open in Arts and Medicine, and women are admitted to certain University bursaries and fellowships.

St. Mungo's College

The classes in St. Mungo's College (vide Glasgow Royal Infirmary) qualify for the medical and dental qualifications of the English, Scotch, and Irish Conjoint Boards, and, under certain conditions, for the various universities, including the University of London. Students who have fulfilled the conditions of the Carnegie Trust are eligible for the benefits of this Trust during the whole course of their studies at St. Mungo's College. Further particulars can be obtained from the Secretary of the Medical Faculty.

UNIVERSITY OF ST. ANDREWS

Four Degrees in Medicine and Surgery are conferred by the University of St. Andrews (United College, St. Andrews, and University College, Dundee)—viz., *M.B.*, *Ch.B.*, *M.D.*, *Ch.M.*, a Diploma in Public Health, Diploma in Dental Surgery (*L.D.S.*), and a Diploma in Public Dentistry (*D.P.D.*).

The extent and standard of the Preliminary Examination is determined by the Scottish Universities Entrance Board, constituted under Ordinance No. 70 of the Scottish University Courts (General No. 3—Regulations as to Admission to the Scottish Universities for purposes of graduation), in accordance with the terms of that Ordinance. A degree in Arts or in Science in any of the Universities of the United Kingdom and in some colonial and foreign universities exempts. The Preliminary Examination for graduation in Medicine and Surgery, Arts or Science, of the University of St. Andrews is accepted as equivalent to the Registration Examination required by the General Medical Council (the certificate to include the required subjects). Also the Final Examination for a degree in Arts or Science.

Degrees of Bachelor of Medicine and Bachelor of Surgery.—Candidates must have been engaged in medical study for at least five years. In each of the first four years the candidate must have attended at least two courses of instruction in one or more of the subjects of study specified below, each course extending over a session of not less than five months, either continuous or divided into two terms, or alternatively, one such course along with two courses, each extending over a session of not less than two and a half months. During the fifth or final year the candidate shall be engaged in clinical study for at least nine months at the Infirmary of Dundee or at one or more of such public hospitals or dispensaries, British or foreign, as may be recognised for the purpose by the University Court. The candidate must have received instruction in each of the following subjects of study, including such examinations as may be prescribed in the various classes—viz., Anatomy, Practical Anatomy, Chemistry, Materia Medica, Physiology, Practice of Medicine, Surgery, Midwifery and the Diseases peculiar to Women and Infants, Pathology, Bacteriology, Practical Chemistry, Physics, Elementary Botany, Elementary Zoology, Practical Physiology, Practical Pathology, Forensic Medicine, and Public Health. The candidate must have attended for at least three years the Medical and Surgical Practice either of the Infirmary of Dundee or of a General Hospital elsewhere with not fewer than 80 patients, with a distinct staff of physicians and surgeons, and recognised for the purpose by the University Court. Additional subjects of study are Practical Pharmacy, Mental Diseases, Practical Midwifery, Operative Surgery, Vaccination, Children's Diseases, Fevers, Ophthalmology, Diseases of the Ear, Throat, and Nose, Anæsthetics, Dermatology, Venereal Diseases, Tuberculosis, and Post-mortem Examinations.

With respect to the places and institutions at which the studies of the candidate may be prosecuted the following regulations shall have effect: 1. Two of the five years of medical study must be spent in the University of St. Andrews. 2. The remaining three years may be spent in any University of the United Kingdom or in any Indian, Colonial, or Foreign University recognised for the purpose by the University Court, or in such medical schools or under such teachers as may be recognised for the purpose by the University Court. Women are admitted to graduation in Medicine.

Professional Examinations for the Degrees of Bachelor of Medicine and Bachelor of Surgery.—Each candidate will be examined both in writing and orally, and also clinically where the nature of the subject admits, in the following divisions—viz., first, in Botany, Zoology, Physics, and Chemistry; second, in Anatomy and Physiology; third, in Materia Medica, Pathology and Bacteriology, Forensic Medicine and Public Health; and fourth, in Surgery, Clinical and Operative Surgery, Practice of Medicine and Clinical Medicine, and Midwifery and Gynæcology (Systematic and Clinical).

University College, Dundee

The Medical School in St. Andrews University is carried on as follows. Part or whole of the medical curriculum of St. Andrews University must be taken here. Provision is made by St. Andrews University for instruction in the work of the first two years, including Anatomy and Physiology, in both St. Andrews and Dundee. The last three years of the curriculum must be taken in Dundee in the medical school.

Post-graduate courses are given in connexion with the Dundee Royal Infirmary during the spring and summer months.

Dundee Royal Infirmary

This institution has 450 beds. In addition to the ordinary Medical and Surgical Wards, there are special departments for Midwifery (In- and Out-door), for Diseases of Women, of Children, of the Eye, of the Ear, Nose, and Throat, and of the Skin; and for Pathology, Radiology, Electrotherapeusis, and Electrocardiography. The Pathological Department has recently been reconstructed and enlarged. Clinical teaching is given to students by the Honorary Staff; post-mortem examinations are conducted by the Pathologist. All courses of instruction are recognised by the University of St. Andrews and the other Universities and Boards of the United Kingdom. Ten Resident Medical Officers are appointed every six months. Clinical clerks and dressers are attached to the Physicians and Surgeons, and Students are appointed as assistants in the pathological department. Post-graduate classes are held in May and June. Further information may be obtained from the Medical Superintendent.

SCOTTISH MEDICAL CORPORATIONS GRANTING DIPLOMAS

CONJOINT EXAMINING BOARD

The Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow have made arrangements by which, after one series of examinations, held in Edinburgh or Glasgow, or both, the student may obtain the diplomas of the three bodies. This is the Scottish Conjoint Board. The three bodies grant their Single Licences only to candidates who already possess legal qualifications in Medicine or Surgery.

The hospitals which are recognised by the Scottish Conjoint Board as places where professional study for their diplomas can be pursued are all those institutions which feed the medical faculties of the universities, as well as all the places which are recognised by the English and Irish Conjoint Boards.

Professional Education.—The candidate must produce certificates or other satisfactory evidence of having attended the following separate and distinct courses of instruction: Physics, 1 term; Elementary Biology, 2 terms; Elementary Inorganic and Organic Chemistry, 2 terms; Anatomy Lectures, 2 terms; Practical Anatomy, 5 terms; Physiology Lectures, 2 terms; Practical Physiology (including Histology, Biochemistry, and Biophysics), 3 terms; Materia Medica and Practical Pharmacy, 2 terms; Pathology (including Practical Pathology), 3 terms; Practice of Medicine, 2 terms; Clinical Medicine, 3 terms; Principles and Practice of Surgery, 2 terms; Clinical Surgery, 3 terms; Midwifery and Gynæcology, 2 terms; Diseases of Children, 1 term; Medical Jurisprudence, 1 term; and Public Health, 1 term. The certified attendance on lectures, demonstrations, and practical work must not be less than three-fourths of the total number of roll-calls. Every student undergoes a course of Practical Midwifery, but before attending at labours he is required to attend a course of lectures on Surgery and Midwifery and to hold the offices of Clinical Medical Clerk and Surgical Dresser.

The student must attend for 27 months the Medical and Surgical practice of a public general hospital containing on an average at least 80 patients available for clinical instruction and possessing distinct staffs of physicians and of surgeons. He must act as Surgical Dresser and Medical Clinical Clerk for not less than nine months in the wards in each case, and receive practical instruction in administration of anæsthetics. He must attend for three months the practice of a public dispensary especially recognised by any of the above authorities, and three months' attendance at the out-patient department of a recognised general hospital. This attendance should be made after the student has passed the First and Second Examinations.

Candidates are also required to attend the following three-monthly courses: Diseases and Injuries of the Eye; Insanity; Infectious Diseases; Gynæcology; Tuberculosis; Diseases of the Skin; Diseases of the Ear, Nose, and Throat; Radiology; Orthopædics; Diseases of Children. The curriculum lasts for five years, the fifth year being devoted to clinical work.

There are four professional examinations:—

First Examination includes Systematic and Practical Biology, Chemistry, and Physics.

The Second Examination must be Written, Practical, and Oral, and consist of the following subjects: (1) Anatomy and Embryology, and (2) Physiology, including Histology (if not included in Anatomy), Biochemistry, and Biophysics. Candidates may be admitted to this Examination on production of the necessary certificates of curriculum.

The *Third Examination* must be Written, Practical, and Oral, and consist of the following subjects: (1) Pathology, including Bacteriology and Morbid Anatomy, and (2) Pharmacology (Theoretical and Practical), including Pharmacological Chemistry, the Principles of Therapeutics, and Prescription Writing. Candidates may be admitted to this Examination on production of the necessary certificates of curriculum.

The *Final Examination* must consist of the following subjects[1]: (1) Medicine, including Therapeutics, Applied Anatomy and Physiology, and Clinical Pathology with Practical Medicine; (2) Surgery, including applied Anatomy and Physiology, Clinical Pathology, with Practical Surgery; (3) Midwifery and Diseases of Women, Clinical Obstetrics and Gynæcology, with Practical Midwifery; and (4) Medical Jurisprudence and Public Health. Medicine, Surgery, and Midwifery must be taken together, and Medical Jurisprudence and Public Health, and not earlier than on the conclusion of five Winters and five Summers of Medical Study, provided that a period of 33 months has elapsed since passing the Second Professional Examination. The Schedule for the

---

[1] Candidates at the Final Examination may be examined on Diseases of Children, Fevers, Tuberculosis, Insanity, Skin Diseases, Diseases and Injuries of the Eye, Diseases of the Ear, Throat, and Nose, Radiology, Venereal Diseases, Orthopædics, Vaccination, and Anæsthetics.

Final Examination must contain a summary of the entire Course of Study, and, properly attested or proved by Certificates, must be lodged with the Inspector, and the fee paid, not later than two weeks before the examination. At the same time there must be produced a Certificate to show that the Candidate is not less than 21 years of age. No Candidate can be exempted from examination on any subject of the Final Examination unless he has already passed in the subject at this Board.

In addition to the Written and Oral Examinations all Candidates must be subjected to Clinical Examinations in Medicine, Surgery, and Midwifery and Gynæcology, which shall include the Examination of Patients, Physical Diagnosis, the Clinical use of the Microscope and of other instruments, Clinical Chemistry, Surgical Appliances, Bandaging, Surface markings, Skiagrams, &c. The Oral Examination includes the recognition of specimens. All Candidates for the Final Examination must complete the three portions (Medicine, Surgery, and Midwifery) within a period of 19 months.

There are four periods of examination annually.

The Registrar in Edinburgh is Mr. David Thomson, 18, Nicolson-street; and the Registrar in Glasgow, Mr. David Willox, 242, St. Vincent-street, to whom fees and certificates must be sent for the respective examinations, and from whom particulars of fees can be obtained.

School of Medicine of the Royal Colleges, Edinburgh

The Lectures in this School qualify for graduation at Edinburgh and other Universities, for the Examinations of the Conjoint Boards of Edinburgh and Glasgow, London, and Dublin. The number of students attending varies from year to year, and in recent years the average number has been about 600. In accordance with the Regulations of the University of Edinburgh one-half of the qualifying classes required for graduation there may be attended in this School, the fees paid for such classes being the same as those for the corresponding University classes. Special classes of instruction for Dental students are included in the curriculum. Post-graduate courses are conducted in conjunction with the University. Further particulars regarding the School, also its calendar (price 9*d*., including postage), may be had on application to the Dean of the School, Surgeons Hall, Edinburgh.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

In addition to the Diplomas granted by the Scottish Conjoint Board, the Royal College of Physicians grants its Single Licence to candidates whose names are already on the Medical Register.

The Royal College of Physicians of Edinburgh grants a *Membership* and a *Fellowship*.

Membership.—A candidate, who must be a Licentiate of a British or Irish College of Physicians, or a graduate in medicine of a University, approved by the Council, and 24 years of age, is examined in medicine, therapeutics, and in any branch of the departments of medicine specially professed, such as general pathology, psychology, public health, obstetrics, gynæcology, diseases of children, tropical medicine, or medical jurisprudence.

Fellowship.—The Fellows are selected from the ranks of the *Members*.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

The Royal College of Surgeons of Edinburgh admits to the examination for its Single Licence any candidates who hold a Diploma in Medicine of any British, Indian, or Foreign university or of any British College of Physicians, or of the Society of Apothecaries of London or Apothecaries' Hall, Dublin, granted under the provisions of the Medical Act, 1886, whose preliminary examination and course of professional study is proved to be sufficient to fulfil the requirements of the College, or to those who have passed a full examination for any of the above. Female practitioners are admitted to the Licence of the College and also to the Fellowship, and the regulations apply to practitioners of either sex.

The College grants a diploma of Fellowship after examination to the holders of British surgical degrees or diplomas and the holders of recognised degrees of the Universities of Canada, Australia, and New Zealand.

The Fellowship.—Candidates must be 25 years of age and in practice for at least two years. The examination is written and viva voce, and includes surgery and surgical anatomy, operative surgery, and clinical practice. One optional subject must also be taken, the range of these specialisms covering nearly every branch of medicine. Candidates are not allowed to appear for more than three times at the examinations, unless by permission of the President's Council. Three weeks' notice of intention to appear for examination must be given by the candidate to the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

The Royal Faculty of Physicians and Surgeons of Glasgow grants a Fellowship and a Licence to be held separately. The Licence is granted as a separate qualification to qualified practitioners in Medicine after examination in surgery, including surgical anatomy and clinical surgery.

Fellowship.—The Fellowship of the Faculty is granted after examination in medicine or surgery, together with an optional subject, which may be anatomy or physiology, or be selected from any special branch of medicine or surgery. Fourteen days' notice must be given by the candidate to the Faculty. In certain circumstances Fellows may be elected as a mark of distinction. Address of Registrar: 242, St. Vincent-street, Glasgow.

MEDICAL EXAMINING BODIES AND SCHOOLS IN IRELAND

UNIVERSITY OF DUBLIN, TRINITY COLLEGE (SCHOOL OF PHYSIC)

Matriculation.—University students take the Entrance of Trinity College and a Junior Freshman Term or a special Medical Preliminary: Extern Students, any examination recognised by the General Medical Council.

Pre-registration Examination in Elementary Physics and Chemistry.—Before beginning the five years' Medical curriculum students must pass an examination in elementary Physics and Chemistry. This examination is held at the end of September, in January, in March, and in July. Courses in preparation for it may be taken in the School of Physic.

Degrees in Medicine (M.B.), Surgery (B.Ch.), and Midwifery (B.A.O.).—Candidates for these degrees must be of B.A. standing and must be for at least five academic years on the books of the Medical School, reckoned from the date of registration. The Arts course may be taken concurrently with the Medical course, and the B.A. degree need not be taken before the final medical examinations, but the Medical degrees are not conferred without the Arts degree. The following courses must be attended: (1) Botany, Zoology, Physics, and Chemistry: Descriptive and Applied Anatomy; Histology, Physiology and Applied Physiology; Pathology and Bacteriology; Materia Medica and Therapeutics; Medical Jurisprudence and Hygiene; Practice of Medicine; Surgery; Midwifery and Gynæcology. (2) Three courses of nine months' attendance on the Clinical Lectures of Sir Patrick Dun's or other recognised Hospital. (3) Practical Vaccination, one month's instruction. (4) Mental Disease, three months. (5) Practical Midwifery with Clinical Lectures, including Antenatal and Infant Hygiene Clinics, also not less than 20 personally conducted cases, five months, one of which must be as a resident intern student. (6) Ophthalmic Surgery, three months. Three groups of examinations have to be passed. Preliminary Scientific Examination, including Physics and Chemistry, Botany, and Zoology. Intermediate Medical, Part I., including Anatomy and Physiology, Biochemistry and Histology; Part II., including Applied Anatomy and Applied Physiology; and the Final Examination, which is divided into Part I., Materia Medica and Therapeutics, Pathology and Bacteriology; and Part II., Medicine, including Clinical Medicine, Hygiene, Jurisprudence, and Mental Diseases; Surgery, including Operative and Ophthalmic Surgery; Midwifery and Gynæcology. Part I. may be passed in the fourth year, and Part II. completed at the end of the fifth.

Doctor in Medicine.—A Doctor in Medicine must have passed all the qualifying examinations and must be a B.A. of three years' standing. He must also submit a thesis and pass an Examination before the Regius Professor of Physic.

Master in Surgery.—A Master in Surgery must be a Bachelor in Surgery of the University of Dublin of not less than three years' standing and must produce satisfactory evidence of having been engaged for not less than two years from the date of his registration in the study or study and practice of his profession. He must then pass a special examination.

Master in Obstetric Science.— A Master in Obstetric Science must be a Bachelor in Obstetric Science of two years' standing, and must produce evidence of having been engaged in the study or practice of Obstetric Medicine and Surgery during two years. He is then required to pass a special examination.

Diploma in Gynæcology and Obstetrics.—A post-graduate diploma is conferred upon registered medical practitioners who take a six months' course at the Rotunda Hospital or other recognised institution, a six months' course in Trinity College, and then pass a special examination. The minimum time required for the complete course is nine months.

Bachelor in Dental Science and Master in Dental Science.—The regulations under which these degrees are awarded can be obtained by application to the Registrar of the School of Physic.

All Degrees and Courses of Instruction are open to women students.

Scholarships and Prizes.—1. Medical and Surgical Travelling Prizes, £100, awarded in alternate years. 2. Bicentenary Memorial Prize, £30, awarded yearly, and given to the Travelling Prizeman. 3. Sir John Banks Prize and Medal. 4. Edward Hallaran Bennett Prize and Medal. 5. FitzPatrick Scholarship, awarded on results of Final Examination (interest on £1000). 6. Medical Scholarship, £20 per annum for two years, awarded in Chemistry, Physics, Botany, and Zoology. 7. Medical Scholarship in Anatomy and Physiology, £20 per annum for two years. 8. Henry Hutchinson Stewart Scholarships, one in Botany, Zoology, Chemistry, and Physics, and another in Anatomy and Physiology, awarded annually and valued at £10 per annum for three years. 9. Henry Hutchinson Stewart Scholarship in Mental Diseases, awarded from time to time, £50 per annum for three years. 10. John Mallet Purser Medal, awarded annually in Physiology. 11. Daniel John Cunningham Medal and Prize, awarded annually in Anatomy. 12. Begley Studentship, £40 per annum for four years, awarded annually. 13. Kingsmill Jones Memorial Prize, awarded annually in Natural and Experimental Science, £15. 14. O'Sullivan Memorial Scholarship, £48, awarded annually for excellency of record in school. 15. Adrian Stokes Memorial Fellowship, awarded every second year, the holder to carry out original work in Pathology and Bacteriology, about £320. 16. Aquilla Smith Prize, awarded annually in the Final Medical Examination, Part I., about £10. 17. Walter G. Smith Prize, awarded annually in Materia Medica and Therapeutics, about £10. 18. De Renzy Centenary Prize in Public Health, awarded annually, £15.

Post-graduate Instruction.—Arrangements have been made, with the approval of the Board of Trinity College, for a post-graduate course of instruction at the School of Physic during the autumn from Monday, Sept. 17th, to Saturday, Oct. 6th. Women graduates can be accommodated at Trinity Hall.

NATIONAL UNIVERSITY OF IRELAND

Matriculation.—All students must pass a matriculation examination; the examination taking place in June and September in Dublin, and at certain local centres, includes five subjects, three of which must be Irish, English, and mathematics. All students must pass in Irish except students not born in Ireland, and other students whose home residence shall have been outside Ireland during the three years immediately preceding their matriculation; but all such students will be expected to attend a course of instruction in Irish Literature and History prior to obtaining any degree in the University. The following are the subjects for examination: (1) Irish. (2) Latin. (3) Greek. (4) French. (5) German. (6) Italian. (7) Spanish. (8) Portuguese. (9) Welsh, or any other modern language approved by the Senate. (10) English. (11) Mathematics. (12) History. (13) Geography. (14) Applied Mathematics, or Physics as an alternative. (15) Chemistry. (16) Botany. (17) Agricultural Science. (18) Commerce. (19) Music, and for women candidates only (20) Physiology and Hygiene. Students entering for degrees in Medicine or Dentistry, if not already registered by the General Medical Council, must take Irish, Latin, English, Mathematics, and a fifth subject.

The medical degrees granted are :—

M.B., B.Ch., B.A.O.; M.D., M.Ch., M.A.O., Ph.D.—Printed forms of application for admission to any medical examination may be had from "The Registrar, The National University of Ireland, 49, Merrion-square, Dublin."

The Constituent Colleges of the National University of Ireland at which the full curriculum for medical degrees can be obtained are University College, Dublin; University College, Cork; and University College, Galway.

University College, Dublin

Matriculation.—Almost all the students of the College are matriculated students of the National University of Ireland. The pre-registration examination in physics and chemistry is taken after matriculation either at the beginning of or during the winter session. The course is of five years' duration and dates from the passing of the pre-registration examination.

Degrees of M.B., B.Ch., and B.A.O.—The First Examination includes Applied Physics, Applied Chemistry, Botany, Zoology, and Applied Biology. The examination may be taken in two parts: Part I., Physics and Chemistry; Part II., Botany and Zoology. Honours may be obtained only when both parts are taken as one examination. The Second Examination includes Anatomy and Physiology. Both must be passed at the same time. The Third Examination (Part I.) includes Pathology, Materia Medica, Pharmacology, and Therapeutics. Part II. (Third Examination), taken at the end of the Fourth Winter Session, includes Hygiene and Medical Jurisprudence.

The Final Examination in Medicine, Midwifery, Surgery, and Ophthalmology includes both the theoretical and the clinical branches. No student can enter for the M.B., B.Ch., or B.A.O. until the end of the fifth year after registration, when the curriculum has been completed. The degree of M.D. may be obtained either by examination or on published work.

A Post-graduate Course is held each year, beginning about the middle of June. The D.P.H. Course extends over the year, beginning at the opening of the session.

University College, Cork

In the School of Medicine students must have passed the Matriculation Examination of the University or some other recognised examination, and a preliminary examination recognised by the General Medical Council.

Medical Students who have passed the First Professional Examination of the Conjoint Boards of Ireland, England, or Scotland may be admitted to the rank of second-year students on making application to the Council. Similarly, students who have passed the Second Professional Examination of the same Boards may be admitted to the rank of third-year students; and those who have passed the Third Professional Examination of the Dublin Colleges, or of the Edinburgh Colleges and Glasgow Faculties, may rank as fourth-year.

The school is provided with physiological, toxicological, pathological, and pharmaceutical laboratories, materia medica, anatomical, and pathological museums, as well as a collection of surgical and obstetrical instruments and appliances. There are dissecting-rooms, well-appointed physical, chemical, and biological laboratories, a large natural history museum in the adjoining building, and part of the College ground is laid out as a botanical garden. The plant houses are well filled with plants and are open to the students in the class of Botany. The Library contains about 70,000 volumes and is open daily during term time to students. The Medical Museum occupies a large room erected at the northern end of the medical buildings. There are Students' Clubs for men and women students of the College and various athletic clubs.

Residence of Students.—Students not living at home, or with relatives or friends, sanctioned by their parents or guardians, are required to live in a hostel or in recognised lodgings, and register their addresses each session. The Honan Hostel, adjoining the College, is equipped by private endowment. A number of sets of rooms, together with recreation and common rooms, are provided for lay students who may desire to live there. For full particulars apply to the Warden. The Ursuline Convent, Blackrock, has a house of residence, quite separate from their Secondary School, for Catholic women students.

Clinical Instruction.—Students may attend the South Charitable Infirmary and County of Cork General Hospital, Cork North Charitable Infirmary and City of Cork General Hospital, the Mercy Hospital, the Cork District Lunatic Asylum, the Victoria Hospital for Diseases of Women and Children, the County Lying-in Hospital, Bon Secours, Fever, the District, and Ear, Eye, and Throat Hospitals.

Complete information with regard to class fees, scholarships, and prizes can be obtained from the Dean of the Medical Faculty, and in respect of the hospitals from the Secretaries.

University College, Galway

The College contains a well-lighted and ventilated dissecting room and an anatomical lecture theatre; physiological, pathological, pharmaceutical, chemical, and physical laboratories; anatomical, pathological, gynæcological, and materia medica museums; as well as large natural history and geological museums and an extensive library in which students can read and from which they can borrow books. In the School of Medicine there are 12 Entrance Scholarships, varying in value from £30 to £60 each, for which Medical Students compete with other students on the Entrance Course. In the Second, Third, and Fourth years three Scholarships in each year, value from £30 to £40 each, are reserved for Medical Students. H. H. Stewart Scholarships (£10 a year for three years) are awarded by the University in Anatomy and Physiology at Second Medical Examination amongst Students of the three constituent Colleges. Travelling Studentships (£200 a year for two years) are offered by the University for competition amongst Medical Graduates of the three Colleges of not more than two years' standing. Women students are eligible for all College and University Degrees, Distinctions, and Prizes. There are extensive grounds, a portion of which is occupied by a Botanic Garden and a portion is at the disposal of the College Athletic Union. There are several student societies in the College, including a Biological Society. There are abundant facilities for research and Post-graduate work in the Chemistry, Physiology, and Pathology departments. There are ample facilities for Women Students.

Clinical Instruction is given in the Galway Central Hospital and in the Galway Tuberculosis and Fever Hospitals. The CENTRAL HOSPITAL (300 beds) is completely renovated. In addition to the surgical and medical departments, there are now eye and ear, throat and nose, gynæcological and obstetrical, pathological, X ray, electrical and massage departments. Medical and Surgical Clinics are held on alternate days during term. Two Resident Physicians and two Resident Surgeons are appointed every six months. Resident Students are admitted. The hospital is open to qualified medical men for postgraduate work.

HOSPITALS AFFORDING RECOGNISED PRACTICE [1]

The following hospitals afford practice recognised by the Irish Universities and Corporation.

Sir Patrick Dun's Hospital

Classes both in Medicine and Surgery are held each morning at Grand Canal-street, Dublin, from 9 o'clock from the beginning of October till the end of June. Special classes for junior students will be held in the wards during the months of October, November, and December. A resident surgeon and resident physician, with salaries, are appointed annually. Six resident pupils are appointed every six months. Twelve surgical dressers and twelve clinical clerks are appointed each month. There are facilities for women students.

The practice of the hospital is open to all students, and the certificates are recognised by Dublin University, the National University, and Royal Colleges of Surgeons of England, Ireland, and Scotland. It is an official " Treatment Centre " for venereal diseases.

At the end of last year an out-patient department was fully equipped. It has medical, surgical, gynæcological, ear, nose and throat departments, and an accident department, with theatre and dressing dispensary. A valuable asset to the teaching responsibilities of the institution has thus been added.

Prizes and Medals.—Clinical medals and prizes amounting to about £21 each will be awarded in medicine and in surgery respectively in accordance with the will of the late Rev. Samuel Haughton, M.D., S.F.T.C.D. Candidates who fail to obtain these medals and prizes will be awarded special certificates in medicine and surgery provided they show sufficient merit.

Adelaide Hospital

Two resident surgeons and four or more resident pupils are elected every six months.

Prizes.—The Hudson Scholarship, £30 and a Gold Medal, as well as the Hudson Prize, £10 and a Silver Medal, are awarded at the end of the session for proficiency in medicine, surgery, gynæcology, and pathology. In addition to this prizes are awarded in gynæcology and dermatology, and in clinical medicine and surgery for junior students. Wallace Beatty Memorial Bursaries are granted at the discretion of the Medical Board at the beginning of the Winter session. The certificates of attendance are recognised by all the Universities and licensing bodies in the United Kingdom. Post-graduate work in the hospital is in conjunction with the course in Trinity College.

---

[1] This list of the institutions recognised by the Conjoint Board of Ireland is supplemented in the regulations of the Colleges by those hospitals mentioned as recognised institutions in Scotland and England. The recognised facilities for clinical instruction in some of the Irish centres have been described. The secretaries of the hospitals will always be ready to answer inquiries or to give additional information.

Mater Misericordiæ Hospital

This hospital, under the care of the Sisters of Mercy, containing 410 beds, is open at all hours for the reception of accidents and urgent cases. Clinical instruction is given by the staff. Ophthalmic surgery and surgery of the nose and throat are taught in the special wards and in the dispensary. Surgical operations are performed daily. Connected with the hospital are extensive dispensaries, which afford valuable opportunities for the study of general medical, dermatological, surgical diseases, and accidents; a fully equipped biochemical laboratory, a modern electro-massage department, an electrocardiograph room, and radiological department. Instruction is given on pathology and bacteriology. A special post-graduate course in connexion with the medical school of University College, Dublin, is held each June. Four house physicians, eight house surgeons, and 18 resident pupils are elected annually. Dressers and Clinical clerks are appointed regularly and certificates given for merit. Leonard Prizes will be offered for competition annually. Certificates of attendance are recognised by all the Universities and licensing bodies in the United Kingdom. There is a private hospital for the reception of medical and surgical cases. A training school and a home for trained nurses are connected with the hospital, and nurses who have passed a qualifying examination can be obtained on application to the Lady Superioress. Entries can be made with any of the physicians or surgeons, or with the Registrar, 8, Fitzwilliam-place, Dublin.

Mercer's Hospital *

This hospital, situated in the centre of the city of Dublin, is in closest proximity to the Medical Schools, any of which can be reached on foot within five minutes, and from its position receives a large number of cases of emergency surgery in addition to the ordinary medical and surgical practice. Extensive alterations and reconstruction have brought the wards up to date. Additions have been made in the radiographic and electrocardiographic departments. Classes for pupils are held on alternate mornings in the medical and surgical wards. There is a large out-patient department available for the teaching of medicine, surgery, and gynæcology. Arrangements for clinical instruction are made with Cork-street Fever Hospital. A gold medal is awarded annually to the best pupil on the books of the hospital, and an annual prize of £25 has been added. A house surgeon and a house physician are appointed annually, and there is residential accommodation for six men and two women pupils. Clinical clerks and dressers are appointed from the classes.

Richmond, Whitworth, and Hardwicke Hospitals

These House of Industry hospitals, North Brunswick-street, Dublin, contain 325 beds—140 for surgical cases, 75 for medical cases, 78 for fever and other epidemic diseases, and an auxiliary wing with 32 beds, devoted mainly to throat, nose and ear, and skin diseases. Three resident physicians and three resident surgeons are appointed each half year. Resident clinical clerks are appointed each quarter, and it has always been the aim of the Medical Board to ensure that each student spends at least six months in residence. In addition, junior students are appointed as extern clinical clerks and surgical dressers. Women students are eligible on the same terms as men. Ample facilities exist for post-graduate work in the various special departments, as well as in general medicine and surgery. Extensive alterations and improvements have recently been made in the X ray, electrotherapeutic, and electrocardiographic departments. Two open-air huts to accommodate ten patients have been erected in the spacious Whitworth grounds. A new students' residency has been opened. This contains facilities for 20 male and 8 female resident students.

Royal City of Dublin Hospital

The hospital contains 160 beds and a special wing for the treatment of fevers and contagious diseases founded by the late Mr. Drummond. There is a large nursery where special opportunities are afforded for the study of diseases of children, both medical and surgical. There are also special wards for ophthalmic, aural, and gynæcological cases; also a department for the Erlangen Treatment by deep therapy. There is a largely attended out-patient department, where students are allowed to attend accidents and dress cases under supervision. Six resident pupils are appointed every three months. A house surgeon and a house physician are appointed annually.

Dr. Steevens' Hospital

This hospital, at Dublin (Kingsbridge), contains 180 beds. There is accommodation for 10 resident pupils, each of whom is provided with a separate bedroom, and board is supplied by the hospital at a reasonable rate. There is an electric massage department, a "sun-ray" and diathermy department, and an X ray department. There are also two V.D. wards and a largely attended V.D. treatment centre, as well as a large ward reconstructed and re-equipped and opened as open-air ward for tuberculous and other diseases of bone (25 beds) for females, two open-air verandahs for male surgical tubercular cases (14 beds), and children's ward (12 cots). Information as to terms for residency can be had from the Resident Surgeon at the Hospital.

Meath Hospital and County Dublin Infirmary

The hospital contains 150 beds, available for clinical teaching, both medical and surgical. There is a separate fever block which contains 40 beds. A special ward has been set apart for the reception of children. Special departments are as follows: Ear, Nose, and Throat, Dental, Diseases of Women, Skin, and Genito-urinary System. Clinical Teaching includes classes for both Senior and Junior Students. The Joseph Smyth Scholarship in Medicine, value £50, is awarded biannually. Gold and Silver Medals are given annually to the best answers in an examination in Clinical Medicine and Surgery. Prizes are also awarded to the Junior classes at the Sessional Examination. Two House Surgeons and a Resident Casualty Officer are selected each half-year from fully qualified pupils of the hospital. The Meath Hospital is within a few minutes' walk of the University of Dublin, the Royal College of Surgeons, The National University, and the Cecilia-street School of Medicine.

Jervis-street Hospital, Dublin *

This hospital contains 120 beds. Eight resident medical officers are appointed each year and facility is thus given to past students of the hospital to acquire experience as house surgeons. Resident students are provided with apartments, fuel, and light, free of charge. Arrangements have been made by which students of the hospital can have special fever training in Cork-street Fever Hospital, free of charge.

St. Vincent's Hospital and Dispensary

This hospital has 200 beds. Clinical lectures in medicine and surgery are held from October to June. Special classes for juniors from October to December. Pathological and bacteriological demonstrations are given every Thursday, and instructions in the use of laryngoscope and otoscope for senior students every Saturday. Medals and Prizes: the Bellingham gold medal in Medicine and the O'Ferrall gold medal in Surgery are offered for competition at the end of the summer session, as well as junior prizes, also the

---

* No returns.

* No returns.

McArdle Memorial Prize, value £20. There are a large extern department and a new pathological laboratory. A new electrocardiographic department has been installed.

Rotunda Hospital

The Rotunda Hospital, Dublin, is the largest combined gynæcological and maternity hospital in the British Empire. Over 4000 confinements are attended annually, and upwards of 1000 gynæcological patients admitted. Students can take out their necessary gynæcological and midwifery practical courses. The work of the hospital is carried on continuously through the year, and consists of daily clinical instruction in the maternity department, and examination and operations in the gynæcological department. Qualified students are given facilities for studying and assisting in the management of all abnormal cases so far as is practical. An antenatal dispensary is held three times weekly and all students are encouraged to attend. A special class in gynæcological examination and diagnosis is conducted by the Assistants to the Master. In addition there is a special class in operative obstetrics, limited in number. The pathological laboratory is under the supervision of a skilled pathologist, who gives special classes at intervals. A Biochemist has just been appointed who is carrying out the Aschheim-Zondek test for pregnancy, and who is prepared to help any Post-graduates who are keen on doing research work on the material in the hospital. There is a fully equipped X ray installation under the care of a competent radiologist. A ward has been opened for the treatment of infantile conditions, and is under the care of a pædiatrician, who gives instruction in the out-patient department, which is held daily. The appointments on the staff of the hospital are given to qualified past students of the hospital who have taken the L.M., and consist of Extern Assistants for six months, one being appointed every three months. From these the Assistants to the Master are appointed. Women students can reside in the hospital on the same terms as men. The L.M. is granted by examination after a six months' course. The mess room and sleeping quarters have been decorated recently and reading rooms are provided. Three tennis courts and a standard squash rackets court are now available for the mess.

Coombe Lying-in Hospital

The Coombe Lying-in Hospital and Guinness Dispensary for the Treatment of Diseases peculiar to Women, Dublin, contains 70 beds, and consists of two divisions, one of which is devoted to lying-in cases and the other to the treatment of diseases peculiar to women. The hospital gives to men and women students and post-graduates a thorough training in obstetrics and gynæcology. Lectures are delivered, practical instruction given, and gynæcological operations are performed in the theatres daily. There is a large general dispensary, held daily, at which instruction is given on the diseases of women and children. There is a special afternoon dispensary held by the Master and his assistants, at which practical instruction in gynæcology is given. There is no extra charge for attendance at this dispensary, or at the prenatal clinic, held on three evenings a week, at which there are about 3000 attendances annually. Every year about 1200 women are delivered in the hospital and about 1500 on the district. There is accommodation for intern pupils, who enjoy exceptional advantages of acquiring a thorough knowledge of this branch of their profession. Women students can reside in the hospital. Clinical assistants are appointed from amongst the post-graduates as vacancies occur. Certificates of attendance at this hospital are accepted by all licensing bodies. Students can attend at any time. Plans for a new hospital of 136 beds, and a new residency for students, are now complete, and the building operations will begin in the near future.

Further particulars may be had on application to the Master or the Registrar at the Hospital.

National Maternity Hospital

This hospital at Holles-street, Dublin, consists of intern and extern maternity, gynæcological wards, and a dispensary for the treatment of diseases of women, an infant clinic, and an antenatal and postnatal branch. Every facility is given for the carrying out of practical work. Under-graduate and post-graduate courses are arranged at any time. Certificates of attendance at this hospital are recognised by all the licensing bodies. Clinical lectures are given daily and oral lectures four times per week. The L.M. Diploma is given by special examination, which is held four times a year. Total number of admissions last year 1700.

Further particulars can be obtained from the Master or from the Secretary.

QUEEN'S UNIVERSITY OF BELFAST

There are six degrees in the Faculty of Medicine of the University—viz., Bachelor of Medicine (M.B.), Bachelor of Surgery (B.Ch.), Bachelor of Obstetrics (B.A.O.), Doctor of Medicine (M.D.), Master of Surgery (M.Ch.), and Master of Obstetrics (M.A.O.). The University also grants a Diploma in Public Health and a Diploma in Psychological Medicine, particulars of which will be found in the University Calendar. The degrees of M.B., B.Ch., and B.A.O. are the primary degrees in the Faculty of Medicine, and are conferred at the same time and after the same course of study. No student is admitted to the final examination for these degrees until he has shown: (1) that he is a matriculated student of the University; (2) that he has completed the prescribed course of study in the Faculty of Medicine extending over a period of not less than five academic years from the date of his registration as a student of Medicine; (3) that he has passed the several examinations prescribed; (4) that he has attended in the University during three academic years at least the courses of study prescribed for such degrees (the Senate may accept, for not more than two academic years of the required five, courses of study pursued in any other University or School of Medicine approved by the Senate); and (5) that he has attained the age of 21 years. Every candidate for admission shall matriculate or fulfil such other test of fitness as may be prescribed by the Senate, or may be exempted from the matriculation examination by having passed similar examinations elsewhere.

For information as to Scholarships and Prizes, inquiry should be made of the Secretary of the University.

Primary Degrees of M.B., B.Ch., B.A.O.—All candidates for these degrees must satisfy the examiners in the subjects of four examinations.

The First Medical Examination.—The subjects of this examination are Chemistry (Inorganic and Organic), Experimental Physics, Botany, and Zoology. The examination will be divided into two parts which may be taken separately: I., Chemistry and Physics; II., Botany and Zoology.

The Second Medical Examination.—The subjects are Anatomy and Practical Anatomy, Physiology and Practical Physiology. Candidates who have previously passed the First Medical Examination may present themselves for this examination at the close of their second year.

The Third Medical Examination.—The subjects are: (1) Pathology and Practical Pathology; (2) Materia Medica, Pharmacology, and Therapeutics; (3) Medical Jurisprudence; (4) Hygiene. Candidates who have previously passed the Second Medical Examination may present themselves for Part I. of this examination at the close of the third year, and for Part II. at the end of the Winter Session of the fourth year. Attendance on a course in any subject of the Third Medical Examination shall not entitle a student to a certificate of attendance unless he has previously passed in all the subjects of the Second Medical Examination.

The Fourth Medical Examination.—The subjects are: (1) Medicine; (2) Surgery; (3) Midwifery and Gynæcology; (4) Ophthalmology and Otology. Candidates who have previously passed the Third Examination may present themselves for the Fourth Examination at the close of the fifth year, provided that they have fulfilled the necessary requirements as to attendance, &c., on the courses of instruction in the subjects of examination and on the clinical courses in the hospitals. Attendance on a course in any subject of the Fourth Medical Examination shall not entitle a student to a certificate of attendance unless he has passed in the subjects of Part I. of the Third Medical Examination.

Degrees of M.D., M.Ch., and M.A.O.—These degrees are not conferred until the expiration of at least three academic years, or in the case of graduates of the University in Arts or Science of at least two academic years, after admission to the primary degrees in the Faculty of Medicine. Every candidate must show that in the interval he has pursued such courses of study, or been engaged in such practical work as may be prescribed. These degrees may be conferred by the Senate either (*a*) after an examination, which includes written, oral, clinical, and practical examinations; or (*b*) on the submission of a thesis or other evidence of original study or research, to be approved by the Faculty of Medicine after an oral or other examination of the candidate on the subject.

The Medical School.—The Donald Currie Chemical Buildings contain a lecture theatre, a preparation room, a chemical museum, a large class-room for elementary practical chemistry, laboratories for qualitative and quantitative analysis, rooms for water and gas analysis, dark room for photographic purposes and balance room, provided with all modern appliances. The Anatomical Department contains a large and well-lighted dissecting-room, a lecture-room, a professor's and demonstrator's room, a bone-room, and a laboratory for microscopic and photographic work. The Medical Museum is in the same building. The Jaffé Laboratories for Physiology comprise a lecture theatre, laboratories for practical work in chemical physiology, histology, and experimental physiology, and in addition small private research rooms, including balance, galvanometer, and centrifuge rooms. The J. C. White laboratories are fully equipped for research in biochemistry. The Institute of Pathology, which is adjacent to the Royal Victoria, Royal Maternity, and Children's Hospital, provides fully equipped accommodation for Pathology and Bacteriology, including class-rooms, demonstration room, lecture theatre, library museum. and research laboratories. There is an ample supply of material for investigation by graduates in morbid histology, clinical pathology, and the bacteriology of infectious diseases. A course in pathology or bacteriology is given to graduates, and members of this class have an opportunity of seeing the methods employed in the various investigations carried out in the department for the Public Health Committee of the Corporation in connexion with water-supply, sewage disposal, meat- and milk-supply, and the diagnosis of cases of infectious diseases. The certificate issued to members of the class in bacteriology qualifies for the D.P.H. degree. The Pharmaceutical Laboratory is fitted and equipped for the work of practically instructing students in the compounding and dispensing of medicines.

Clinical Instruction.—The following institutions are recognised by the University as affording proper opportunities for clinical instruction: the Royal Victoria Hospital, the Mater Infirmorum Hospital, the Belfast Hospital for Sick Children, the Royal Maternity Infirmary and Hospital, the Ulster Hospital for Women and Children (56 beds), the Benn Ulster Eye, Ear, and Throat Hospital (30 beds), the Belfast Ophthalmic Hospital (30 beds), the City Fever Hospital, Purdysburn (360 beds), the Union Fever Hospital (200 beds), and the Belfast District Lunatic Asylum, where the Purdysburn Villa Colony has 1350 beds.

Complete information can be obtained from the respective Secretaries.

Royal Victoria Hospital, Belfast

There are 436 beds. Students eligible for McGrath, McQuitty, Malcolm, Coulter Smyth, and Elwood Scholarships aggregate annual value £185. Twelve house surgeons and house physicians. Thirty-six resident pupilships, three months each, annually for senior students, of which a proportion is allotted to women students, special departments for radiology, clinical pathology, V.D., dermatology, gynæcology, vaccine therapy, electrocardiography, dentistry, radium therapy. Post-graduate lectures and demonstrations are given on Wednesdays throughout the year with the exception of holiday seasons.

Mater Infirmorum Hospital, Belfast

This hospital contains 270 beds and is open at all hours for the reception of accidents and urgent cases. Clinical instruction is given daily by Physicians and Surgeons. Surgical operations are performed daily. The out-patient departments in medicine and surgery, also the special dispensaries for gynæcology, ear, eye, and throat, electrotherapeutics, venereal diseases, varicose veins and hæmorrhoids are very largely attended and afford valuable opportunities to students for the study of those subjects. There is a well-equipped electro-medical and massage department. There is also a dental dispensary. A house physician and two house surgeons are elected every six months. Resident pupils are admitted as the vacancies arise. Three Exhibitions and a Gold Medal are competed for annually in June. Certificates of attendance upon this hospital are recognised by all the Universities and licensing bodies in the United Kingdom.

Belfast Hospital for Sick Children

At the hospital in Falls-road there are 73 beds, and clinical instruction is given. During the winter and summer sessions courses of lectures are delivered on the medical and surgical diseases incidental to infancy and childhood. Demonstrations in ophthalmology and pathology are given, and ample opportunities are afforded in the wards and in the out-patient department for gaining a practical and theoretical knowledge of the diseases of infancy and childhood. This hospital grants Certificates in Diseases of Children, which are recognised by the various examining bodies. Certificates are also granted for post-graduate study. A Gold Medal is offered for competition at the close of the session. A Davis Scholarship is awarded every two years for the best thesis on some branch of children's diseases.

Belfast Infirmary and Hospital

There are 1800 beds. Clinical courses are given quarterly, and a course for D.P.H. in hospital. An intern venereal clinic in infirmary is under the Corporation scheme. The maternity wards are recognised for practical midwifery training. The certificates of the vaccination class are recognised by the Local Government Board. There is a department for cancer with 32 beds, also X ray, bacteriological, and massage departments.

Royal Maternity Hospital, Belfast

This new building is in the grounds of the Royal Victoria Hospital and will supersede the maternity hospital in Townsend-street. It will be formally opened in October. There are 100 beds and an antenatal department catering for a large district. There is also an infant clinic and a department for venereal diseases and a separate septic block. The University obstetric tutor resides in the hospital and acts as senior resident medical officer. There are three house surgeons in addition, and resident accommodation for 15 resident students or post-graduates.

IRISH MEDICAL CORPORATIONS GRANTING DIPLOMAS

CONJOINT EXAMINING BOARD

The Conjoint Board of the Royal College of Physicians of Ireland and Royal College of Surgeons in Ireland requires of candidates the passage either of its own preliminary examination in the subjects of general education or proof that the candidate has passed one of the tests accepted by the General Medical Council as well as passing in the Pre-Registration Examinations in Chemistry and Physics and Biology.

Professional Examinations.—There are three professional examinations, the first of which cannot be completed earlier than the end of the second winter session, nor the final before the conclusion of full five years of medical study. Before being admitted to any of them the candidate must show that he has studied the different subjects in practice and theory for the requisite periods, certificates to this effect being accepted from the authorities of most of the recognised medical schools at home and abroad. The first examination consists of Part I. (*a*) Biology, (*b*) Applied Chemistry and Physics ; Part II., Anatomy and Physiology. The second examination deals with (*a*) Pathology, (*b*) Materia Medica, Pharmacy, and Therapeutics, (*c*) Forensic Medicine, Hygiene, and Public Health, (*d*) Ophthalmology, and may be taken separately.

Final Examination.—This is divided into three divisions, which cannot be completed until at least five years have passed in medical studies other than those for the Pre-Registration Examinations, and five years at least since the beginning of the curriculum. The divisions are (*a*) Medicine, including Fevers, Mental Diseases, and Diseases of Children ; (*b*) Surgery, including Operative Surgery ; (*c*) Midwifery, including Diseases of Women and Children, and the Practice of Vaccination.

Diploma in Psychological Medicine.—There are two examinations in connexion with this Diploma : Part I. consists of (*a*) Anatomy and Physiology of the Nervous System ; (*b*) Psychology. Part II. : (*a*) Neurology, including Clinical and Pathological Neurology ; (*b*) Psychological Medicine, including its legal relationships.

Further information can be obtained from the Secretary of the Committee of Management, Royal College of Surgeons, St. Stephen's Green.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The College issues its Licences in Medicine and in Midwifery to practitioners whose names appear on the Medical Register of the United Kingdom.

The Licence in Medicine.—The subjects of examination are : Practice of Medicine, Clinical Medicine, Pathology, Medical Jurisprudence, Midwifery, Hygiene, and Therapeutics.

The Licence in Midwifery.—Candidates must produce certificates of registration. A registered medical practitioner of five years' standing may be exempted from the examination by printed questions.

The Membership.—Examinations for Membership are held in February, June, and November.

The Fellowship.—Fellows are elected by ballot. An applicant must have been a Member of the College for at least one year and must have attained the age of 27 years.

Further particulars can be obtained from the Registrar of the Royal College of Physicians of Ireland, 6, Kildare-street, Dublin.

ROYAL COLLEGE OF SURGEONS IN IRELAND

The College issues its Licence in Surgery to practitioners whose names are entered either on the Medical Register for the United Kingdom, the Colonial Medical Register, or the Foreign Medical Register of the year in which he presents himself for examination, and who satisfies the Council that he has passed through a course of study and Examinations equivalent to those required by the Regulations of the Irish Conjoint Board.

Candidates are examined in General Surgery (paper and oral), Clinical Surgery, Surgical Pathology (oral), Operative Surgery, Surgical Anatomy (paper), and Ophthalmic and Aural Surgery (clinical).

Diploma in Midwifery.—A diploma in Midwifery is granted after examination to persons possessing a registrable qualification.

Fellowship Examinations.—Candidates for the Fellowship shall make application to the President and Council to be admitted to examination. They are required to pass two examinations—Primary and Final. Candidates may present themselves for the Final Examination immediately after passing the Primary part, provided they have complied with the necessary regulations. The subjects for the Primary Examination are (*a*) Anatomy, including Dissections ; and (*b*) Physiology and Histology. The subjects for the Final Examination are Surgery, including Surgical Anatomy and Pathology. For admission to the Final Examination the candidate must have passed the Primary Examination, and must be a Licentiate or Graduate in Surgery of a university or licensing body recognised by the General Medical Council ; all such candidates must not be less than 25 years of age.

Further particulars can be obtained from the Registrar of the College, Stephen's Green West, Dublin.

Schools of Surgery

The Schools of Surgery are attached by Charter to the Royal College of Surgeons and have existed as a department of the College for over a century. They are carried on within the College buildings and are specially subject to the supervision and control of the Council, who are empowered to appoint and remove the professors and to regulate the methods of teaching pursued. The buildings have been reconstructed, the capacity of the dissecting-room nearly trebled, and special pathological and bacteriological laboratories are fitted with the most approved appliances in order that students may have the advantage of the most modern methods of instruction. Winter Session commences in October ; Summer Session in April. Scholarships and Prizes : Carmichael Scholarship, £15 ; Mayne Scholarship, £8 ; Stoney Memorial gold medal ; Operative Surgery, gold and silver medals ; Barker Prize, £26 5s. ; H. Macnaughton-Jones gold medal in Obstetrics and Gynæcology ; and class prizes and medals. Prospectus and guide for medical students can be obtained post free on written application to the Registrar, Royal College of Surgeons, Stephen's Green W., Dublin.

APOTHECARIES' HALL OF IRELAND

The Licence of this Hall is granted to students who present certificates of having fully completed the course of study as laid down in the curriculum and who pass the necessary examinations. The diploma of the Hall entitles the holder to be registered as a practitioner in medicine, surgery, and midwifery, with also the privileges of the Apothecary's Licence.

Candidates must pass three Professional Examinations, called the First and Second Professional Examinations and the Final Examination, which are conducted at separate times, partly in writing and partly practically and orally. The Examinations are held thrice a year—viz., in March, June, and November, or such other dates as may be determined.

Candidates who produce satisfactory evidence of having passed an examination for a Degree or Licence in Medicine, conducted by any University or Royal

College in the British Empire, or by any Foreign University whose Degrees are recognised in the Foreign List of the Medical Register, will be exempted from the Primary Examination.

The subjects for the First Professional Examination are: Anatomy, Physiology and Histology, including Biochemistry; and for the Second Professional, Materia Medica and Pharmacy, Pathology, and Medical Jurisprudence and Hygiene.

For the Final Examination the subjects are: (*a*) Medicine and Clinical Medicine and Clinical Methods. (*b*) Surgery—Clinical, Ophthalmic, and Operative; and Surgical Anatomy. (*c*) Midwifery and Gynæcology, and Practical Pharmacy and Materia Medica (if not taken at Intermediate Examination).

Each candidate before receiving his diploma must produce evidence that he has attained the age of 21 years. The details of the course of education required and syllabus of the examinations will be supplied by the Registrar at 95, Merrion-square, Dublin.

WE take this opportunity of thanking the officials of Government Departments and the Deans and Secretaries of the various institutions for their kind coöperation in enabling us to bring the information contained in our Students' Number up to date.

This is the last issue of the Students' Number prepared with the collaboration of Mr. E. M. Ryder, who is now retiring from the staff of THE LANCET after 43 years of devoted service.

THE L.C.C. HOSPITAL SERVICE

THE hospital service of the London County Council provides opportunities for valuable experience for medical graduates who intend to be general practitioners or consultants, as well as for those who intend to make the public health service their career. Under the operation of the Local Government Act, 1929, the L.C.C. became responsible for the management of 74 hospitals (excluding mental hospitals)—namely, 28 general hospitals, 17 fever and other infectious diseases hospitals, 6 tuberculosis hospitals and sanatoria, 9 hospitals and convalescent homes for children, 12 hospitals and institutions for chronic sick patients, and 2 colonies for sane epileptics; 2 convalescent hospitals were subsequently acquired, making a total of 76.

Medical superintendents of the hospitals, who are expected to be experienced hospital administrators, receive £900 to £1650 a year, corresponding to hospitals varying in accommodation from 160 to 1390 patients. In addition, medical superintendents are provided with an unfurnished house or quarters, with payment by the Council of local and water rates. The subordinate staff is classified thus:

Grade.	Scale of annual salary.
Deputy Medical Superintendent, Grade I.	£650–£50–£800
Deputy Medical Superintendent, Grade II.	£600–£30–£750
Senior Assistant Medical Officer, Grade I.	£550–£25–£650
Senior Assistant Medical Officer, Grade II.	£500–£25–£600
Assistant Medical Officer, Grade I. ..	£350–£25–£425
Assistant Medical Officer, Grade II. ..	£250 (fixed)

In addition all these officers are provided with board, lodging, and washing, valued at £150 a year. All the positions mentioned involve full-time duties, and it is a condition of service that such officers shall not undertake any other paid employment. The staffing provides, where necessary, for house physicians or house surgeons, remunerated at the rate of £80 a year, with residence, and for clinical assistants, who are non-resident and receive £100, with meals when on duty. These officers are not employed in a whole-time capacity and are granted adequate leisure for study.

Vacancies in the higher grades are filled, as far as possible, by promotion from the existing staff. All full-time medical staff are allowed liberal annual leave with pay, and full pay during sickness for a reasonable period. For subordinate staff, the extent and fluidity of the hospital service provides unique opportunities for a variety of experience, and facilities exist for specialisation and for officers to follow courses of study outside the service with a view to improving their professional qualifications.

During the past year 113 vacancies have been filled, including 5 positions as medical superintendents, 1 as deputy medical superintendent, 8 as senior assistant medical officers, 67 as assistant medical officers, 31 as house surgeon, house physician, or clinical assistant, and 1 as medical officer of a children's hospital. During the year also a large number—more than 200—of part-time consultants have been appointed to the various units and groups of these hospitals. These appointments, which vary from 1 to 6 sessions a week, include physicians, surgeons, obstetricians and gynæcologists, anæsthetists, pædiatrists, neurologists, orthopædists, radiologists, dermatologists, ophthalmologists, urologists, and specialists in ear, nose, and throat.

In addition, other part-time consultants were appointed for special purposes—e.g., venereal diseases specialists, plastic and thoracic surgeons, &c.—and the services were made available of a tuberculosis officer at each general hospital having a tuberculosis ward.

Post-graduate facilities.—These are as follows:—

HAMMERSMITH HOSPITAL: In connexion with the British Post-Graduate Medical School, of which a full account is given on pp. 407 and 408.

PADDINGTON HOSPITAL: Post-graduate instruction in orthopædic surgery by clinical demonstrations, in collaboration with Fellowship of Medicine.

ST. ALFEGE'S HOSPITAL: Facilities are afforded to the Final Fellowship Class of Guy's Hospital to examine selected cases. The demonstration is undertaken by a surgical tutor of the class.

ST. ANDREW'S HOSPITAL: Consultant surgeon holds weekly classes for two periods of about 10 weeks previous to F.R.C.S. examinations.

ST. JAMES' HOSPITAL: The South-West London Post-Graduate Association has its headquarters at this hospital where three sessions of lectures are given annually—Christmas, Lent, and Summer. Usually 8 or 9 demonstrations are given per session. Instruction in orthopædic surgery is also given, in collaboration with the Fellowship of Medicine.

LAMBETH HOSPITAL: Post-graduate instruction is given in collaboration with the Fellowship of Medicine at fortnightly classes.

ST. PETER'S HOSPITAL: Post-graduate students from the London Hospital, who are reading for the final F.R.C.S. examination, attend to receive clinical instruction by the consulting surgeon.

Post-graduate courses.—Courses of instruction in hospital administration for candidates for the Diploma in Public Health are held at the NORTH-WESTERN HOSPITAL and at the BROOK HOSPITAL.

Under-graduate facilities.—Certain hospitals are affiliated to medical schools for the purpose of clinical teaching and, in addition, under-graduates are accepted as resident students for experience in obstetrics. The fever hospitals provide facilities for under-graduate instruction in infectious disease.

Small-pox.—Provision is also made for demonstrations in the diagnosis and treatment of small-pox for both under-graduate and post-graduate students.

Special Units.—Special departments in general hospitals are available—namely, at ST. JAMES' HOSPITAL for the treatment of cases by plastic surgery; at LAMBETH HOSPITAL for the treatment of patients by radium therapy; at NEW END HOSPITAL for the treatment of patients suffering from thyroid disease; and at ST. STEPHEN'S HOSPITAL for rheumatic cases.

THE LANCET

LONDON: SATURDAY, AUGUST 25, 1934

THE MEDICAL CURRICULUM

AN annual summary of the educational courses offered by the various universities, colleges, and societies to students intending to obtain a medical degree or diploma will, as it is published each year, resemble very much in form its immediate predecessors; but on almost every page in the issue of 1934 new information is afforded in order to bring the record up to date; and the additions point in two directions, both of which are creditable to medicine while each is embarrassing to those who supervise the training for the profession. For while on every side we can witness the far-ranging activity that prevails at all the educational centres, simultaneously we have evidence of the opportunities afforded for the acquisition of special knowledge along important lines. Hence the ancient problem is accentuated of what should be demanded from students, having regard to the public duties and responsibilities so soon to be assumed by them, as most essential for their equipment. Extension of the period of training, so that it may go hand in hand with the progress—the multiplying progress—of medicine, its ancillary sciences and dependent branches, seems impossible, and yet efforts to that end must not be sacrificed to expediency. But there are practical reasons why some defining line should be drawn as to what can be expected from the student. While he cannot reach registration with a full range of academic knowledge at his fingers' ends at the outset—an impossibility that is not apparent to many public critics of medical service—neither can he have the experience to be obtained from actual contact with the scientific, professional, and public questions which he will have to encounter. A student to be thus armed would remain in leading strings all his life; yet the limitations imposed already on the duration of his training call for the reflexion that time and money have value; they mean much to the student as well as to those upon whom he is dependent in many cases for his support until he can establish a livelihood.

THE IMPORTANCE OF THE START

The difficulty of the task before those who are attempting to shape the curriculum so that the student following it with success may feel ready to face the future with confidence is thus indicated. There is, as far as accurate definition can go, no limit to what it might be serviceable for him to learn, but a period is imposed primarily by the State and secondarily by material considerations in the time that *should* be occupied by his studies. The curriculum is now under much scrutiny, and the General Medical Council is prepared to begin at the beginning. At the summer session last year Sir NORMAN WALKER, in a presidential address, reminded the Council that the body was primarily concerned with maintaining a minimum qualification for admission to the Register, and that each licensing body is its own master in the matter of further requirements. And he continued with a significant reference to previous pronouncements by the Council upon preliminary education, to the effect that the training of the student destined for medicine ought not to differ from that of candidates for other professions. How true is the adage that the more things change the more they remain the same! For that is what the Council thought and said some 70 years ago. Sir NORMAN WALKER went on to say that those who are entrusted with an advisory voice in the education of medical students must press for the very thorough grounding of the student in certain preliminary subjects, and the Council will do great service if opinions from it, as the controlling body, are expressed in this direction. For the point up to which study previous to registration should be carried is not sufficiently uniform in the different licensing quarters, probably because registration at the commencement of the curriculum, most unfortunately, has not been made compulsory. It is right that all the licensing bodies should have their own say in the guarding of their portals, but it must be insisted that the preparation of candidates for professional training will bear fruit throughout the whole educational course, and that low grading beforehand will bring retribution. Professional learning has from its start a significance for the properly prepared student which it cannot have for one who is compelled to work without comprehension of basic facts. This is he who too often finds the tests imposed upon him by a series of examiners particularly burdensome, and his unfamiliarity with groundwork leads both to his individual disappointment and to clamant criticism of the system of examination.

THE WIDE INTEREST IN THE CURRICULUM

All this has formed the subject of close or desultory discussion for many years; but now the interest aroused is more intense than it ever has been, while the intention to arrive at a solution of the main question—What should the medical curriculum include?—shows the character of inquiries which are now taking place. The General Medical Council, the British Medical Association, the Board of Education, and the authorities at the universities and medical schools have shown noticeably during the last two years their awareness of the need for reviewing the curriculum, knowing well the difficulties attendant. But these difficulties have received such frequent notice, not always of a reasonable character, that an undue impression has been created of the seriousness of the situation. The opinions of those who find the whole medical training afforded in our schools to represent a hopeless muddle are seen to be unjustified when we weigh such evidence as is to be found in the present pages as to the structural soundness of the general scheme, and observe the numerous places in which reforms are being or have been quietly made, conducing to simplicity and economy. At the present moment the General Medical Council is planning a revision of the curriculum from its position as the standardising authority. Discussions on the various points, as well as statements from the presidential chair, have shown the attitude of the Council to be wise as well as correct; preserving its right of control and supervision, it makes no attempt to interfere with the autonomy of the qualifying bodies in arranging their own patterns of training. But it welcomes assistance from without, such as for example will come from the deliberations and conclusions of the important committee now sitting, at the instance of the faculty of medicine of the University of London. This committee has the possible revision of the whole curriculum as its object, and the Universities of Oxford and Cambridge, the English Colleges, and the Society of Apothecaries have sent representatives to a conference with the University of London. They have not yet reported, but we can be certain that their terms of reference will give them an opportunity of debating the method in which all the subjects are dealt with by the teachers and by examiners; and from such a body we may specially look for a lead as to the respective parts which academic and practical training should play in fitting the newly qualified man for his immediate future.

The report of the Committee on Medical Education of the British Medical Association must be of the first assistance to the G.M.C., and will form a text upon which much action should be taken by the Council. This valuable document at the outset is in flat opposition to querulous condemnation of the existing course of medical education as a whole. It starts with pointing out the value of general education and suggests that the course of study in the usual school subjects, and in chemistry, physics, and biology, should not be shaped for medical students only. All will agree that early segregation of the medical student is wrong, and the two years of training before registration should be spent by the medical student in general training as his contemporaries spend them who intend to enter one of the other professions. The examinations which he will have to pass before registration should be flexible, and with whatever certificate the student emerges he should have obtained scientific knowledge which is fundamental and not utilitarian. As will be seen by consultation of the first pages of this issue, the admission of students at the Universities of Great Britain and Ireland proposing to take a degree in any faculty is fairly uniform, even though a comparison of the different university regulations discloses minor divergencies in application. Of the medical student, it must be remembered that he may not intend to seek a university degree, but his admission to registration is guarded by the diploma-granting bodies in a similar manner. So that while certain of the formalities of university matriculation for the medical student seeking a diploma from one of the licensing colleges or societies may be absent, the test of his fitness to start on a medical course remains practically the same. The qualifications for admission to the universities of Great Britain and Ireland are regulated by school examinations, and the certificates obtained at these examinations provide the proof of the student's suitability for his proposed career, previous to recognition by the General Medical Council as a registered student. It is an anomaly, already mentioned, that such registration is not compulsory, for it is clear that the student, before embarking upon medical study proper, should have acquired such an introduction to the principles of chemistry, physics, and biology as to enable him to begin his specialised work with appreciation of its significance, and without the drawback of fundamental general ignorance, which has to be removed after entrance upon clinical education.

THE REPORT OF THE EDUCATION COMMITTEE OF THE B.M.A.

Even a cursory consideration of the formalities which guard the entrance of the student into the medical profession will dispel the idea that it is easy for the ignoramus to start on his professional career; the Report of the B.M.A. is definite on the point. When we turn to the section of the Report dealing with the first two years of professional training proper, we find five terms allotted to the study of anatomy and physiology and one term to the study of pharmacology, and of the introductory phases of general pathology exemplified by elementary bacteriology. On this period of the curriculum the Report makes thoroughly shrewd recommendations devised to save time for the acquisition of the important by the suppression of instruction in matters where it is not so much needed. All will agree that much of the details of anatomy and of what may be termed repetitional physiology form unnecessary baggage. The traveller's pack will not be the lighter for his being relieved of them, but he will be enabled to carry things more necessary for his arduous journey. During these two years the student should be able to obtain knowledge of the principles of asepsis and antisepsis, when the reasons for his introduction to bacteriology will become plain to him; at the same time some familiarity with work in the post-mortem room will prepare him for the clinical instruction which lies ahead. In this way the work of the first two years will provide a liaison course between the study of normal structure and function and that of deviations from them. The Report says little concerning teaching in the wards, class-rooms, and laboratories of medicine, surgery, obstetrics and gynæcology as at present conducted, and thus affords proof of the essentially good clinical teaching of the British schools; the brevity of the Report at this point is an eloquent answer to much carping. More stress it is suggested might be laid, at any rate in certain centres of education, on the conduct of minor operations and on the facilities afforded for familiarity with more serious conditions, and there may be some surprise that the standard of obstetric work comes off without directly adverse comment. But it will be remembered that last year detailed proposals for stiffening this side were made by the G.M.C. These proposals are adopted by the B.M.A. Report, while the absence of regular teaching in a general way of the subjects of postnatal and antenatal care of the mother, and of child welfare is noted. Such extension of the training is admitted universally to be necessary and would form a direct introduction for the student to the humane and social sides of his future calling. Similar advantages will be obtained for him if the proposals of the Report can receive effect that time should be found for the study of physico-therapy and psychotherapeutics. Such additional matter might form the subject of direct instruction in accordance with a time chart, but the instruction will be far more vivid if it is obtained in the course of other and more general teaching; the student is thus at each phase made aware that, though he will be dealing with material of very varied make up, there exist general principles and laws of wide application to assist him. For he should be taught to look at the patient as one whose particular troubles will always be influenced by his general physical capacity, by his mentality, and by the influence which his environment must have in all directions.

A DRASTIC PROPOSAL

So far the considerations of the Report of the Education Committee of the B.M.A. should receive acceptance by all, but the closing recommendation is sure to be challenged, and it is the most drastic of all. It is said that the present curriculum, but with less specialisation, should close with a final written and oral examination, but that the student should not be eligible to obtain his legal qualification without a further period of nine months of practical experience to be gained in one of five ways: (1) in a resident appointment in any approved hospital; (2) as clinical assistant in a hospital or clinic; (3) as pupil assistant to an approved general practitioner; (4) as pupil to an approved M.O.H.; (5) in regular attendance at hospital practice in a medical school. The first impression made by the proposal is that it is admirable, while the second is that to put it into effect would be accompanied with practical difficulty. Will the student find time to meet successfully his final examinations at the proper date and yet have nine months free to acquire the further clinical experience? As a resident at a hospital his procedure would be clear, and the inconvenience to the hospital authorities of employing unregistered internes could easily be got over. Here the proof that his time had been employed in the manner designed by the scheme would be forthcoming easily. But as the pupil of the M.O.H. or the approved general practitioner the evidence of an employment of his time in accordance with the intention of the scheme would be difficult to come by, if only because in each case the duties set before the pupil for discharge might not lend themselves easily to definition. Clearly the proposal to introduce what is a form of post-graduate activity into the under-graduate period is a highly important one, and the perplexities in giving effect to it must not be exaggerated; on the contrary, it is to be hoped that it will obtain the close attention that it merits and that no one will come to a hasty conclusion concerning it. A procedure is here formulated which would enable the young general practitioner to enter upon his calling more fitted to do public service, and that was the prime object that the Education Committee of the B.M.A. had before them. The proposal is fundamental in its significance.

THE SCHEME IS SOUND

Two years ago a group of writers in a position to speak with authority on the subject replied in these columns to the sweeping question—What is wrong with the medical curriculum? and suggestions were forthcoming which in many directions tally with the B.M.A. Report. Taken as a whole these articles, like the B.M.A. Report, found little or no fault with the clinical part of the existing curriculum, but pointed rather to directions in which opportunities must in the future be given for the students to acquire fundamental knowledge on subjects as yet relegated to the post-graduate period. While the possibility was indicated in several directions, in accordance with the bent of the individual writers, where rearrangements for specialisation might be made during under-graduate training, the recommendations in the main concerned the providing of proper equipment for men entering general practice. These form the largest as well as the most important section of the profession, and on them falls from the outset a trial of their ability in responsible situations. The immediacy with which the young practitioner has to face the burden of practice creates the essential difficulty in fitting his training to his needs. He who desires to specialise in a particular branch of medicine, or to join a particular medical service, will undergo post-graduate training as a matter of routine; he will not be called upon to discharge duties in circumstances which he has not been trained to meet, and his duties will be circumscribed. But the practitioner, without being in an exact sense neurologist, pathologist, or sanitarian, must have knowledge upon which he can draw to guide his conduct, when questions coming under any of these and other important headings arise in the course of his daily work. To bring this about the training before entrance to the profession requires to be improved so that the professional knowledge shall be firmly based and more easy of acquisition. And throughout the curriculum opportunities for learning under supervision how to apply practically the clinical wisdom which he is gaining need to be more freely afforded. These two things would seem to be wanted. And though they can be stated thus succinctly, the bringing of them about is taxing the ingenuity of many whose devotion to the subject is well known. But the deep interest in the training of the student, now being manifested, must bring about real results, while it is good to feel that existing pessimism is ill-grounded.

THE MEDICAL SERVICES

NAVAL MEDICAL SERVICE

THE revised regulations and conditions of service arising out of the Warren Fisher Committee report have recently been published by the Admiralty, and it is considered that the Naval Medical Service now offers to well-qualified medical men a very satisfactory career, with excellent opportunities for the practice of their profession and for specialisation in many subjects; the pay is good, and so is the prospect of promotion to the higher ranks with an adequate pension on retirement.

The following information embodies the principal changes in conditions.

Entries will be on a Short Service basis, and will be for an initial period of 3 years, to be extended to 5 years at the discretion of the Admiralty.

Officers leaving the service at the end of 3 years will be eligible for a gratuity of £400, whilst those who leave at the end of 5 years will receive £1000.

Officers may be transferred to the Permanent List at the discretion of the Admiralty on completion of 5 years' Short Service. A gratuity of £1000 will be paid, but the Officer will be required to render a minimum of 25 years' service in order to qualify for full pension, including seniority granted, if any, in respect of Civil Hospital time. With regard to the latter, antedate of Seniority of not more than one year may be allowed in respect of resident appointments in Civil Hospitals held prior to entry to the R.N. Medical Service. The antedate will count for seniority and eligibility for increase of pay, and if the officer is transferred to the permanent list it will count also as service for the purposes of promotion and retired pay, or gratuity on retirement.

Opportunities will be afforded for officers to specialise during the course of their career, and the number of Specialists posts carrying additional emoluments has been increased from 60 to 83.

The age of retirement has been increased in the case of Surgeon Commanders from 50 to 55, and in the case of Surgeon Captains from 55 to 57, thus affording officers the prospect of a longer career on full pay.

Candidates must not be above the age of 28 years.

MEDALS AND PRIZES

Gilbert Blane Medal.—This Medal is awarded annually to the Surgeon Lieutenant-Commander who obtains the highest aggregate marks at the examination for promotion to the rank of Surgeon Commander. The award is subject to the approval of the Presidents of the Royal College of Physicians and Surgeons respectively and the Medical Director-General of the Navy.

Other awards and prizes open to Naval Medical Officers are the Chadwick Naval Prize, the North Persian Forces Memorial Medal, and the Parkes Memorial Prize.

PAY AND ALLOWANCES

Full Pay (Current Rates)

		£		£	
SURGEON LIEUTENANT (short service and permanent service)	from	434	to	477	per annum.
SURGEON LIEUTENANT-COMMANDER (promoted after six years' service)	,,	574	,,	608	,,
SURGEON COMMANDER (promoted after a further six years' service)	,,	739	,,	1052	,,
SURGEON CAPTAIN (promoted by selection)	,,	1067	,,	1314	,,
SURGEON REAR-ADMIRAL (promoted by selection)		1724			,,
MEDICAL DIRECTOR-GENERAL..		2185			,,

Allowances

An outfit allowance of £50 towards cost of uniform is given.

Allowances when in charge of hospitals and sick quarters ..	10*s.* and 5*s.* per diem.
Eighty-three Specialist allowances of	5*s.* per diem.
Allowances to Senior Medical Officers in flagships	5*s.* and 2*s.* 6*d.* per diem.

Accelerated promotion can be gained under certain conditions: provision allowance and lodging allowance are paid when victualling and accommodation are not provided. Servant's allowance is also payable in certain appointments.

The extra allowances alluded to in this Table are not to be looked upon as very exceptional. About a quarter of the Medical Officers of the Navy are drawing extra allowances.

PENSION

Naval Officers retire at certain ages according to the rank they have attained. Except for those promoted to the 40 higher posts, the usual retiring age is 55 as Surgeon Commander, the appropriate pension according to scale being £540 per annum.

The current scale of pensions is as follows:—

	Maximum retired pay.		
SURGEON VICE-ADMIRAL ..	£1076 per annum on vacating office.		
SURGEON REAR-ADMIRAL ..	£909 per annum at age of		60.
SURGEON CAPTAIN	£810	,, ,,	57.
SURGEON COMMANDER	£540	,, ,,	55.
SURGEON LIEUTENANT-COMMANDER AND SURGEON LIEUTENANT	£405	,, ,,	45.

Officers permitted to withdraw receive gratuities on the following scale:—

	£
Over 10 and under 15 years' service ..	500
,, 15 ,, ,, 18 ,, ,, ..	1800
,, 18 years' service	2700

The old regulation by which officers were admitted direct to the Permanent Service by examination is now abolished. No examination for entry is held, but candidates will be required to present themselves before a Selection Board at the Admiralty presided over by the Medical Director-General of the Navy, to whom application should be made for further details.

Dental Branch

Candidates, who must be qualified dental surgeons and below the age of 28 years, are required to produce certificates of birth, registration, and of character, and must be physically fit for active service anywhere. An outfit allowance of £50 is payable to officers finally entered and commissioned. The rank of Surgeon Lieutenant-Commander (D) is attained on the completion of six years' satisfactory service. Promotions to Surgeon Commander (D) and Surgeon Captain (D) are made strictly by selection from the rank next below and are confined to officers who prove fitted in every respect for these ranks. The present establishment of dental officers is: 1 Surgeon Captain (D), 3 Surgeon Commanders (D), 60 Surgeon Lieutenant-Commanders (D) and Surgeon Lieutenants (D).

Provision has been made for candidates who have held, or who, at the time of passing the examination hold or are about to hold, an appointment as Dental Officer in a recognised Civil Hospital. The time concerned, provided it does not exceed six months, may reckon for increase of full pay while on the active list.

On the completion of two years' service in the rank of Surgeon Lieutenant-Commander (D), dental officers on the Active List are eligible for a three months' post-graduate course at a dental hospital and school at the public expense, and will draw full pay while attending the course.

Pay.—The current rates of full pay for Dental Officers are as follows :—

	£ £
Surgeon Lieutenant (D)	362–444
Surgeon Lieutenant-Commander (D) (promoted after six years' service)	535–657
Surgeon Commander (D) (promoted by selection to fill vacancies in Establishment)	699–894
Surgeon Captain (D) (promoted by selection to fill vacancy in Establishment)	1028–1275

The Regulations regarding Pension and Withdrawal Gratuities are the same as for Medical Officers in the corresponding Ranks.

In 1919, when new rates of pay for all Naval Officers were fixed, it was decided that 20 per cent. of these rates should be considered as due to the then high cost of living. The rates of pay shown above are those payable on and after July 1st, 1934, and represent a reduction owing to the decrease in the cost of living. The 20 per cent. above mentioned is to be regarded as variable and subject to change at six-monthly intervals, either upwards or downwards according as the cost of living rises or falls.

ARMY MEDICAL SERVICE

Royal Army Medical Corps

THE appointment of officers to the Royal Army Medical Corps will, in the first instance, be by means of a Short Service Commission for a period of five years. In the fifth year of service an officer will be given the choice of retiring with a gratuity of £1000 or of applying for a permanent commission. Those retiring with a gratuity after five years' service will be liable to be called up for duty in the event of a national emergency arising during the twelve years following their retirement.

New entrants are commissioned in the rank of Lieutenant, and the first three months of their service are on probation, during which time they undergo a course at the Royal Army Medical College in London, in Hygiene, Tropical Medicine, Entomology, &c., &c., in addition to their military training at the Royal Army Medical Corps Depôt at Aldershot. A grant of £50 is made for the purchase of uniform.

An entrant who is holding or who is about to hold at the time of entrance an approved whole-time appointment at a recognised Civil Hospital may be seconded while holding such appointment up to a maximum period of 12 months. A candidate who has held such an appointment within six months of entry may be granted an antedate up to 12 months in respect of the period the appointment was held. The period of secondment or antedate will not reckon in diminution of the period of five years which he is required to serve on a short service commission, but on completing one year of actual service in the R.A.M.C. the period of secondment or antedate will count for seniority.

If appointed to a permanent commission the period of secondment or antedate will count as service for promotion to the rank of Major, increases of pay in the ranks of Captain and Major, and retirement on retired pay or with gratuity.

PROMOTION

Promotion to Captain will be after one year's commissioned service on full pay. If appointed to a permanent commission promotion to the rank of Major will be on completion of 10 years' commissioned service. Promotion to the ranks of Lieutenant-Colonel and Colonel will be by selection to fill vacancies within the establishment which is designed to allow promotion to those ranks on the average after 17 and 25 years' service respectively.

PROFESSIONAL OPPORTUNITY

The possibilities for good work are very great. There is scope for original research in tropical diseases, in preventive medicine, and in bacteriology, as well as in the large clinical field open to the specialist in Medicine, Surgery, Gynæcology, Diseases of the Ear, Nose, and Throat, Ophthalmology, and Venereal Diseases. Child Welfare is also undertaken systematically by officers of the R.A.M.C.

FOREIGN SERVICE

The tour of foreign service in India or the Mediterranean Stations is five years, that of the Colonies three years, but in the case of those officers retiring on a gratuity after five years' service, arrangements would be made for them to return to England at public expense by the end of that period.

TABLE SHOWING PAY AND ALLOWANCES (HOME RATES)

Appointment.	Pay.*	Rations †	Servant.	Married.‡			Unmarried.		Approximate total per annum.

After 6 years' service ..	1 7 0	1 3	2 0	4 6	2 8	2 0	2 6	0 8	721	611
„ 8 „ „ ..	1 9 4	1 3	2 0	4 6	2 8	2 0	2 6	0 8	763	654
Major	1 13 10	1 3	2 0	4 6	2 10	2 0	4 0	1 3	849	774
After 13 years' service ..	1 18 4	1 3	2 0	4 6	2 10	2 0	4 0	1 3	931	856
„ 16 „ „ ..	2 0 6	1 3	2 0	4 6	2 10	2 0	4 0	1 3	970	896
„ 18 „ „ ..	2 5 0	1 3	2 0	4 6	2 10	2 0	4 0	1 3	1052	978
Lieutenant-Colonel	2 11 10	1 3	2 0	4 6	3 0	2 0	4 6	2 4	1180	1131
After 3 years' service as such	2 16 4	1 3	2 0	4 6	3 0	2 0	4 6	2 4	1262	1214
Colonel	3 3 0	1 3	2 0	5 6	3 11	2 0	5 6	2 8	1419	1360
Major-General	4 5 6	1 3	4 0	11 0	4 10	2 0	11 0	3 10	1983	1928
Director-General	5 10 4	1 3	6 0	13 9	5 5	2 0	13 9	4 5	2410	2356

* The rates of pay shown in the above Table are the rates issuable with effect from July 1st, 1934, and represent the standard rates as laid down in the Pay Warrant, 1931, less a deduction of 10 per cent. on account of the fall in the cost of living since 1919. In the case of the Director-General the rate of pay shown is the standard rate less a deduction of 8 per cent., but a special deduction of 5 per cent. has been made from the total of his pay and allowances.

† These rates apply when rations cannot be issued in kind.

‡ A married officer for the purposes of furniture, lodging, fuel, and light allowances is one who is or has been married and is 30 years of age or over.

POST-GRADUATE STUDY

A permanent commissioned officer will, between his sixth and tenth year of service, undergo a course of post-graduate study at the Royal Army Medical College and the London hospitals of five months' duration, followed by a course of study of a special subject selected by himself, provided he has shown special aptitude in the post-graduate course or during his previous service. During this course of study he remains on full pay, and the fees for the course are paid by the State.

When qualified in his special subject, the officer up to and including the rank of Lieutenant-Colonel becomes entitled to specialist pay at 4*s.* 6*d.* per day when holding a specialist appointment.

PAY AND ALLOWANCES (HOME RATES)

The rates of pay and allowances for officers are at present as shown in the Table, but the allowance rates vary slightly from time to time. In addition, specialist pay and charge pay are given under certain conditions as noted below.

ADDITIONAL PAY

An officer below the substantive rank of Colonel holding an appointment as specialist receives 4*s.* 6*d.* a day, in addition to his ordinary pay.

The Adjutant, R.A.M.C. Depôt, receives 5*s.* a day in addition to his ordinary pay.

CHARGE PAY	Daily. *s.*	*d.*
(*a*) An officer below the substantive rank of Colonel in charge of a hospital of 50 beds and over, or in charge of a medical or surgical division of a general hospital with at least 300 beds	5	0
(*b*) Senior Medical Officer, Royal Arsenal ..	5	0

Assistant Professors at the Royal Army Medical College (Lieutenant-Colonels) receive pay and allowances of their rank plus £89 a year.

GRATUITY; SHORT SERVICE OFFICERS

The gratuity of £1000 granted on retirement, after five years' service as a medical officer, to a short service officer who does not obtain a permanent commission is generous, and should go a long way to enable an officer on leaving the Service towards establishing himself in Civil life.

Entry takes place twice yearly at the beginning of May and November.

Regulations for admission, giving full details and application forms, should be obtained from the Assistant Director-General, Army Medical Services (A.M.D.1), The War Office, Whitehall, London, S.W.1.

RETIREMENT AND RETIRED PAY: OFFICERS HOLDING PERMANENT COMMISSIONS

The following are the rates of retired pay:—

1. Retired pay consists of two parts: (*a*) a service element based on the officer's total service; (*b*) a rank element for the rank from which the officer retires. An officer with less than 20 complete years' service will not be eligible to retire voluntarily on service retired pay.

2. The scale will be as follows, subject to the reduction of 10 per cent. referred to below:—

(*a*) Service element.—£15 a year for each completed year of service as a medical officer.

(*b*) Rank element.—

Rank from which retired.	After completing 1 year's service in the rank.	After completing each additional year's service.	Maximum rank element.
	£	£	£
Major	12	12	120
Lieutenant-Colonel	150	30	240
Colonel	290	50	390
Major-General ..	440	50	540
Lieutenant-General	590	50	690

The retired pay of an officer retiring with less than one complete year's service in the rank from which he retires will be assessed as though he had retired from the rank below.

Maximum rates of retired pay (*a*) and (*b*) together:—

	£		£
Major	450	Major-General ..	1000
Lieutenant-Colonel ..	600	Lieutenant-General ..	1200
Colonel	800		

The above rates are those laid down in the Pay Warrant. They have been reduced by 10 per cent. as from July 1st, 1934, and are subject to further revisions.

3. Officers may be permitted to retire with a gratuity in accordance with the following scale:—

With less than 10 years' service as a medical officer	£1000
After 10 years' service as a medical officer ..	£1500
,, 15 ,, ,, ,, ,, ..	£2800
,, 18 ,, ,, ,, ,, ..	£3500

The Army Dental Corps

This Corps is administered by the Director-General, Army Medical Services. Regulations for admission to The Army Dental Corps should be obtained from the Under Secretary of State, War Office, and carefully studied.

OFFICERS: APPOINTMENT AND PROMOTION

1. Commissions as Lieutenants in The Army Dental Corps may be given to persons duly qualified under regulations approved by the Army Council.

2. An officer who is commissioned after holding an approved whole-time appointment in a recognised civil dental hospital or in the dental department of a recognised civil general hospital may be granted an antedate covering the period of his appointment, but not exceeding six months, provided that the interval between the termination of the hospital appointment and the date of entry into the Service does not ordinarily exceed six months. The period of such antedate will reckon towards promotion, increase of pay, gratuity, or retired pay.

3. An officer is eligible for promotion to the rank of Captain on completion of three and a half years' service and to the rank of Major on completion of 12 years' service in the Corps, provided he has previously qualified in such manner as may be prescribed by the Army Council.

4. Promotion to the rank of Lieutenant-Colonel and Colonel to fill the establishments laid down from time to time for those ranks is made by selection from those senior in the rank below. Dental officers are also eligible for special promotion by brevet.

PAY

The following are the rates of pay for officers of The Army Dental Corps.

	Per diem. £	*s.*	*d.*
Lieutenant		18	0
Captain	1	2	6
Captain after 8 years' total service ..	1	5	2
Captain ,, 10 ,, ,, ,, ..	1	7	0
Major	1	11	6
Major, after 15 years' total service	1	16	0
,, ,, 18 ,, ,, ,, ...	1	18	4
,, ,, 20 ,, ,, ,, ...	2	2	10
Lieutenant-Colonel	2	9	6
Lieutenant-Colonel after 3 years' service as such	2	14	0
Colonel	3	0	10

CHARGE PAY

The officer in charge of the Dental Laboratories, Aldershot, receives charge pay at the rate of 5*s.* a day if holding the rank of Captain, or 2*s.* 6*d.* a day if holding the rank of Major.

ALLOWANCES

The allowances for officers of The Army Dental Corps are at the same rates as for officers of the Royal Army Medical Corps.

RETIREMENT AND RETIRED PAY OR GRATUITY

(1) The rates of retired pay will be the same as for officers of the Royal Army Medical Corps.

(2) Voluntary retirement on retired pay will not be allowed until after 20 years' service.

(3) Earlier retirement on gratuity may be allowed:—

After 8½ years' } service as a Dental { gratuity of £1000.
" 15 " } Officer, { " £2000.
" 18 " } { " £3000.

The aim of the Corps is the prevention of wastage on account of dental disease or dental deficiency, and, to enable this to be carried out, every recruit is inspected by a dental officer immediately after joining and all necessary treatment carried out. The soldier is reinspected at least once a year and the dental efficiency maintained at the best standard possible.

INDIAN MEDICAL SERVICE

THIS Service shares in the general conditions of change to which the whole of Indian State and civil affairs are at the present being subjected. While it is the view of many senior officers that the period of depression is passing, the grounds on which this view is held would be challenged by many. The Service is, in fact, obtaining excellent recruits, of whom the Director-General remarked not long ago that they were to be envied in embarking on a great adventure in which the part played by the Service would be greater than it had ever been in the past. The India Office is now inviting applications for permanent commissions on very favourable terms to young members of the medical profession. These terms include a gratuity of £1000 on retirement after six years' service, or one of £2500 after 12 years' service, together with free return passages for those who no longer desire to remain in the Service. An announcement made by the India Office admits frankly that it is not possible to state at present what, if any, prospects of employment on the civil side will be open to I.M.S. officers under the proposed new constitution. We find it difficult to imagine the abolition of the civil side of the Service, having regard to past magnificent work and present urgent needs.

THE NEW REGULATIONS

Competitive examination remains suspended for the present and admission to the Service is on written application to the India Office. As sound bodily health is a first essential candidates may, if they wish it, undergo a preliminary examination by a Medical Board which meets weekly at the India Office.

Candidates must be under 32 years of age at the time of application, and must possess a qualification registered in Great Britain and Northern Ireland, under the Medical Acts in force at the time of appointment. Arising out of the recommendations of the Lee Commission the Secretary of State for India in Council after consultation with the Government of India has decided that the Indian Medical Service constituted on the same broad lines as in the past shall be retained primarily to meet the needs of the Indian Army. In order to maintain the necessary minimum war reserve of military medical officers, and to provide for European medical attendance for European officers of the Superior Civil Services and their families, local governments will be required to employ a stated number of Indian Medical Service officers. The Government of India will draw on the same Service to meet the requirements of the civil administration for which they are responsible. For the present 237 such posts have been reserved, and including the leave reserve will provide employment for 302 officers; 212 of these officers will be British medical men and 90 Indians. As the proportion of European to Indian civil officers diminishes these figures will be subject to periodical scrutiny, and, if necessary, to revision. It will be a definite condition of service for all future entrants to the Service that they will be liable to serve on either the civil or the military side. All officers are required to perform one year's military duty subsequent to permanent appointment before they can be considered eligible for civil employment. Executive medical officers in both civil and military employment may attend persons unconnected with Government service provided their duty admits of it. On the military side, however, the opportunities for private practice are not great. The commissions of officers who before appointment have obtained certain higher qualifications or have held resident appointments in certain hospitals may be antedated by one year.

RATES OF PAY

The monthly rates of pay for European officers of non-Asiatic domicile in the Service are as tabulated below. The rupee, it may be remembered, has now been definitely stabilised at 1s. 6*d*.

Rank and service in rank.	Basic pay.	Overseas pay.	Year of total service.
	Rs.	Rs.	
Lieut.	500	150	First
Captain:—			
1. During first three years' service as Captain.	650	150	Second
		150	Third
		150	Fourth
2. With more than three and less than six years' service as Captain.	750	£15	Fifth
		£15	Sixth
		£25	Seventh
3. With more than six years' service as Captain.	850	£25	Eighth
		£25	Ninth
		£25	Tenth
		£25	Eleventh
		£30	Twelfth
Major:—			
1. During first three years' service as Major	950	£30	Thirteenth and over
2. With more than three and less than six years' service as Major	1100		
3. With more than six years' service as Major	1250		
Lieut.-Colonel:—			
1. Until completion of 23 years' total service	1500		
2. During twenty-fourth and twenty-fifth years' total service	1600		
3. After completion of 25 years' total service	1700		
4. When selected for increased pay ..	1850		

NOTE TO TABLE

Until the completion of 23 years' total service basic pay is regulated according to rank and service in rank (column 1) which, owing to the system of accelerated promotion, may be in advance of the time-scale of promotion. Overseas pay is regulated solely with reference to length of total service (column 4). In addition to the above rates various allowances are admissible for a large number of special appointments on both the military and the civil side which may be held by members of the I.M.S. Special high rates of pay are also attached to the numerous administrative appointments open to officers in both branches of the Service. The appointment of Director-General, I.M.S., which is held by an I.M.S. officer, carries pay of Rs.3500 per mensem. The appointment of Director of Medical Services in India, carrying pay at Rs.3200 per mensem, may also be held by an officer of the Indian Medical Service.

Owing to the state of financial emergency prevailing in India, the existing monthly rates of pay and allowances are at present subject to a temporary reduction of 5 per cent.

Officers on arrival in India will be posted for one year to specially selected stations. Officers in military employment, when in command or second-in-command of the larger station hospitals, receive special allowances. On the civil side there are public health, bacteriological, research, and professorial appointments carrying special enhanced rates. Officers on appointment receive an outfit allowance of £50.

PENSIONS AND ALLOWANCES

The rates of pensions are as shown in the Table below.

Service.	Rates per annum.	Service.	Rates per annum.
After 17 years ..	£400	After 23 years ..	£620
„ 18 „ ..	430	„ 24 „ ..	660
„ 19 „ ..	460	„ 25 „ ..	700
„ 20 „ ..	500	„ 26 „ ..	750
„ 21 „ ..	540	„ 27 „ ..	800
„ 22 „ ..	580		

The above rates are subject to periodical revision upwards or downwards, to an extent not exceeding 20 per cent. in all, on account of a rise or fall in the cost of living, as compared with the year 1919. A deduction of 7½ per cent. is at present being made on this account.

There are additional pensions not subject to the above reduction ranging from £65 to £350 per annum for officers who have held high administrative appointments as colonels or major-generals.

Officers on appointment are provided with free passage to India, normally by transport. The wives and families of officers who are married prior to the date of the officers' embarkation on first appointment will also be given free passage to India subject to the payment of messing charges. Officers are granted a certain number of return passages home at Government expense during their career. There are special allowances for officers whilst on study leave.

Further particulars can be obtained on application to the Secretary, Military Department, India Office, Whitehall, London, S.W.1. Letters should be marked "Recruitment for I.M.S."

MEDICAL BRANCH OF THE ROYAL AIR FORCE

THE Air Council attach great importance to attracting into the service the best type of medical man, since on the capacity of the Medical Branch depends in a peculiar degree the safety and efficiency of the Air Force. The duties of a medical officer in the Air Force include not only the prevention and treatment of those ordinary diseases to which the personnel of any fighting service are liable, but the special study of the mental and physical stresses imposed on the airman in diverse circumstances and climates—a new branch of medicine which still provides considerable scope for research.

As promotion to the higher ranks of the Service is by selection, and as a certain proportion of the higher ranks are reserved for purely professional as opposed to administrative appointments, it will be seen that there are excellent prospects for the young medical officer who exhibits ability and energy in his professional work.

The work to be done, therefore, has a high professional interest, combined with good rates of pay and allowances, so that a career is offered which should prove both attractive and interesting. The life is one which is certain to appeal to the man of wide outlook who desires opportunities for travel, sport, and games, and can find interest and enjoyment in aviation.

His duties will, as a matter of course, give him flying experience as a passenger, which is necessary for the proper study of the medical problems of aviation and for gaining first-hand knowledge of the conditions under which his comrades serve. He may also, if he wishes, undergo a certain amount of training as a pilot, when this can be arranged without interference with his duties.

The establishment consists partly of permanent and partly of short-service officers, and an officer on entry is granted a short-service commission for a period of three years on the active list (extensible to five years if the officer so wishes, on the recommendation of the Director of Medical Services) and of four years in the Reserve of Air Force Officers. Selections for permanent commissions are made from officers holding short-service commissions, and those who are not selected are transferred to the Reserve at the expiration of their period of service on the active list.

For those entrants who desire it, the opportunity of obtaining a permanent commission is one approaching 50 per cent., so far as can reasonably be estimated at present. But the short-service commission with its gratuity after three or five years is in itself an attraction to many entrants who desire to enlarge their experience and outlook from the point of view of subsequently entering private practice, and who, on entry, have not made up their minds to the adoption of a permanent career in the Service.

For certain purposes medical officers may be allowed to count as service their time spent in approved whole-time post-graduate appointments in civil hospitals under certain well-defined and generous conditions.

At about five years' service all permanent officers who are judged suitable will be given the opportunity to take a course of specialist study. The period allowed will vary with the subject of study, but normally about nine months will be available to each officer, during which full pay and allowances will be issued. Their subsequent career will normally be as follows. Approximately three-quarters of the employment of squadron leaders and senior flight lieutenants is in specialist posts, though these are not generally of a full-time specialist character. On reaching the rank of wing commander, the policy is to allow a proportion of officers to become permanent specialists and to be employed continuously throughout the remainder of their career in full-time specialist posts. Rather more than a quarter of the officers will become permanent specialists and continue to be employed as such throughout their service in the ranks of wing commander and group captain. In addition there are a number of hygiene posts in the former rank open to specialists in that subject, bringing the proportion of specialist posts in the rank up to nearly a half of the total posts. In the rank of group captain, apart from the posts already mentioned as available for the permanent specialist, employment is nearly equally divided between posts in charge of a large hospital and headquarter administrative posts. This statement indicates the position as regards specialist employment as at present foreseen. No guarantee can be given, of course, that the career of an individual will necessarily conform to this forecast.

New entrants into the Royal Air Force Medical Branch are commissioned as Flying Officers (Medical), and are eligible for promotion to the rank of Flight Lieutenant (Medical) after one year's service on full pay. Permanent officers are normally promoted to the rank of Squadron Leader after ten years' total service. Accelerated promotion may be granted after the completion of eight years' service to officers qualified to hold specialist appointments. Promotion within establishment to the ranks of Wing Commander and above is by selection. The number of permanent commissions granted yearly is regulated with a view to all suitable permanent officers being promoted to Wing Commanders and of a substantial majority of Wing Commanders being promoted to Group Captains. While the aim is to give entrants a career as above, no guarantee of promotion can be given to the individual officer, of course, since the number of vacancies for promotion must depend on the requirements of the Service from time to time.

There is no competitive examination on entry; candidates must be under 28 years of age. British subjects, the sons of British subjects, and of pure European descent, and are interviewed by a Board presided over by the Director of Medical Services, Royal Air Force, before acceptance. Each candidate must produce:—

1. Birth certificate. 2. Medical registration certificate. 3. A declaration containing the following information:

(*a*) Age and place of birth. (*b*) That he is a British subject, the son of British subjects, and of pure European descent. (*c*) That he is ready to engage for general service at home or abroad as required. (*d*) The qualifications he is possessed of, and what medical or other appointments he has held (if any). (*e*) That he is willing to fly as a passenger whenever called upon to do so.

Each candidate is required, before acceptance, to pass a medical examination to ensure that he labours under no constitutional or mental disease or weakness, nor any imperfection or disability which may interfere with the efficient discharge of the duties of a medical officer in any climate, in peace or war.

On appointment entrants undergo an initial course of three months, during which they are given instruction in the special medical aspects of aviation, the organisation and administration of the Royal Air Force, and the general and special duties to be performed by officers in the Medical Branch.

In order to avoid the necessity for further examinations the position of entrants in order of seniority in the Air Force List is determined at the end of the initial course by a system of marking and reports on the actual work done during their instruction.

UNIFORM AND EQUIPMENT

Medical officers are required to provide themselves with the uniform, service dress, and mess dress of their rank, and with the distinguishing badges of the Royal Air Force Medical Branch. The provision of full dress is entirely optional at present. An allowance of £50 towards the cost of uniform is made on joining to candidates who have not had previous commissioned service in H.M. Forces.

EMOLUMENTS

The emoluments of medical officers of the Royal Air Force are given in outline below. The rates of pay are fixed on an inclusive basis, and the fact that specialist pay and charge pay are not payable as separate emoluments was taken into account when the rates were fixed. The standard rates of pay and retired pay were fixed on the basis of the high cost of living in 1919, 20 per cent. of each standard rate being detachable and subject to alteration in relation to the cost of living. The rates were accordingly altered periodically between 1919 and 1932, but in the latter year it was decided in principle that variations in relation to the cost of living should cease and that pay should be consolidated; no final decision as to the date or terms of consolidation has been reached. The current rates represent a reduction of approximately 10 per cent. on the standard rates, and will continue to be issuable until further notice.

ALLOWANCES AT STATIONS ABROAD

In addition to the current pay shown above, officers stationed abroad are provided with furnished quarters (with fuel and light) and rations, or allowances in lieu, and receive colonial and servant allowances. The present total of the allowances (including colonial and servant allowances) payable when provision in kind is not available is as follows :—

Rank.	Egypt		Palestine		Malta		Malaya	
	M.	S.	M.	S.	M.	S.	M.	S.
	p.a. £	p.a. £	p.a. £	p.a. £	p.a. £	p.a. £	p.a. £	p.a. £

M. = married ; S. = single.

The married rates are payable only when the officer is accompanied by his family. If unaccompanied he is treated as unmarried for the purposes of his own accommodation, or allowances in lieu, and receives a consolidated allowance in respect of the separated family as follows :—

Flying Officer	£109 p.a.
Flight Lieut. and Squadron Leader..	£136 „
Wing Cmdr. and Group Captain ..	£173 „

Iraq and Sudan.—Families are normally not allowed in these countries, and officers are provided with accommodation, &c., for themselves, and receive colonial and servant allowances. The present rates of colonial allowance amount to £142 p.a. (Iraq) and £46 p.a. (Sudan). In addition, married officers receive the consolidated allowance for separated families at the rates shown above.

Aden and Transjordan.—Families are only allowed at these stations if public married quarters are available. Married officers accompanied by their families are accordingly provided with married accommodation, &c., and receive a servant allowance of 2*s.* a day and a colonial allowance of 10*s.* a day at Aden and 7*s.* in Transjordan. All other officers are provided with unmarried accommodation and receive servant allowance of 2*s.* a day and colonial allowance of 5*s.* a day at Aden and 3*s.* 3*d.* a day in Transjordan. In addition, married officers separated from their families receive the consolidated allowance at the rates shown above.

---

* Except for periods of service under Indian administration. For such periods officers receive pay and allowances at rates and subject to conditions authorised from time to time by the Government of India.

† These allowances are issued only when accommodation, fuel and light, rations, and personal attendance are not available in kind. Normally, provision in kind is available for junior officers. "Married" rates of allowances are payable only to married officers who have reached the age of 30 or the rank of Squadron Leader. The rates and general scheme of allowances are liable to revision as circumstances may require.

The rates of colonial allowance payable in Aden and Palestine and Transjordan are under review and will probably be reduced.

Retired Pay

The minimum period of service qualifying for retirement on retired pay is 20 years.

Standard scales of retired pay are as follows:—

AIR OFFICERS

Air Vice-Marshal ..	.. £790 to £1010 per annum.
Air Commodore ..	.. £650 „ £950 „ „

OFFICERS BELOW AIR RANK

Age on retirement.	Standard yearly rate of retired pay.	Years of service.	Addition for each extra year of service.*	Deduction for each deficient year of service.*
	£		£	£
40	300	17	15	15
41	337	17	15	15
42	375	18	15	15
43	412	18	15	15
44	450	19	15	15
45	487	19	15	15
46	525	20	15	15

54	765	24	22	15
55	790	24	22	15

* Limited to five years.

The maximum standard rates of retired pay and the compulsory retiring ages for the several ranks are:—

Rank.	Yearly rate of retired pay.	Compulsory retiring age.
	£	
Air Vice-Marshal ..	1010	60
Air Commodore ..	950	57
Group Captain.. ..	900	57
Wing Commander ..	600	55
Squadron Leader ..	500	55

Gratuities.—A permanent officer allowed to retire before having qualified for retired pay may be granted a gratuity, namely:—

£1000 if he has 5 but less than 10 years' commissioned service.
£1500 „ „ 10 „ „ 15 „ „ „
£2800 „ „ 15 or more than 15 „ „ „

Short-service officers who complete their full period of service on the active list will normally be granted gratuity as follows on transfer to the Reserve:—

After 3 completed years	.. £400
„ 5 „ „	.. £1000

These gratuities will not be payable to officers granted permanent commissions, but their service on a short-service commission will count towards retired pay.

THE GUILD OF ST. LUKE was founded 70 years ago by a few medical students, chiefly to meet their own religious needs. It now makes a wider appeal, and its membership is open to all students and practitioners of medicine, both men and women, who are members of the Church of England, the clergy of which are eligible as Clerical Associates. The Chapter meets at St. Nicholas Cole Abbey, London, E.C. Particulars of the objects and activities of the Guild can be obtained on application to the Secretary, Guild of St. Luke, 43A, Matheson-road, W.14.

COLONIAL MEDICAL SERVICE

THE Colonial Medical Service consists of the Medical Services in Bahamas, Barbados, Bermuda, British Guiana, British Honduras, British Solomon Islands Protectorate, Ceylon, Cyprus, Falkland Islands, Fiji, Gambia, Gibraltar, Gilbert and Ellice Islands Colony, Gold Coast, Hong-Kong, Jamaica, Kenya, Leeward Islands, Malaya, Mauritius, Nigeria, Northern Rhodesia, Nyasaland, Palestine, St. Helena, Seychelles, Sierra Leone, Somaliland, Tanganyika, Trinidad, Uganda, Windward Islands, and Zanzibar.

The various Colonial government medical departments employ some 1200 European medical officers and about the same number of qualified Asiatic and African medical officers who are appointed locally. Included in this total are about 30 qualified European women medical officers. About 850 trained nursing sisters and health visitors are employed, most of whom are Europeans. There are large numbers of subordinate personnel, sanitary inspectors, medical assistants, and dressers, most of whom are natives of the areas in which they serve.

Throughout nearly the whole of the Colonias Empire such diseases as malaria, yaws, leprosy, and hookworm disease menace the health of the indigenous people and retard the progress of development. In equatorial Africa sleeping sickness and plague persist, in West Africa yellow fever has not yet been eradicated, and in the Near and Far East outbreaks of cholera and plague occur from time to time. But in addition to tropical diseases, those maladies usually met with in this country are prevalent throughout the Empire.

An officer in the Colonial Medical Service thus has unique opportunities for the practice of his profession. On joining his medical department his duties include medical, surgical, and public health work. He may be posted to an outlying or bush station where he will be responsible for all the medical activities in connexion therewith; or he may be attached for duty at one of the large hospitals. Every encouragement will be given him to pursue any specialist work in which he may be interested in so far as the exigencies of the Service permit. Great importance is attached to a candidate's post-graduate experience, as in the outlying districts he will frequently be called on to deal with emergencies without being able to seek the advice and assistance of his colleagues.

VACANCIES

Vacancies for medical officers may occur at any time of the year, and are dealt with as circumstances require. The almost complete cessation of recruitment during the war period, coupled with the post-war expansion of staffs, particularly in the larger Colonies, resulted in an abnormally high rate of recruitment. The average for the six years, 1924 to 1929, was 104 vacancies per annum. In 1930 the number of vacancies fell to 77, due to the establishments of medical departments being almost at full strength. As a result of the general financial depression only 35 vacancies were filled in 1931, and the number was further reduced to 12 and 22 in 1932 and 1933 respectively. For the present, therefore, vacancies are likely to be very infrequent. In normal circumstances vacancies occur most frequently and regularly in Tropical Africa and Malaya. In the Bahamas, Barbados, Bermuda, Ceylon, Jamaica, and Mauritius, junior posts are practically always filled by the appointment of qualified local candidates. The vacancies for which candidates are selected from outside the Service are those for ordinary medical officers. Appointments for specialists are almost invariably reserved for officers who are already in the Service, and who have shown outstanding merit in a particular branch of medicine or surgery. Under normal conditions about six vacancies were to be expected annually, usually in

West Africa and in Malaya, for women medical officers.

QUALIFICATIONS

Applicants must be under 35 years of age, and preference is given to candidates under 30. For certain appointments candidates must be of European parentage.

Preference will be given to applicants who have held hospital or public health appointments or who have special knowledge of anæsthetics, radiology, surgery, medicine, ophthalmology, gynæcology and midwifery, diseases of the ear, nose, and throat, or venereal diseases. In the case of women medical officers experience in maternity and child welfare is almost essential.

Selected candidates will normally be required to undergo a course of instruction at the London School of Hygiene and Tropical Medicine or at the Liverpool School of Tropical Medicine or at Edinburgh University before taking up their appointments. The cost of tuition will be paid by the Government, but candidates must make their own arrangements for board and lodging. An allowance of £25 a month will be paid to them monthly in arrear while they are under instruction. Candidates who are successful in obtaining the diploma in tropical medicine and hygiene of London, Liverpool, or Edinburgh are granted a refund of their examination fees. If an officer has not taken a course of instruction in tropical medicine prior to appointment, he is usually required to take one during his first leave of absence and to obtain a satisfactory certificate before he can be confirmed in his appointment.

GENERAL CONDITIONS OF SERVICE

New entrants to the Service will be liable to transfer to any scheduled post therein, whether or not such transfer represents promotion, provided that:

(a) No officer whose first appointment is to an office in a Dependency in which he was ordinarily resident at the time of appointment shall be liable to be transferred to an office outside that Dependency unless and until he shall have accepted an office in another Dependency.

(b) No officer shall be transferred without his own consent to an office which in the opinion of the Secretary of State is of less value (due regard being had to climate and other circumstances) than that which he already holds.

Officers who do not hold scheduled posts are eligible to apply for transfer to such posts. Appointment, confirmation, promotion, retirement, and transfer of Medical Officers will be governed by the directions of the Secretary of State.

No officer of the Service is entitled, as of right, to private practice, the Service being envisaged as essentially a Service of whole-time officials whose primary duty is to the State.

In view of the present financial stringency it has been found necessary in certain Colonial Administrations to impose a temporary levy on salaries. The actual value of an appointment is often much greater than is indicated by the salary alone. An applicant should take into consideration whether the post is pensionable; whether free quarters are provided; whether any special local allowances are payable; whether free passages are provided on first appointment and when proceeding on leave; and whether free or assisted passages are provided for the wives and children of married officers. If local income-tax exists in a colony it is much lower than that payable at home.

The majority of appointments are pensionable. Officers appointed to pensionable posts serve on probation in the first instance, the probationary period varying in different services—e.g., two years in East Africa, three years in West Africa. Some appointments are temporary, and service in these does not qualify for pension unless the appointment is subsequently made pensionable.

Information as to the conditions and cost of living in the colonies, protectorates, and mandated territories is contained in a publication of that title (Colonial No. 56), which may be obtained from H.M. Stationery Office, price 3s. Further information as to the staffs, the climate, and local conditions will be found in Appendix III. of the Dominions Office and Colonial Office List, which also contains the rules as to leave of absence, free passages, &c. Leaflets concerning nearly all the tropical dependencies are issued for the use of intending settlers and others by the Oversea Settlement Department, Dominions Office, Caxton House, Tothill-street, London, S.W.1. A memorandum on Medical Appointments issued by the Colonial Office will be sent without charge on application to the Director of Recruitment.

Applications for medical appointments in the Colonial Service should be addressed to the Director of Recruitment (Colonial Service), Colonial Office, 2, Richmond-terrace, Whitehall, London, S.W.1. For the present no candidate will be considered by the Secretary of State for the Colonies who did not—if of suitable age—serve in some branch of His Majesty's Forces during the Great War, unless his reasons for not having done so are considered entirely satisfactory by the Secretary of State.

PARTICULAR CONDITIONS OF SERVICE

Tropical Africa

EAST AFRICA

Selected candidates are appointed as medical officers on probation in the first instance for two years, at the end of which period their appointments are made permanent if their service has been satisfactory, and a native language test has been passed. Later on a special course of study must be taken while on leave. Candidates can generally take their wives with them on first appointment.

Officers are provided with quarters free of rent or the Government may provide temporary accommodation, or an allowance in lieu of quarters may be paid. The salary of a medical or sanitation officer is £600 per annum, rising by annual increments of £30 to £840, and thence by increments of £40 to £920, subject to an efficiency bar at £840. Senior medical officers and senior sanitation officers are paid on the scale £1000 by annual increments of £50 to £1100. Officers who possess the Diploma in Public Health on entering, or who acquire it while in the Service, receive two special increments in the scale.

Officers are permitted to retire with gratuity, if they wish, instead of waiting to retire on pension as follows: (a) after nine years' service, of which at least six must have been spent in East Africa, £1000; (b) after twelve years' service, of which at least eight must have been spent in East Africa, £1250. If an officer elects to retire with gratuity he thereby forgoes all claim to pension.

The highest grades and salaries in the medical departments are as follows:—

Kenya.—Director of Medical and Sanitary Services, £1500; Deputy Director of Medical Service, £1200.

Uganda.—As Kenya.

Tanganyika Territory.—As Kenya.

Nyasaland.—Director, £1300; Medical Entomologist, £1000–£50–£1100.

Zanzibar.—Director of Medical and Sanitary Services, £1300; Resident Surgical Officer, £1000–£50–£1100.

Northern Rhodesia.—Director of Medical Services, £1300; Deputy Director of Medical Services, £1200.

There are also the following posts: medical superintendent and principal of medical school, Mulago Hospital (Uganda), £1150; sleeping sickness officer (Tanganyika Territory), £1000–£50–£1100; senior bacteriologists (Kenya and Uganda), £1000–£50–£1100.

Health officers are selected from the ranks of medical officers as occasion arises.

Leave of absence on full salary is granted in the normal case after a tour of resident service (varying from 12 to 15 months in Somaliland, 30 to 48 months in Kenya, 20 to 36 months in Northern Rhodesia, and 20 to 30 months in the other East African Dependencies, at the discretion of the Governor). Except in Kenya, Northern Rhodesia, and Somaliland the leave granted amounts to six days for each completed month of residence (or three days when for any reason the officer is not returning to East Africa), exclusive of the periods of the voyages to and from East Africa. Officers serving in certain stations in Nyasaland are allowed five or two and a half days' leave in respect of each month of service instead of six days or three days respectively.

Officers serving in Northern Rhodesia are allowed four days or two days. Officers serving in Somaliland are allowed seven or three and a half days after a tour of 12 to 15 months. Officers serving in Kenya are allowed three days for each month of residential service during their first two tours of service and four days for each month of residence during subsequent tours.

Free first-class passages are provided for the officer on first appointment and on leave, and in certain cases assistance towards family passages is given.

Pensions.—Officers on the pensionable establishment may retire (or be retired by the Government) on attaining the age of 50 years; but they may be retained in the Service, with their own consent, for such further period as the Government may recommend. Earlier retirement in the event of ill-health is also provided for. Pension of existing officers is computed at one-four hundred and eightieth of pensionable emoluments—i.e., salary and value of free quarters in respect of each month's pensionable service—at the time of retirement, subject to an average of emoluments for the last three years before retirement; but for new entrants the basis of calculation is one-six hundredth.

WEST AFRICA

Officers hold their appointments in the first instance on probation for three years from the date of their first arrival. After being placed on the permanent establishment this period is counted for pension. Officers are not allowed to take their wives and young children out with them without the sanction of the Governor. When, as is usually the case, an officer has obtained permission to be accompanied by his wife a grant of one-half the cost of his wife's passage to and from West Africa is made subject to certain conditions.

Leave.—European officers in West Africa may be granted vacation leave on full salary not exceeding in all one week's leave in the United Kingdom for every completed calendar month of total residential service in West Africa, plus the time necessarily taken on the journey to the United Kingdom, and, if the officer is returning to West Africa for further service, the time necessarily taken on the journey from the United Kingdom to the Colony. Vacation leave may be granted without any special grounds after 18 consecutive calendar months of residential service in West Africa. An officer will not be required to serve a tour of more than 24 consecutive calendar months' residential service except in special circumstances; and the Governor may grant vacation leave to any officer at any time after he has completed 12 consecutive calendar months' residential service. Within the above limits, the actual length of each officer's tour will be at the discretion of the Governor. Vacation leave on full salary may also be granted to an officer if he is invalided from West Africa after less than 12 consecutive calendar months' residential service, and sick leave on full salary may be granted for any period not exceeding six calendar months. In addition, local leave may be granted up to 27 days in any one tour.

The scale of salaries of the officers of the Medical Department, Nigeria, is as follows:—

Appointment.	Salary.	Remarks.
Director of Medical and Sanitary Service.	£1800	Duty allowance £360.
Deputy Director, Health Service.	£1500	Duty allowance £300.
Deputy Director of Medical Service.	£1500	Duty allowance £300.
Specialist Officers ..	£1300	Duty allowance £260. After five years' approved service the Deputy Director is eligible for a salary of £1400 with dutyallowance£280.
Assistant Director of Medical Service.	£1300	Duty allowance £260.
Assistant Director of Health Service.		
Senior Health Officers ..	£1050–£50–£1200	Duty allowance £210.
Senior Medical Officers	£1000–£50–£1150	Seniority allowance £100.
Deputy Director, Tsetse Investigation.	£800–£40–£960	Staff pay £150; Seniority allowance £72.
Senior Sleeping Sickness Officer.		
Research Medical Officer		
Superintendent, Dispensers' Training School.		
Pathologists	£660–£30–£720–£40–£960	—
Medical Officers of Health.		
Medical Officers ..		
Lady Medical Officers..		

The highest grades and salaries in the other West African medical departments are as follows:—

The Gambia.—Senior Medical Officer, £1000–£50–£1150.

Sierra Leone.—Director, Medical and Sanitary Services, £1400; Surgical Specialist, £1300; Assistant Director of Health Service, £1300.

The Gold Coast.—Director, Medical and Sanitary Services, £1600; Deputy Director of Medical Service, £1400; Deputy Director of Health Service, £1400; Specialist Officers, £1300.

The salary of a medical officer is at the rate of £660 a year, rising by annual increments of £30 to £720 a year. Then, if confirmed in the appointment, £720 a year, rising by annual increments of £40 to £960, with seniority allowance at the rate of £72 a year. Before passing £800, medical officers are required to take a special course of study for three months. If they obtain satisfactory certificates at the end of the course they draw their further increments up to £960 a year. A medical officer who has served for three years on the maximum salary of this scale (£960) without obtaining promotion is eligible, if recommended by the Governor, to be placed on the scale £1000–£50–£1150, with £100 seniority allowance (as for senior medical officers).

Research and Pathology.—There are a number of appointments for pathologists in Nigeria and the Gold Coast. The salary and other conditions attached to these posts are similar to those of medical officers of health.

African Medical Officers.—There are a number of Government appointments for African medical officers in the West African Colonies. These appointments carry a salary on the scale £500–£20–£600, and there are higher scales, £600–£30–£720 and £740–£820. In addition, in Nigeria and on the Gold Coast, arrangements have been made for the employment of a few young African medical men temporarily on the hospital staffs, with a view to appointment to the Government service later, if suitable. In such cases a salary of £400 a year is paid.

Eastern Colonies and Protectorates

MALAYA

Medical officers are appointed on the following scale of salaries: £700, rising to £770 during three years' probation; then, if they are placed on the pensionable establishment, rising to £805, and thence by annual increments of £35 to £1120, with a strict efficiency bar at £840.

Above the concluding figure of £1120 there are certain higher appointments, as follows: director of medical services, Straits Settlements, £1890; director, Institute for Medical Research, Federated Malay States, and principal, King Edward VII. College of Medicine, Singapore, £1540 each; some posts at £1470; and some posts at £1190, rising annually by £42 to £1400. Salaries are paid in dollars at 2*s.* 4*d.*

Information about general conditions in Malaya is obtainable from the Malayan Information Agency, 57, Charing Cross, London, S.W.1.

Leave.—Eight months' full-pay leave is normally granted: (*a*) after a tour of four years' resident service during the first eight years of resident service; (*b*) after a tour of three years' resident service during the next six years of resident service; (*c*) after a tour of two and a half years' resident service after 14 years' resident service. Additional leave on half-pay may be granted on special grounds. Officers are provided with free passages on first appointment for themselves and their families (i.e., wife and children) up to five persons, inclusive of the officer. On completion of each full tour, free return passages are given to all officers (with wife and children under the age of 10).

HONG-KONG

Officers are appointed on probation for three years. A diploma of public health is required for appointment as a health officer. The scale of salaries of the medical department is: director of medical and sanitary services, £1500–£50–£1800; deputy director £1300–£50–£1400; senior medical officer and senior health officer, £1200–£40–£1280; malariologist of port, bacteriologist, each £920–£40–£1280; port health officer and second port health officer, £860–£40 and one of £20 to £1280; health officers, £860–£40–£1220; assistant bacteriologist, radiologist, each £860–£40–£1220; medical officers, £700–£40–£1180. The currency of Hong-Kong is based on the silver dollar. For purposes of local payment salaries fixed in sterling are converted into dollars at the current rate of exchange. If furnished or unfurnished quarters are provided a rental of 7 per cent. or 6 per cent. on salary respectively is charged. In certain instances a rent allowance is paid instead.

West Indian Colonies

Jamaica.—District medical officers, if on a whole-time basis, draw £600–£25–£800 with travelling allowance and unfurnished quarters or an allowance in lieu. The public hospital, Kingston, has a staff of seven, the senior medical officer drawing £700–£50–£800. The chief post in the colony is that of superintending medical officer, £1000–£50–£1200. Whole-time officers are not allowed private practice. The age for voluntary retirement is 60. Pension is reckoned at the rate of one-sixtieth of the retiring salary for each year of service.

Trinidad and Tobago.—In Trinidad and Tobago Government medical officers receive salary at the rate of £400 per annum, rising by annual increments of £25 to £600. An officer appointed to a district receives, in addition to his salary, a travelling allowance varying from £100 per annum in a normal district to £150 per annum, and is allowed private practice, for which there is good scope. Officers employed in institution work receive a duty allowance varying from £50 to £300. Medical officers having completed 10 years' resident service are pensionable at the age of 55.

Windward Islands (Grenada, St. Lucia, St. Vincent). The chief medical officer, Grenada, receives £750, and also an allowance of £50 as bacteriologist. The chief medical officer, St. Lucia, receives £600–£700 plus transport and subsistence allowances; the post is pensionable, but private practice is not allowed except as a consultant. The chief medical officer, St. Vincent, receives £500–£600, with free quarters valued at £40. Most of the remaining appointments are district appointments with the right to private practice attached; the salaries paid by Government are, in Grenada, on the scale £500–£600, in St. Lucia, £400–£500, in St. Vincent, £400–£450. The Governor has the power to transfer a medical officer from one island to another. Appointments are pensionable.

Leeward Islands (Antigua, St. Christopher and Nevis, Dominica, Montserrat, Virgin Islands).—The appointments are similar in number and character to those in the Windward Islands, and are pensionable. An officer when first sent out is not appointed to a particular island but to the service of the Leeward Islands, with a salary of £350, and is later appointed to a definite district at a salary varying from £340 to £400–£25–£450, and the Governor decides as to the district which is to be allotted to him. He is liable to be transferred at the Governor's discretion to any medical district in the Leeward Islands. The medical officers, except in St. Christopher and Nevis, receive fees for successful vaccinations, post-mortem examinations, evidence at courts of justice, and certificates of lunacy. They are also, as a rule, allowed private practice.

British Guiana.—There are the following appointments in the medical service of the colony: surgeon-general, £1000–£1200 per annum, with consulting practice; resident surgeon and surgeon specialist, Georgetown, £1100; ophthalmologist, £700; medical superintendent, Leprosy Hospital, £700; 27 medical officers, £500–£25–£700. Most of the senior posts in institutions carry duty allowances (varying from £50 to £300 per annum) and quarters.

British Honduras.—The salary of an assistant medical officer is £500–£25–£650. The principal medical officer draws £825–£25–£850, paid in dollars. Unless they already possess a diploma of public health, medical officers are liable to be required, before they join the colony, to undergo a course of instruction at a laboratory of public health or analogous institution. The appointments are pensionable.

In British Guiana, Jamaica, and Trinidad officers are allowed to accumulate full-pay leave (at the rate of six weeks for each year's service) up to six months, and no leave of absence may (except in very special circumstances) exceed six months in all unless the officer has served for five years or more without leave, in which case two months on half-pay may be taken in addition to six months' full-pay leave.

Western Pacific

Fiji.—The chief medical officer receives £1000–£50–£1100, with free unfurnished quarters; the medical superintendent, Colonial War Memorial Hospital, £800–£25–£1000, and free quarters; the medical superintendent, Leper Asylum, £500–£25–£725, with completely furnished quarters and one servant; the medical officer of health, £750–£25–£900, no quarters provided. District medical officers receive £500–£25–£725, with partly furnished quarters or £50 house allowance (at the option of the Government). In certain districts horse allowances or car allowances are granted. In others a medical officer is provided with a launch or boat. District medical officers are allowed private practice on the understanding that their official duties are not neglected. In some districts the medical officer is also district commissioner and receives an additional allowance of from £175 to £235 and free partly furnished quarters. In most districts there is private practice, the value of which has been estimated at from £100 to £600 a year.

Western Pacific.—The staff in the British Solomons Islands Protectorate consists of a senior medical officer, £700–£50–£900, with partly furnished quarters and a local allowance of £50; one travelling medical officer, £550–£25–£650, with partly furnished quarters, a local allowance of £50, and a consolidated travelling allowance of £200.

In the Gilbert and Ellice Islands Colony there is a senior medical officer, £650–£25–£700, and an allowance of £100 to compensate for absence of private practice; partly furnished quarters are provided. One medical officer at £600–£25–£650, one at £700–£25–£800. Both these officers receive an allowance of £100 to compensate for absence of private practice; partly furnished quarters are provided.

Mediterranean Colonies

Cyprus.—There is a director of health, £1000–£25–£1200; district medical officers, £400–£20–£600, one of whom is allowed full private practice, and another consulting practice. The surgeon specialist, £600–£25–£750, is allowed consulting practice.

Gibraltar.—The surgeon of the Colonial Hospital receives £730, with private practice. There is one assistant surgeon, £600, for 3 years, thereafter £650–£25–£700, and one medical officer, £500–£25–£600–£50–£700. Both are allowed private consulting practice only. Free unfurnished quarters are provided. The Report of a Salaries Revision Committee is at present under consideration.

Island Group

Falkland Islands.—The senior medical officer is paid at the rate of £800 per annum, with free furnished quarters and £200 in lieu of private practice. Two medical officers receive £700–£25–£800 and £600–£25–£700 respectively, with quarters. Private practice is not allowed.

Seychelles.—The chief medical officer receives £600 and the resident surgeon £487 10*s.* per annum, with quarters. There are three assistant medical officers, two receiving £487 10*s.*, the other £275 10*s.* per annum, paid in rupees. Private practice is allowed.

St. Helena.—The colonial surgeon receives £550, with fees estimated at £20, and £30 transport allowance. Private practice is allowed.

Middle East

Palestine.—The grades and salaries of higher appointments in the department of health are: director, £1200, plus £200 expatriation allowance. Deputy director (not deputy director laboratories), £900–£50–£1100, plus £150 expatriation allowance; specialist surgeon (who is allowed a certain amount of private practice), and senior medical officers, £800–£25–£1000, plus £100 expatriation allowance. Government analyst, £550–£25–£800, plus £100 expatriation allowance. Payment is in Palestinian pounds, now equal to sterling. The remainder of the staff is recruited locally. Three months' leave with full pay can be taken every two years. Most of the senior appointments have been or will be made pensionable.

APPOINTMENTS NOT WITHIN THE COLONIAL SERVICE

Appointments in the self-governing Dominions and the territories administered by them—viz., Canada, the Commonwealth of Australia (including Papua, Norfolk Island, and the mandated territory of New Guinea), New Zealand (including the Cook Islands and the mandated territory of Samoa), the Union of South Africa (including the mandated territory of South West Africa), the Irish Free State, and Newfoundland—are entirely under the control of the respective Dominion Governments. For information with regard to them application should be made to the High Commissioners or Agents-General in London.

Sudan Medical Service

This service is responsible for carrying out civil and military medical and public health duties in the Sudan.

The staff consists of: (*a*) A director. (*b*) A senior physician and a senior surgeon to the Khartoum Civil Hospital. (*c*) An assistant director. (*d*) Medical officer of health, Khartoum Province. (*e*) 34 British "senior medical inspectors" and "medical inspectors" whose pay commences at £E.720 and rises, subject to the recommendation of the director, by five biennial increases to £E.1080, and after 13 years' service to £E.1200. All rates of pay are subject to an abatement of 7½%. The senior medical inspectors are eligible, by selection, for the senior posts. All medical inspectors are appointed, in the first place, on probation for two years, and if at the end of that time they are accepted for permanent service under the Sudan Government, the first increase of pay is subject to their passing an examination in Arabic.

In addition to the above there are (*f*) a number of medical officers trained at one of the Syrian medical schools, and (*g*) Sudanese medical officers trained at the school of medicine at Khartoum. There are several native (*h*) assistant medical officers, who have been given a purely practical training in one of the larger hospitals in the Sudan.

Amongst the attractions of the service are: The great variety of the work met with among many different races of the Sudan; *leave* of 90 days, generally granted every year after the first 18 months of service; *study-leave,* which may be given for some definite purpose. The pension for medical inspectors who retire after 20 years' service is not less than £E.500 a year. If, however, he serves for a longer period, or is appointed to one of the higher posts, he will receive a larger pension. Private practice is allowed, but is limited to a few of the larger towns, and may be carried on so long as it does not interfere, in any way, with official duties. These duties include acting as consultant to the principal hospitals and the supervision of medical and public health work, the inspection of schools, the examination of candidates for Government service and pension, and the training of assistant medical officers and native sanitary overseers. The Khartoum Medical School is staffed mainly by members of the medical service, who receive additional remuneration for their work as teachers. A registrar of the medical school is also selected from the service, who receives £E.250 a year extra pay.

Inquiries for further information should be made to the Deans of the Principal Medical Schools, and to Dr. Hodson, 69, Harley-street, W.

Southern Rhodesia.—Appointments are under the control of the Government of Southern Rhodesia. Information from the High Commissioner, Crown House, Aldwych, London, W.C.2.

Malta.—Inquiries should be addressed to the secretary to the Head of the Government, Valetta, Malta.

North Borneo.—Application to the British North Borneo Company, 17, St. Helen's-place, London, E.C.3.

Sarawak.—Appointments are in the hands of H.H. the Rajah. Information from the Sarawak Government Offices, Millbank House, London, S.W.1.

Basutoland, Swaziland, and the Bechuanaland Protectorate.—Appointments are made upon the recommendation of the resident commissioners, subject to the approval of the High Commissioner for South Africa and confirmation by the Secretary of State for Dominion Affairs. These appointments are usually filled by the selection of local candidates.

Shanghai Municipal Appointments.—Inquiries regarding appointments under the Shanghai Municipality, including appointments in the Shanghai Police Force, should be addressed to Messrs. J. Pook and Co., 68, Fenchurch-street, London, E.C.3.

Chinese Maritime Customs.—Inquiries regarding appointments should be addressed to the Inspector General of the Chinese Maritime Customs, 26, Old Queen-street, London, S.W.1.

Consular Appointments.—Application for appointments of a Consular nature should be addressed to the Foreign Office, London, S.W.1.

Trade Commissionerships.—Applications for appointment as trade commissioner in the colonies and elsewhere should be addressed to the Department of Overseas Trade (Development and Intelligence), 35, Old Queen-street, London, S.W.1.

WOMEN'S MEDICAL SERVICE FOR INDIA

AMONG careers open to medical women abroad the Women's Medical Service for India deserves honourable mention. The Service is open to fully qualified medical women of British or Indian nationality, and with the present amount of Government subsidy the number of medical officers is limited to 44. Medical women proceeding to India to join the Women's Medical Service receive a sufficient sum for a first-class passage to India. On landing they are posted to one of the larger women's hospitals to gain Indian experience and to learn the language. For a further period they are appointed to act temporarily for medical women on furlough. They are then definitely appointed to the charge of hospitals. Private practice is allowed, provided it does not interfere with official duties. The only exception is in administrative or educational posts, when an allowance in lieu of practice is given. The amount obtained from practice varies according to the station, but in most cases it forms a fair addition to the salary, varying from £150 to £1000 a year.

Excellent opportunities for surgery—especially gynæcological—are found in the Women's Medical Service. To those who are not keen surgeons opportunities are likely to open in the future in connexion with maternity and child welfare.

The cost of living in India is much higher than formerly, but it should be possible for a medical woman (with house provided) to meet actual household expenses for about Rs.300 per mensem, leaving the remainder of her salary for dress and personal expenses. To this must be added the necessary saving to meet additional expense for furlough and leave spent in the hills.

Rates of pay are as follows :—

Years of service.	Overseas allowance per mensem.	Salary per mensem.	English equivalent* per annum.
1 to 3	Rs.100	Rs.450	£440
4 to 6	"	Rs.500	£480
7 to 9	"	Rs.550	£520
10 to 12	"	Rs.600	£560
13 to 15	Rs.150	Rs.650	£600
16 to 18	"	Rs.700	£640
19 to 21	"	Rs.750	£680
22 to 24	"	Rs.800	£720
over 24	"	Rs.850	£760

* At rupee value 1s. 4*d.*

Furnished quarters are provided, representing an additional Rs.150 per mensem.

Leave on average pay is earned at the rate of 2/11ths of the period spent on duty.

Study-leave is granted to the extent of 12 months in the total service and will not be granted more than twice in the course of an officer's service. During study-leave an officer draws half average pay, with a study allowance at the rate of 12*s.* a day during the course of study. Officers of European domicile are entitled to four free return first-class passages from a port in India to a port outside India in their whole service. The first passage is not granted until after the expiry of four years' approved service, and thereafter passages may be granted at intervals of not less than four years. There is a Provident Fund to which members of the Service contribute 10 per cent. of their pay. The Service contributes another 10 per cent., which accumulates at interest and is repaid on retirement.

Admission to the Service is made by selection in India and England—preference being given to those with Indian experience. Vacancies are few. Candidates in the United Kingdom should apply to the Hon. Secretary, United Kingdom Branch of the Countess of Dufferin's Fund, care of India Office, Whitehall, London. Candidates in India should apply to the Chief Medical Officer, Women's Medical Service, Countess of Dufferin's Fund, Simla and Delhi.

PRISON MEDICAL SERVICE

CANDIDATES for the Prison Medical Service are approved by the Secretary of State for the Home Department on the recommendation of the Prison Commissioners. Preference is always given to candidates who have experience of lunacy. Application for employment may be made on a special form, which can be obtained from the Secretary, Prison Commission, Home Office, London, S.W. In the smaller prisons the medical officership is part-time, and is usually filled by practitioners in the locality, preference being given to those who have special experience of lunacy. In the large prisons the medical staff must devote their whole time to the Service. In the case of whole-time service, the appointment is in the first instance to the post of Medical Officer, Class II., and from this rank the Medical Officers, Class I., are selected as vacancies occur. The pay of the whole-time prison medical staff is as follows: Medical Officer, Class II., £505 7*s.* a year, proceeding by annual increments to £726 a year, the maximum being normally attainable after 10 years' approved service: Medical Officer, Class I., £783 15*s.* a year, proceeding by annual increments to £939 14*s.* a year, the maximum being normally attainable after 6 years' approved service. Unfurnished quarters are provided or an allowance in lieu is made. The conditions of service are liable to review. Study-leave is granted annually to two of the whole-time Medical Officers. There are 12 full-time medical officers of Class I. and 15 Class II. and 23 part-time medical officers. The number of vacancies is never large.

PHARMACEUTICAL SOCIETY

THE COLLEGE OF THE PHARMACEUTICAL SOCIETY is a constituent part of the University of London. The Society conducts examinations for registration as (*a*) Chemist and Druggist and (*b*) Pharmaceutical Chemist. Courses of Instruction are given for these examinations, in the latter case in conjunction with University College.

An Intercollegiate two years' course for the Final Examination for the degree of B.Pharm. of the University of London is also given in conjunction with University College. Medical students are admitted to the lectures and laboratory work. Certificates of instruction in the School are received by the Conjoint Board of the Royal Colleges and by the University of London. Graduates of approved Universities may carry out the research work necessary for the thesis for the Ph.D. of the University of London in the Society's Research Laboratories; this degree may be taken in Pharmacy, Materia Medica, Pharmaceutical Chemistry, and Pharmacology. Several scholarships are also offered. Further information may be obtained from the Dean, 17, Bloomsbury-square, London.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (C.B.C.).—Post-graduate medical demonstrations of the technique of the use of a variety of contraceptive methods are given by Mrs. Marie Stopes, D.Sc., F.L.S., and Mrs. Evelyn Fisher, M.D. Each will include clinical demonstrations on women of various types, and those attending will be enabled to practise on patients the use of many different contraceptive devices. The dates of the demonstrations, which are free, can be obtained from the hon. secretary (108, Whitfield-street, London, W.1), as well as information about tickets of admission. There is a museum of contraceptives and a birth control library, which may be consulted any day (except Saturdays) from 10 A.M. to 6 P.M.

SPECIAL DIPLOMAS

DIPLOMA IN PUBLIC HEALTH

THE following epitomises the instruction given at various universities and centres of medical education to medical men desiring to obtain diplomas in sanitary science, public health, hygiene, or State medicine, as this discipline is variously called. Resolutions and rules, designed with a view of ensuring "the possession of a distinctively high proficiency, scientific and practical, in all branches of study which concern the public health," have been adopted at various times by the General Medical Council. The diploma is registrable by the Council, whose rules on the curriculum become binding on the educational bodies concerned. The present resolutions and rules, which came into force in 1931, postpone the granting of a diploma until at least two years from qualification.

London School of Hygiene and Tropical Medicine

The course of study for the Diploma in Public Health will commence on Oct. 1st in the premises in Keppel-street (Gower-street), the gift of the Rockefeller Foundation, which has excellent laboratories and research rooms, a fine lecture theatre and classrooms, library, and museum. The course, which will extend over a period of nine months for those prepared to give whole-time study, is designed in compliance with the requirements of the General Medical Council, and will enable students, who wish to do so, to proceed to the academic Diploma in Public Health of London University. The curriculum has been planned on very practical lines, and includes, in addition to work with Medical Officers of Health in selected areas, a large number of visits to places of public health interest. The course also includes provision for the necessary instruction in infectious disease and hospital management, lectures and demonstrations on physiology applied to hygiene and industry, medical industrial psychology, and sanitary engineering. A series of lectures is given by eminent authorities on special subjects, and these lectures are open to members of the medical profession as well as to students of the School. The London County Council, the City of London, and various other bodies have placed their resources at the disposal of the School for teaching purposes.

D.P.H. Studentship.—In the Public Health Course one place is allotted, without fees, after open competition, the successful candidate being awarded the Fishmongers' Company Studentship.

English Conjoint Board

The regulations for the Diploma in Public Health of the Royal College of Physicians of London and the Royal College of Surgeons of England are as follows:—

Candidates must have obtained a registrable qualification in medicine, surgery, and midwifery. The examination consists of two parts, both of which are held in January, June, and October, and candidates may enter for either part separately, or at the same time; the passing of Part I. must precede that of Part II. The examination will be written, oral, and practical. Part II. includes a practical examination in infectious diseases, food inspection, and inspection of selected premises. Candidates who fail in either part may sit at a subsequent examination on payment of the fees.

Candidates will be admissible to examination in Part I. on producing evidence of having attended during not less than 280 hours at an Institution recognised by the Examining Board in England, after obtaining a registrable qualification, practical instruction in (*a*) Bacteriology and Parasitology (including Immunology, Serology, Medical Entomology, &c.), especially in their relation to diseases of man and to those diseases of the lower animals which are transmissible to man; (*b*) Chemistry, Physics, Radiology, and Electrology in relation to Public Health; (*c*) Physiology and Biochemistry in their application to nutrition and hygiene; (*d*) Meteorology and Climatology in relation to Public Health.

Candidates will be admitted to Part II. of the Examination on producing evidence (1) Of having been in possession of a registrable qualification in medicine, surgery, and midwifery, during not less than two years, of being registered by the General Medical Council, and of having completed the curriculum for the Diploma extending over a period of twelve calendar months (or an academic year of whole-time study covering a period of not less than nine calendar months) subsequent to the attainment of a registrable qualification. (2) Of having attended, after obtaining the registrable qualification, instruction during not less than 120 hours at an Institution recognised by the Examining Board in England in the following subjects: (*a*) The Principles of Public Health and Sanitation; (*b*) Epidemiology and Vital Statistics; (*c*) Sanitary Law and Administration (including Public Medical Services); (*d*) Sanitary Construction and Planning. (3) Of having attended for three months the clinical practice of a hospital for infectious diseases recognised by the Examining Board in England, and of having therein received instruction in the methods of administration. (At least 24 daily attendances of not less than 2 hours are necessary.) (4) Of having been engaged during a period of not less than six months in acquiring a practical knowledge of the duties, routine and special, of public health administration under the supervision of a medical officer of health, and of having received from such officer or other competent medical officer during not less than three hours on each of 60 working days, practical instruction in those duties and also those relating to (*a*) Maternity and Child Welfare Service; (*b*) Health Service for children of school age; (*c*) Venereal Diseases Service; (*d*) Tuberculosis Service; (*e*) Industrial Hygiene; (*f*) Inspection and Control of Food, including meat and milk. (Instruction in (*a*) to (*f*) must include attendance at the centres, clinics, institutions, and premises concerned.) The above certificate (4) must be obtained from a medical officer of health who devotes his whole time to public health work, or from a medical officer of health of a sanitary area having a population of not less than 50,000, or in Ireland the medical superintendent of health of a county or county borough having a population of not less than 50,000.

University of London

The course of study for the Academic Diploma in Public Health extends over twelve calendar months (or an academic year of whole-time study covering a period of not less than nine calendar months). The examination is in two parts and candidates must pass in all subjects of Part I. before being admitted to Part II. The course for Part I. consists of not less than 280 hours' practical instruction in (*a*) Bacteriology and Parasitology; (*b*) Chemistry, Physics, Radiology, and Electrology in relation to Public Health; (*c*) Physiology and Biochemistry in their application to nutrition and hygiene; (*d*) Meteorology and Climatology in relation to Public Health. The course for Part II. consists of not less than 120 hours' instruction in (*a*) Principles of Public Health and Sanitation; (*b*) Epidemiology and Vital Statistics; (*c*) Sanitary Law and Administration; (*d*) Sanitary Construction and Planning.

Parts I. and II. of the Examination are held twice a year.

Candidates for the M.D. Degree may offer Hygiene as a subject in which to graduate (not registrable as a public health diploma). The regulations may be obtained on application to the Academic Registrar, University of London, South Kensington, S.W.7.

University of Durham

The degree of Bachelor of Hygiene (B.Hy.), and the Diploma in Public Health (D.P.H.). A period of not less than two years must elapse between the attainment by a candidate of a registrable degree or qualification in Medicine, Surgery, and Midwifery, and his admission to the Final Examination for the degree of Bachelor of Hygiene or for the Diploma in Public Health of the University *as the case may be*. The curriculum extends over a period of not less than twelve calendar months (or an academic year of whole-time study, covering a period of not less than nine calendar months), subsequent to the attainment of a registrable degree or qualification. Candidates for the B.Hy. must take out the curriculum for Part I. of the Examination at the University of Durham, but for the D.P.H. may do so either at the University or at any medical school or institution recognised by the University. The examination is divided into two parts. Part I. is practical, written, and oral, and includes the subjects of Bacteriology and Parasitology (including Immunology, Serology, Medical Entomology, &c.), especially in their relation to diseases of man, and to those diseases of the lower animals which are transmissible to man; Chemistry, Physics, Radiology, and Electrology, in relation to Public Health; Physiology and Biochemistry in their application to nutrition and hygiene; and Meteorology and Climatology in relation to Public Health. The subjects in Part II. include the Principles of Public Health and Sanitation; Epidemiology and Infectious Diseases; Vital Statistics; Sanitary Law and Administration (including Public Medical Services); Sanitary Construction and Planning; and Public Health Administration. This part of the examination is written and oral, and includes practical examinations in Infectious Diseases, Food Inspection, Inspection of premises, dwelling-houses, factories, workshops, schools, &c. Candidates are not admitted to the examination in either part until after they have completed the prescribed courses of instruction in the required subjects.

Doctor of Hygiene (D.Hy.): Candidates must be Bachelors of Hygiene of the University of two years' standing, and are required to satisfy the examiners that they have conducted original research in the subject of Public Health.

University of Birmingham

The University grants the Degree M.D. (State Medicine) under the following conditions: Graduates in medicine of *this University* may become candidates for the degree when they possess a Diploma in Public Health (D.P.H.) recognised for registration by the General Medical Council; or a recognised Degree in Public Health or Hygiene; they must have been engaged for at least one year subsequently to obtaining a registrable Diploma in Public Health, in post-graduate study of State Medicine, pursued in a laboratory of the University or in a hospital associated with the University, or whilst holding an appointment in the Public Health Service, or partly in each of such places, provided that the full period of post-graduate study occupies not less than one year and is taken after a subject of study has been approved by the Faculty of Medicine. The candidate presents a thesis on some public health subject and must pass a written and viva voce examination in the principles and practice of public health.

A candidate whose thesis is of exceptional merit may be exempted from the whole or any part of the examination, and Honours are awarded at the discretion of the Examiners.

Graduates in medicine of other Universities who possess a degree of a British or Colonial University recognised for registration by the General Medical Council and approved by the Senate of the University, and who have taken not less than three years of their curriculum in the Birmingham Medical School, may become candidates for the Degree of M.D. (State Medicine) under similar conditions as are required in the case of graduates of the University of Birmingham. Graduates in medicine of other approved Universities who are not past students of the Birmingham Medical School may become candidates for the Degree of M.D. (State Medicine) under the above regulations on completing *two* years of post-graduate study under the general conditions laid down above.

The University grants a Diploma in Public Health under conditions approved by the General Medical Council. The examination is held in March and June (Part I.), October and March (Part II.), each part being written, oral, and practical. No candidate will be allowed to pass Part II. until he has passed Part I. Candidates may enter for Parts I. and II. separately or at the same time. The fee for each part of the examination is £6 5s.

University of Liverpool

The University grants a Diploma in Public Health (D.P.H.), and every facility is afforded for training in Sanitary Science and State Medicine.

University of Leeds

The University grants a Diploma in Public Health, and every facility is afforded for training in Sanitary Science and State Medicine. The examination, which is held twice in each year—namely, in March and September—is in two parts, and is written, oral, and practical. Candidates must pass in Part I. before being admitted to Part II. Instruction in Entomology and Meteorology is given in the first term, and in Sanitary Chemistry and Bacteriology, Physiology, and Biochemistry, as applied to nutrition, Radiology and Electrology, in the first and second terms. Practical work under arrangement with the Leeds City Council. Prospectus can be obtained from the Academic Sub-Dean of the Medical School.

University of Bristol

Diploma in Public Health. Candidates must be at least 23 years of age, shall be fully registered medical practitioners of not less than two years' standing as such, and shall have passed the examination prescribed by regulations.

University of Wales

Candidates for the Diploma in Public Health, the curriculum for which extends over a period of not less than twelve calendar months, or an academic year of whole-time study covering a period of not less than nine calendar months, subsequent to the attainment of a registrable qualification, must produce evidence of having pursued at the Welsh National School of Medicine courses of instruction in Bacteriology and Parasitology, Chemistry, Physics, Radiology and Electrology, and Meteorology and Climatology in relation to Public Health, and Physiology and Biochemistry in their application to nutrition and hygiene. Candidates must also satisfy the examiners that they have received instruction approved by the University in the Principles of Public Health and Sanitation, Epidemiology and Vital Statistics, Sanitary Laws and Administration, and Sanitary Construction and Planning. The candidate must produce evidence that he has attended for three months on the clinical practice of a hospital for infectious diseases containing not less than 100 beds, and has received therein instruction in the methods of administration, and has been engaged in acquiring a practical knowledge of the duties, routine and special, of a public health administration. The examination for the diploma is divided into two parts, Part I. and Part II. A candidate must pass in all the subjects of Part I. before being admitted to Part II. of the examination. In Part I., and also in Part II., a candidate must pass in all the specified subjects at one time. Part I., practical, written, and oral, comprises Bacteriology and Parasitology. Part II. of the examination, which is written and oral, comprises:—The principles of Public Health and Sanitation, Epidemiology and Vital Statistics, Sanitary Law and Administration (including Public Medical Services), and Sanitary

Construction and Planning. No candidate can be admitted to Part II. of the examination until after the lapse of not less than two years from the date of his obtaining a registrable qualification. The examination in Part I. will be held in June, that in Part II. in October. Full information may be obtained from the Registrar of the University, University Registry, Cathays Park, Cardiff.

University of Edinburgh

Candidates for the Diploma in Public Health must be graduates in medicine and surgery of the University, or hold corresponding degrees or registrable medical qualifications which must be registered before admission to examination. The course is divided into two parts. In each part the candidate *must pass in all the specified subjects at one examination.* Candidates are not admitted to Part II. until they have passed Part I., nor until after the lapse of not less than two years from the date of obtaining a registrable medical qualification. The subjects of the examination are: Part I. (written, oral, and practical), Bacteriology and Immunology; Entomology and Parasitology; Chemistry, Biochemistry, and Physiology in their application to nutrition and hygiene; Physics, Radiology, Electrology, Meteorology, and Climatology in relation to Public Health. Part II. (written, oral, and practical), Hygiene, Sanitation, and Sanitary Construction; Epidemiology and Infectious Diseases; Sanitary Law and Vital Statistics; Public Health Administration. There is also included practical examinations in Infectious Diseases, Food Inspection, and Inspection of Premises. The course, which extends over an academic year of full-time study, begins in October, and provision is made by the University for instruction in all the subjects. Detailed particulars may be obtained from the Dean of the Faculty of Medicine.

University of Aberdeen

Every candidate for the Diploma in Public Health must be a graduate in medicine of the University of Aberdeen, or of any other University whose medical degrees are recognised as qualifying for registration by the General Medical Council of the United Kingdom. No candidate will be admitted to the Final Part of the Examination for the Diploma until after the lapse of not less than two years from the date of his obtaining a registrable qualification in Medicine, which qualification shall have been registered before such admission. The whole of the prescribed curriculum of study must be undertaken after the candidate has obtained a registrable qualification in medicine, and shall extend over not less than twelve calendar months (or an academic year of whole-time study covering a period of not less than nine calendar months). At least one *academic* term must be spent at the University of Aberdeen. Candidates shall produce evidence of having complied with the following requirements in respect of study and training:—1. Practical instruction in the following subjects within a laboratory or laboratories approved by the University during not less than 280 hours: (*a*) Bacteriology and Parasitology (including immunology, serology, medical entomology, &c.) in relation to diseases of man and diseases of lower animals transmissible to man; (*b*) Chemistry, Physics, Radiology, and Electrology in relation to Public Health; (*c*) Physiology and Biochemistry in their application to nutrition and hygiene; (*d*) Meteorology and Climatology in relation to Public Health. The above instruction to extend over not less than five months or two academic terms. 2. A course or courses of instruction extending over not less than 120 hours dealing with: (*a*) The Principles of Public Health and Sanitation; (*b*) Epidemiology and Vital Statistics; (*c*) Sanitary Law and Administration (including Public Medical Services); (*d*) Sanitary Construction and Planning; such course or courses to be given at an institution or by a teacher or teachers approved by the University. 3. Practical instruction, clinical and administrative, within a recognised hospital for general infectious diseases; such instruction to extend over three months, and to include 24 daily attendances of not less than two hours each. 4. Practical instruction and experience, during not less than six months (including attendance of at least three hours on each of sixty working days) in the duties, routine and special, of public health administration, under the supervision of a medical officer of health, who shall certify that the candidate has received from this officer or other competent medical officer practical instruction in these duties and also in those relating to: (*a*) Maternity and Child Welfare Service; (*b*) Health Service for Children of School Age; (*c*) Venereal Diseases Service; (*d*) Tuberculosis Service; (*e*) Industrial Hygiene; (*f*) Inspection and Control of Food, including meat and milk. (Instruction in (*a*) to (*f*) shall include attendance at the centres, clinics, institutions and premises concerned.) The medical officers of health recognised for this purpose by the General Medical Council are: (*a*) a medical officer of health who devotes his whole time to public health work; or (*b*) the medical officer of health of a sanitary area having a population of not less than 50,000; or (*c*) in Ireland, the medical superintendent officer of health of a county or county borough having a population of not less than 50,000. The examination for the diploma is divided into two parts, each of which extends *over not less than three days. A candidate* must pass in all the subjects of Part I. before being admitted to the examination for Part II. In Part I. and also in Part II. a candidate must pass in all the specified subjects at one time.

University of Glasgow

Degree of B.Sc. in Public Health.—Candidates must *be graduates in* Medicine of a University of the United Kingdom, or of some other University recognised for the purpose by the University Court. Candidates must produce evidence (1) that, after they have obtained a registrable Degree in Medicine, a period of not less than two years has elapsed; (2 that, after they have obtained a registrable degree in Medicine, they have, during a period of not less than 21 calendar months, pursued the course of work and instruction prescribed, and have satisfied the examiners *in the prescribed examinations.*

There are two examinations. Part I. includes the following subjects: (i) Bacteriology and Parasitology (including Immunology, Serology, and Medical Entomology); (ii) Chemistry, Physics, Radiology *and Electrology in relation to Public Health*; (iii Physiology and Biochemistry in relation to Public Health; (iv) Meteorology and Climatology in relation to Public Health; (v) Higher Chemistry in relation to Public Health; (vi) Higher Physics and Geology. A candidate must pass in the subjects marked (i), (ii), (iii), and (iv) of Part I. at one examination. Part II includes the following subjects: (vii) Hygiene and Sanitation (including sanitary construction and planning); (viii) Epidemiology and Infectious Diseases; (ix) Sanitary Law and Vital Statistics; (x Public Health Administration; (xi) Applied Hygiene The examination for Part II. includes practical examinations in Infectious Diseases; Food Inspection Inspection of Premises, such as dwellings, factories workshops, bakehouses, dairies, cowsheds, schools hospitals, clinics, and the like. The examination in Applied Hygiene *may be on a selected subject pro*fessed by the candidate. A candidate must pass in the subjects marked (vii), (viii), (ix), and (x) of Part II at one examination. *Diploma in Public Health (D.P.H.).*—Candidates for this Diploma must be *legally qualified medical practitioners* who are matriculated students of the University. A period of not less than two years must elapse between the attainment by the candidate of a registrable medical qualification and his admission to the final examina*tion (Part II.) for the* Diploma. The candidate must during a period of not less than twelve calendar months subsequent to his attainment of a registrable medica qualification pursue the course of work and instruction prescribed, and pass the prescribed examinations. The examination, which is both written and oral, is divided into two parts, Part I. and Part II., each of which extends over not less than two days. No candidate is admitted to either part of the examination until he has completed the prescribed courses of instruction in the subjects of that part. No candidate is admitted to Part II. until he has passed in all the subjects of Part I., nor until after the lapse of not less than two years from the date of his obtaining a registrable medical qualification, nor unless he presents a certificate showing that his name and qualification have been duly registered in the Medical Register. Part I. includes: (i) Bacteriology and Parasitology (including Immunology, Serology, and Medical Entomology); (ii) Chemistry, Physics, Radiology, and Electrology in relation to Public Health; (iii) Physiology and Biochemistry in relation to Public Health; (iv) Meteorology and Climatology in relation to Public Health. A candidate must pass in all the subjects at one examination. Part II. includes: (v) Hygiene and Sanitation (including Sanitary Construction and Planning); (vi) Epidemiology and Infectious Diseases; (vii) Sanitary Law and Vital Statistics; (viii) Public Health Administration. A candidate must pass in all the subjects at one examination. The examination for Part II. includes practical examinations in Infectious Diseases; Food Inspection; Inspection of Premises, such as dwellings, factories, workshops, bakehouses, dairies, cowsheds, schools, hospitals, clinics, and the like.

University of St. Andrews

The Diploma in Public Health is open to those who hold a registered medical qualification of the United Kingdom. The examination is in two parts. (1) (*a*) Bacteriology and Parasitology; (*b*) Chemistry and Physics; (*c*) Meteorology and Climatology. (2) Public Health and Sanitation, Epidemiology and Vital Statistics, Sanitary Law and Administration, and Sanitary Construction and Planning. Before admission to the first examination the candidate must have held his medical qualification for one year, and before admission to the second examination for two years. Graduates in Medicine of the University of St. Andrews may take part or all of the qualifying classes in any University of the United Kingdom, or in any Indian, Colonial, or Foreign University or medical school recognised by the University Court, but holders of other registered medical qualifications must spend at least 8 out of the 12 months' curriculum in St. Andrews University. A complete course is given in the Conjoint Medical School, Dundee.

Scottish Conjoint Board

All candidates for the Diploma in Public Health must have a qualification which has been registered under the Medical Acts. The examination is divided into two parts.

For Part I. the candidate must produce evidence of having received during a period of not less than five months at an institution recognised by the Board practical instruction in: (*a*) Bacteriology and Parasitology (including Medical Entomology), especially in their relation to diseases of man and to those diseases of the lower animals which are transmissible to man, during 180 hours, of which not less than 150 hours have been occupied in practical laboratory work; (*b*) Chemistry and Physics in relation to Public Health during 90 hours, of which not less than 70 hours have been occupied in practical laboratory work; (*c*) Meteorology and Climatology in relation to Public Health during not less than 10 hours. For Part II. evidence must be given of having received instruction during not less than 80 hours in: (*a*) The Principles of Public Health and Sanitation for not less than 30 hours; (*b*) Epidemiology and Vital Statistics for not less than 20 hours; (*c*) Sanitary Law and Administration (including Public Medical Services) during not less than 20 hours; (*d*) Sanitary Construction and Planning during not less than 10 hours; of having attended for three months the clinical practice of a recognised hospital for infectious diseases; and of having been engaged during a period of not less than six months in acquiring a knowledge of Public Health administration in addition to practical instruction in the duties relating to: (*a*) Maternity and Child Welfare Service; (*b*) Health Service for Children of School Age; (*c*) Venereal Diseases Service; (*d*) Tuberculosis Service; (*e*) Industrial Hygiene; (*f*) Inspection and Control of Food, including meat and milk. The fee is 12 guineas for both examinations, or 6 guineas for either of them. A fee of 6 guineas is payable by rejected candidates for either examination. The examination is held twice yearly, in March in Glasgow, and October in Edinburgh. The published regulations provide detailed synopses of the subjects of examination. The Registrar for Edinburgh is Mr. David Thomson, 18, Nicolson-street, and for Glasgow, Mr. David Willox, 242, St. Vincent-street.

University of Dublin (Trinity College)

The Diploma in Public Health is conferred, after examination, under the following conditions. The candidate must be a registered medical practitioner and have obtained a registrable qualification at least two years before the second part of the examination. The candidate must have completed, subsequently to obtaining a registrable qualification, 218 hours' practical instruction in a chemical and bacteriological laboratory, or laboratories, approved by the University, must have received instruction in the following subjects: physics, radiology, electrology, physiology, biochemistry, meteorology, and climatology, the principles of public health and sanitation, epidemiology and vital statistics, sanitary law and administration (including public medical services), sanitary construction and planning; must have studied, practically, outdoor sanitary work for six months under an approved officer of health, and must have attended for three months at a fever hospital where opportunities are afforded for the study of methods of administration. The De Renzy Centenary Prize, value about £15, is awarded to the candidate who obtains the highest marks at the March and June examinations each year, provided sufficient merit is shown. A special prospectus may be obtained by application to the Registrar of the School of Physic, Trinity College, Dublin.

National University of Ireland

At this University there is a Diploma in Public Health; a B.Sc. in Public Health; and a D.Sc. in Public Health.

All information obtainable from the Registrars of the Constituent Colleges—University College, Dublin; University College, Cork; University College, Galway.

University of Belfast

A Diploma in Public Health is given by examination. Courses of instruction are given both for Part I. and Part II. of the examination, extending over a period of one academic year. The curriculum follows that laid down by the General Medical Council.

Irish Conjoint Board

Every candidate for the Diploma in Public Health must observe the following rules: (1) A period of not less than two years shall elapse between the attainment by a candidate of a registrable qualification in Medicine, Surgery, and Midwifery and his admission to the Final Examination for a Diploma or Degree in Sanitary Science, Public Health, or State Medicine. (2) The curriculum for a Diploma or Degree in Sanitary Science, Public Health, or State Medicine shall extend over a period of not less than twelve calendar months (or an academic year of whole-time study covering a period of not less than nine calendar months) subsequent to the attainment of a registrable qualification. (3) Every candidate shall produce evidence of having attended, during not less than 280 hours, at an institution approved by the Licensing Body granting the Diploma or Degree, practical instruction in (*a*) Bacteriology and Parasitology, especially in their relation to diseases of man, and to those diseases of the lower animals which are transmissible to man; (*b*) Chemistry, Physics, Radiology, and Electrology in relation to Public Health; (*c*) Physiology and Biochemistry in their application to nutrition and hygiene; (*d*) Meteorology and Climatology in relation to Public Health. (4) Evidence must be produced of having received, during not less than 120 hours, at an institution approved by the Licensing Body granting the Diploma or Degree, instruction in (*a*) the Principles of Public Health and Sanitation; (*b*) Epidemiology and Vital Statistics; (*c*) Sanitary Law and Administration (including Public Medical Services); (*d*) Sanitary Construction and Planning. (5) Evidence of attendance for three months on the clinical practice of a recognised hospital for Infectious Diseases, and has received therein instruction in the methods of administration. At least 24 daily attendances of not less than two hours each shall be required. (6) Evidence is required that the candidate has, during a period of not less than six months, been engaged in acquiring a practical knowledge of the duties, routine and special, of Public Health Administration under the supervision of a Medical Officer of Health.

The examination for Part I. is practical, written, and oral. The examination for Part II. is written and oral, and includes practical examinations in Infectious Diseases; Food Inspection; Inspection of Premises—dwellings, factories, workshops, schools, &c. No candidate may be admitted to Part II. of the examination for a registrable Diploma or Degree in Public Health until after the lapse of not less than two years from the date of his obtaining a registrable qualification in Medicine, Surgery, and Midwifery.

Royal Institute of Public Health

Facilities are offered at this Institute for the course of instruction for the Diploma in Public Health. The laboratories are well equipped and pleasantly situated. In the Chemical Department lectures and courses of practical instruction are given by Dr. Alan W. Stewart, D.Sc. The Bacteriological Laboratories are under the charge of Dr. E. Goodwin Rawlinson, where practical instruction in Public Health, Bacteriology, and lectures on Immunology are given. The analysis, both chemical and bacteriological, of water, milk, sewage effluents, &c., are undertaken at the Institute. Pathological examinations and investigations are carried out for medical practitioners. The Aschheim-Zondek test for pregnancy is also carried out in the Pathological Department. The Harben Lectures will be delivered in October by Prof. W. J. Tulloch, O.B.E., M.D., Professor of Bacteriology in Dundee University. Further information may be obtained on application to the Secretary at the Offices of the Institute, 23, Queen-square (and Guilford-street), London, W.C.1.

DIPLOMA IN TROPICAL MEDICINE

Although a qualification in tropical medicine has not been made registrable by statute, a diploma is regarded as indispensable for appointments in the Colonial Medical Service and similar positions abroad. Systematic instruction for these diplomas is given at the Incorporated Liverpool School of Tropical Medicine (founded in 1898) and at the London School of Hygiene and Tropical Medicine, Keppel-street, Gower-street, London, W.C.; while the University of Edinburgh and the English Conjoint Board grant a diploma.

London School of Hygiene and Tropical Medicine

The course of instruction in tropical medicine and hygiene is divided into two parts: Section A, a three months' course in clinical and laboratory instruction, and Section B, a two months' course in tropical hygiene. Each section can be taken independently of the other, and the examinations of the Conjoint Board follow closely upon the end of the corresponding course of study. This revised course is recognised by the University of London as a course for associate students. The dates of the courses for the session 1934–35 are as follows:—Section A (Clinical and Laboratory Instruction): first course, Oct. 1st to Dec. 21st, 1934; second course, Jan. 7th to March 30th, 1935; third course, April 8th to June 28th, 1935. Section B (Tropical Hygiene): first course, Jan. 31st to March 22nd, 1935; second course, April 23rd to June 21st, 1935. The course of instruction under Section A includes clinical tropical medicine, applied pathology, medical zoology, and elementary bacteriology. Section B[*] comprises instruction in tropical hygiene, including, in relation to hygiene, bacteriology, medical zoology, anthropology, and vital and medical statistics. Section A is so arranged, in three self-contained groups or blocks, as to allow of the admission of a student at the beginning of any block of work, subject to a place in the laboratory being available. Accordingly, applications can be received for admission to the classes in Protozoology and Hæmatology (approximately four weeks), or in Helminthology (approximately four weeks), or in Entomology (approximately three weeks), with, in each case, if the student so wishes, the corresponding clinical demonstrations, instruction in applied pathology, and special lectures. Further, students wishing to attend the clinics and clinical lectures only can do so for any period of four weeks during the course. The instruction in the Division of Clinical Tropical Medicine is given by the medical staff of the Hospital for Tropical Diseases and by visiting lecturers. In this way the resources of the hospitals of the Seamen's Hospital Society at Endsleigh-gardens, at the Albert Docks, and elsewhere, become available for the clinical instruction of the students at the School.

Liverpool School of Tropical Medicine

The Liverpool University Diploma of Tropical Medicine (D.T.M.) is open only to those who possess a qualification to practise medicine recognised by the university, and who have been through a full course of instruction at this school. The subjects of examination are (*a*) Parasitology; (*b*) Entomology; (*c*) Tropical Medicine, including Ætiology, Symptoms, Pathology, Diagnosis, and Treatment of Tropical Diseases. The advanced course consists entirely of Practical and Clinical Work, given at the Laboratory at the University, and at a recognised hospital in which beds are specially reserved for Tropical Diseases. Applications should be made to the Dean of the Medical Faculty, University of Liverpool.

The University also grants a Diploma in Tropical Hygiene (D.T.H.). The subjects of examination are (*a*) Tropical Hygiene (including Sanitary Engineering, Vital Statistics and Epidemiology, and Applied Parasitology and Entomology; (*b*) Practical Sanitation; (*c*) Bacteriology; (*d*) Chemistry (including Meteorology and Climatology). Two University Fellowships of £100 a year each are open to students of the school, amongst others. Accommodation for research work is to be had at the University Laboratory. The Mary Kingsley Medal is awarded by the school for distinguished work in connexion with *Tropical Medicine*.

University of Edinburgh

Candidates for the Diploma in Tropical Medicine and Hygiene must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualifications of some other licensing body, or of other universities or medical schools specially recognised. The course of instruction, comprising a primary and a second course, is given during the autumn and spring terms, October to March, and includes Tropical Hygiene, Bacteriology, Entomology and Parasitology, Diseases of Tropical Climates (systematic and clinical), Tuberculosis, and Venereal Diseases. Provision is made in the University for instruction in all subjects.

---

[*] The Andrew Balfour Memorial Fund provides yearly two free courses in Section B as Balfour Studentships.

The examinations are written, oral, and practical, and are held at the end of the courses. Candidates are required on the first occasion of presenting themselves for examination in either part to appear for all the subjects of that part. Candidates who fail to pass the entire examination in either part within a period of 12 months after first appearance are required to reappear for all the subjects. The University is included in the list of institutions whose courses of instruction in Tropical Medicine may be taken by officers on appointment to the Colonial Medical Services or during study-leave. Full particulars can be obtained from the Dean of the Faculty of Medicine.

English Conjoint Board

The Board conducts an Examination three times a year for the D.T.M. & H. granted by the Royal Colleges—namely, in January, April, and July. The Examination comprises written, oral, and practical examinations in the following subjects: *Section A*, Clinical Tropical Medicine and Surgery; applied Pathology, Zoology, and Elementary Bacteriology. *Section B*, Tropical Hygiene, including Epidemiology, Medical Zoology, and Bacteriology in relation to Hygiene. Candidates may enter for either or both Sections of the Examination provided that Section A is taken before Section B. (Candidates who are unsuccessful in Section A will not be debarred from presenting themselves for Section B.) Candidates must give 14 days' notice, in writing, to the Secretary at the Examination Hall, 8–11, Queen-square, London, W.C.1, and produce at the same time the necessary certificates of study (after Dec. 18th, 21 days' notice will be required). Candidates must produce evidence of being in possession of a registrable qualification in Medicine, Surgery, and Midwifery, and of having attended subsequently to obtaining such registrable qualification:—(i) *for admission to Section A:* Practical instruction in Pathology, Protozoology, Helminthology, Entomology, and Bacteriology in an Institution recognised for this purpose, together with the clinical practice of a hospital recognised for the study of Tropical Diseases, during not less than three months; (ii) *for admission to Section B:* Instruction in Tropical Hygiene and Sanitation in an Institution recognised for this purpose during a further period of not less than two months. Graduates (M.B., B.S., or M.D.) in Medicine and Surgery of Indian, Colonial, and foreign Universities recognised by the Examining Board in England, whose degrees are not registrable in this country, may enter for the Examination for the Diploma in Tropical Medicine and Hygiene on fulfilling the conditions in regard to study. These conditions may be modified at the discretion of the Committee of Management in the case of a candidate (*a*) who has been employed in foreign (in the case of Naval Medical Officers, one or more commissions abroad must have been held) or Colonial Medical Service, (*b*) who has been engaged in professional work in tropical countries, (*c*) who produces evidence of having been engaged in original investigations in Tropical Medicine or Hygiene. Further particulars from the Secretary, Examination Hall, Queen-square, London, W.C.1.

DIPLOMA IN PSYCHOLOGICAL MEDICINE

The Universities of London, Durham, Leeds, Manchester, Edinburgh, Dublin (Trinity College), Ireland (National University), and the English Conjoint Board grant diplomas in psychological medicine under conditions that are fairly comparable in the standard of the tests and in the duration of the courses; the details on these points can be obtained from the various examination bodies.

University of London

In London, courses of instruction for the Diploma in Psychological Medicine are given annually at the Maudsley Hospital, Denmark Hill, which has recently been definitely recognised as a school of the University of London. The course consists of two parts, commencing in January, and is adapted for the diploma of the Conjoint Board also. The parts may be taken separately; also during the year there are other short courses, lectures, and demonstrations in psychological medicine.

Maudsley Hospital.—Appointments as clinical assistants are obtainable at the Maudsley Hospital. The holding of such appointments for varying periods satisfies the requirements of the different examining bodies in respect of practical study of mental disorders. The appointments and other facilities for clinical experience are open to qualified medical practitioners apart from the courses of instruction. A course for the Diploma in Psychological Medicine is held annually from January to June at the Central Pathological Laboratory of the London County Mental Hospitals, which is situated in the Maudsley Hospital. Facilities and grants-in-aid are given for research work in psychiatry and allied subjects at the Laboratory. Inquiries as to lectures should be addressed to the Director of the Central Pathological Laboratory, Maudsley Hospital, Denmark Hill, S.E.; and as to clinical facilities, to the Medical Superintendent at the same address.

Bethlem Royal Hospital.—A course of lectures and practical instruction for the Diploma in Psychological Medicine, granted by the various universities and the Conjoint Board, is held at Bethlem Royal Hospital, Monks Orchard, Eden Park, Beckenham, twice annually, during the spring and autumn when possible. Part A or Part B, however, may be taken separately. In addition to the above, clinical instruction in Psychological Medicine is given at Bethlem Royal Hospital every morning (except Wednesdays) at 11 A.M. A reduction is made to those who attend the Diploma Course. House physicians are appointed at Bethlem Royal Hospital for a term of six months, which may be extended. These appointments are made at the beginning of February, May, August, and November in each year, and the vacancies are advertised in the medical papers. Apartments, complete board, attendance, and laundry are provided, and a salary at the rate of £150 per annum for the first three months, rising, if commendable service be given, to the rate of £200 per annum for the second period of three months. Clinical assistants are often appointed from time to time for periods of three months or longer. These are non-salaried and non-resident posts, but partial board is provided. The Physician-Superintendent, Bethlem Royal Hospital, Monks Orchard, Eden Park, Beckenham, will supply further particulars.

University of Durham

The university grants a diploma in psychiatry, and at the College of Medicine there is a department of instruction in psychological medicine. The candidate must be a registered medical practitioner, and subsequent to qualification have followed instructions on anatomy and physiology of the brain and nervous system. The examination is divided into two parts, Part I. dealing with anatomy, physiology, pathology, and bacteriology; Part II. with psychology and experimental psychology. Candidates may present themselves for the whole examination or for either part separately. The course of training is very detailed, post-mortem technique being the subject of a series of sessions, the same holding good for psychiatry and experimental psychology.

University of Leeds

The university grants a diploma in psychological medicine to graduates in medicine of at least one year's standing, who can prove that they have received systematic instruction on the normal and morbid anatomy of the brain and have held an appointment in a mental hospital. The examination is divided into three parts: Part I. deals with general psychology and the structural development and physiology of the nervous system; Part II. with the pathology of that system; and Part III. with clinical psychiatry, the administration of mental hospitals, and the medico-legal aspects of insanity. Candidates may present themselves for the three parts simultaneously or separately; they may submit a thesis or published work which, if approved, will gain certain exemptions.

University of Manchester

The university grants a diploma in psychological medicine to graduates of at least one year's standing. The examination is held in two parts. Before presenting themselves for Part I. candidates must, subsequent to qualification, have attended approved courses in the structure of the nervous system and in experimental psychology. Before presenting themselves for Part II. they must produce evidence of having gone through an approved course of instruction in the pathology of the nervous system and in clinical neurology, and of having attended demonstrations in psychological medicine, and received clinical instruction, either as residents or as daily attendants, at an approved hospital for mental diseases. The course extends over a period of three university terms, two of which must be taken in the university, and candidates may present themselves for both parts simultaneously or each separately.

University of Edinburgh

Candidates for the Diploma in Psychiatry must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualifications of some other licensing body, or of other universities or medical schools specially recognised. Candidates are required subsequent to the date of graduation or obtaining a recognised qualification to have held (*a*) a resident appointment for one year in a hospital for mental disorders approved by the Faculty of Medicine, or alternatively (*b*) a six months' appointment as defined in (*a*) and six months' practical study of nervous diseases in a special or general hospital approved by the Faculty of Medicine. There are two examinations for the Diploma. Part I. comprises: 1. Anatomy of the Nervous System; 2. Physiology of the Nervous System; 3. Psychology and Experimental Psychology. Part II. comprises: 1. Neuropathology; 2. Clinical Psychiatry; 3. Clinical Neurology; 4. An additional subject selected by the candidate from a prescribed list. Candidates who have held an asylum appointment for a period of five years or more may be exempted from the course of study in one or more subjects of the curriculum. New regulations are at present under consideration. Full particulars can be obtained from the Dean of the Faculty of Medicine.

University of Dublin (Trinity College)

A post-graduate diploma in Psychological Medicine is conferred upon registered medical practitioners who have held a resident medical appointment at a recognised institution for the treatment of Mental Diseases for 12 months, or who have held such an appointment for six months and have attended clinical instruction at an approved institution for six months. Candidates must also attend special courses of instruction and pass a special examination. Details can be obtained from the Registrar of the School of Physic, Trinity College, Dublin.

National University of Ireland

This University confers a diploma in Psychological Medicine. The diploma may be conferred on registered medical practitioners who although they may not have matriculated at the University shall have completed the prescribed course of study. A certificate of post-graduate work will be required from the candidates, either in the study of mental disease or as medical assistant in an asylum. Application should be made to the Registrars of the Constituent Colleges, University College, Dublin, University College, Cork, and University College, Galway, for all information.

DIPLOMA IN OPHTHALMIC MEDICINE

Special diplomas in ophthalmic medicine and surgery are issued by two examining bodies.

University of Oxford

The diploma in ophthalmology (D.O.) is granted to registered medical practitioners after passing an examination, held annually in June, which is open to candidates who have pursued at Oxford a course of study in ophthalmology over a period of at least two months and who have attended a 12 months' course of clinical ophthalmology at a recognised hospital. Further information regarding these requirements may be obtained from the Dean of the Medical School.

English Conjoint Board

The Conjoint Board grants the D.O.M.S. after an examination held in two parts, twice yearly in February and July. Part I. comprises anatomy and embryology of the visual apparatus, physiology of vision, and elementary optics. Part II. comprises optical defects, ophthalmic medicine and surgery, and pathology with special reference to ophthalmology. The examination in each case is written, oral, and practical or clinical. Candidates may only enter for Part II. on completion of a year of special study of ophthalmology after obtaining a recognised qualification.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY

University of Cambridge

Before admission to any course for the Diploma a candidate shall produce evidence that he holds a medical qualification approved by the committee and also satisfy the committee that he has had sufficient post-graduate clinical experience. The next course, which begins on Oct. 3rd, 1934, occupies nine months. The first four months, which can be spent either in Cambridge or in London, are occupied with (*a*) lectures and practical work in Physics, in preparation for the examination for Part I. in February, (*b*) an introductory course of clinical instruction in Radiology and Electrology, (*c*) a course of instruction in Pathology in relation to Radiology and Electrology. The next three months must be spent in London, and are occupied with (*a*) lectures and demonstrations in Radiology and Electrology (including Radium Therapy) organised by the British Institute of Radiology, (*b*) clinical instruction in the Radiological Department of a hospital approved by the committee. During the final two months of the course a candidate must hold a clinical clerkship or similar appointment in the radiological department of a hospital approved by the committee. This part of the course may be done in London, or elsewhere. The examination for Part II. will be held in July. Further particulars as to courses and examinations may be obtained from Mr. G. Stead, M.A., Secretary for the Diploma, Cavendish Laboratory, Cambridge, or the General Secretary, British Institute of Radiology, 32, Welbeck-street, W.1.

University of London

The course for the post-graduate diploma in Medical Radiology extends over one academic year, and is open to registered medical practitioners and graduates in medicine of this or any other approved University. The subjects are: Part I., Physics and Electro-technology. Part II., (*a*) Radiology and Radio-diagnosis; (*b*) Radiotherapy. The examination is held in March and December (Part I.), and in June and December (Part II.). Particulars may be obtained from the Academic Registrar.

University of Liverpool

Candidates before admission to the examination for the D.M.R.E. must possess a registrable qualification approved by the University in medicine and surgery, and must have attended courses of instruction in (*a*) physics (two terms), (*b*) (i) radiology, and (ii) electrology during nine months in the X ray and electrotherapeutic department of a hospital or hospitals. An examination is held in March and June (Physics) and in June (Radiology and Electrology). Examination in either part may be taken separately. A registration deposit fee of £5 5*s*. is charged on application and credited to the fees, but is not returnable in the event of the candidate failing to register. These courses commence during the first week in October. Application should be made to the Dean, Faculty of Medicine, the University of Liverpool.

University of Edinburgh

Candidates for the Diploma in Radiology (D.R. Univ. Edin.) must be graduates in medicine and surgery of the University of Edinburgh or hold corresponding registrable degrees or qualifications from some other licensing body, or of other universities or medical schools specially recognised. Candidates are not admitted to the examination for the Diploma until after the lapse of not less than one year from obtaining a recognised qualification. The course of study begins in October and extends over a period of not less than three terms. The examination, which is written, oral, and practical, is in two parts: (*a*) Physics, and (*b*) Radiology. Full particulars may be obtained from the Dean of the Faculty of Medicine.

English Conjoint Board

The examination for the D.M.R., R.C.P. and S. comprises Part I. Physics, as applied to Radiology, and Part II. Medical Radiology, with special reference to its clinical application, including Radio-diagnosis, X Ray Therapy, and Radium Therapy. Both examinations, which are written, oral, and practical, are held during January and July. The course of study extends over one academic year of full-time study, subsequent to the attainment of a recognised qualification. Before admission to the examination the following certificates must be produced. For admission to Part I. evidence of having attended a course of instruction in physics as applied to radiology at a recognised medical school or institution for not less than three months. For admission to Part II. evidence of having attended at a recognised hospital courses of instruction, theoretical and practical, in medical radiology, including radio-diagnosis, X ray therapy, and radium therapy, with clinical experience for three terms.

Candidates may enter for Parts I. and II. either together or separately, subject to the production of the required certificates; but no candidate is permitted to proceed to Part II. of the examination until he has passed in Part I. Candidates must give 21 days' notice, in writing, of their intention to present themselves for examination, to the Secretary at the Examination Hall, 8–11, Queen-square, London, W.C.1, forwarding at the same time the necessary certificates of study. The conditions regarding admission to examination may be modified at the discretion of the Committee of Management in the case of a candidate (*a*) who has carried out original investigations in any subject of the examination, or (*b*) whose studies have extended over a prolonged period of time without fulfilling the exact conditions. Exemption will not be granted from any part of the examination.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY

English Conjoint Board

The Board grants the D.L.O. after an examination held in two parts, in June and December. Part I. comprises anatomy, embryology, and physiology of the ear, nose, pharynx, larynx, trachea and bronchi. and œsophagus. Part II. comprises the medicine. surgery, and pathology of the ear, nose, pharynx, larynx, trachea and bronchi, and œsophagus, and the recognition and use of special instruments and appliances. The examination in each case is written, oral, and practical or clinical. Candidates may only enter for Part II. on completion of one year of special study of the diseases of the ear, nose, pharynx, and larynx, after obtaining a registrable qualification, or a degree in medicine and surgery of a University recognised by the Board.

DIPLOMA IN TUBERCULOUS DISEASES

University of Wales

Candidates for this diploma must be registered practitioners of at least 25 years of age. They are divided into two categories. First, they must either have held an appointment for tuberculous work for not less than five years; or, secondly, must have been qualified for at least one year, when they must present certificates of post-graduate study during that period on the clinical and pathological aspect of tuberculosis. The certificates have to be from recognised sources—a university, school, or hospital, where such a course is given, or a certificate from a whole-time member of the staff at an approved tuberculosis hospital or sanatorium will be accepted. A certificate of three months' satisfactory attendance at a tuberculosis institute or dispensary recognised by the Ministry of Health is also recognised as a valid testimonial. The examination is in two parts. Part I., written and oral, deals with clinical and epidemiological problems, the examination of patients, and the recognition of specimens; Part II. is a written and practical examination on the pathology and bacteriology of tuberculosis. This second half of the examination may be remitted for candidates who are in the first category (see above). These candidates may submit a thesis or copies of published articles on the subject in lieu of sitting for examination.

DIPLOMA IN BACTERIOLOGY

University of London

The course of study for the Academic Post-graduate Diploma in Bacteriology extends over one academic year and is open to (*a*) Graduates in Medicine, Science, and Pharmacy of this or another approved University, whose previous training has, in the opinion of the University, fitted them to profit by the Course; and (*b*) registered medical practitioners and other students who, though not graduates, have obtained a qualification and undergone a previous training which, in the opinion of the University, has fitted them to profit by the Course.

A Course necessary to fulfil the regulations of this Diploma has been planned by the London School of Hygiene and Tropical Medicine, Keppel-street, London, W.C., and full particulars with regard to the Diploma may be obtained from the Academic Registrar, University of London, South Kensington, S.W.7.

DIPLOMA IN CLINICAL PATHOLOGY

University of London

The course of study for the Academic Post-graduate Diploma in Clinical Pathology extends over one calendar year, and is open to graduates in Medicine and to registered medical practitioners. The subjects are (1) Morbid Anatomy and Histology; (2) Bacteriology and Serology; (3) Biochemistry. The examination is held in December. Particulars may be obtained from the Academic Registrar, University of London, South Kensington, S.W.7.

EAST SUFFOLK AND IPSWICH HOSPITAL.—In 1933 there were 5009 in-patients, a small increase, and the average number on the general waiting-list was only 114. There were 18,479 out-patients, and the year ended with an adverse balance of £386. In-patients stayed, on the average, 18·69 days, and cost £2 14*s*. 4*d*. each per week. Out-patients cost 6*s*. 8·68*d*. each.

DENTAL SURGERY

TEACHING INSTITUTIONS IN DENTISTRY

REGISTRATION on the Medical Register entitles a practitioner to practise dentistry, although he cannot register as such without degree or licence in dentistry; but few dental appointments at general or special hospitals or dispensaries are available save to those with a special diploma, and, until registered on the Dentists Register, no dental work under the Additional Benefit Scheme of the National Health Insurance Act can be undertaken.

The Examining Bodies in Dentistry which grant degrees and diplomas in the subject are as follows: Royal College of Surgeons of England, Royal College of Surgeons, Edinburgh, Royal Faculty of Physicians and Surgeons of Glasgow, Royal College of Surgeons in Ireland, and the following Universities: Birmingham, Bristol, Durham, Leeds, Liverpool, London, Manchester, Sheffield, St. Andrews, Dublin (Trinity College), Queen's University of Belfast, and the National University of Ireland. The student should apply to the secretaries of the various Conjoint Boards or to the Deans of the medical faculties or medical schools for a syllabus.

TEACHING INSTITUTIONS IN LONDON

Royal Dental Hospital

The Royal Dental Hospital of London, School of Dental Surgery, Leicester-square, is a school of the University of London. The school provides the special dental education required by the University of London for the B.D.S. Degree and the Royal College of Surgeons for the Licence in Dental Surgery. The general part of the curriculum may be taken at any general hospital. The hospital is open from 9 A.M. to 6 P.M., there being one staff for the morning and another for the afternoon of each day. Pupils are received for the training in dental mechanics recognised by the curriculum. The instructor at the commencement of each session gives a course of lectures on Operative Dental Surgery. The two senior house surgeoncies and the six house surgeoncies are held for four months each and are open to all qualified students. The lecturers, in addition to their lectures, give special demonstrations on the Microscopy of Dental Anatomy and Dental Surgery. The lecturer on Dental Mechanics also gives practical demonstrations in the laboratory. There is an Entrance Scholarship in Chemistry and Physics of the value of £25. One Scholarship in Dental Mechanics and Metallurgy, value £25. For full information as to scholarships and prizes, and other matters connected with the course, application should be made to the Dean.

University College Hospital

This Hospital and School, situated at the corner of Great Portland and Devonshire-streets, W., has recently been thoroughly reorganised, and is now fully equipped with all the most modern appliances. Students are entered as students of University College Hospital, and, as such, attend the classes of Anatomy and Physiology in University College, which is a few minutes' walk from the Dental Department in Great Portland-street, hitherto known as the *National Dental Hospital*—the first Dental School to admit Women Students. Practical courses to comply with the R.C.S. curriculum are held. Clinical Lectures and Demonstrations are given, and each student on entering passes through a preliminary course under a demonstrator. A prospectus containing full information as to lectures, fees, and prizes may be had on application to the Sub-Dean for Dental Students, who attends at University College Hospital Medical School, University-street, W.C.1, on Wednesday mornings from 9.30 to 10.30, and at other times by appointment.

Guy's Hospital

The work of the Dental Department begins daily at 9 A.M. both in the anæsthetic rooms and in the conservation room. The Extraction Rooms: These rooms have now been entirely reconstructed. There is ample accommodation for extractions, both with general and local anæsthetics, together with waiting- and retiring-rooms. Patients are admitted between 8.45 and 9.30 A.M., and are seen by the dental surgeon for the day, the staff demonstrators, the dental house surgeons, and the dressers. The Conservation Room is open from 9 A.M. till 5 P.M., and is under the charge of the Director. It affords accommodation for about 100 dental chairs, with the necessary equipment of the most modern type for the use of the Dressers, who, under the supervision of the Staff, perform the various operations of Dental Surgery. There is a separate room for denture patients affording accommodation for 15 chairs and a separate department for children with accommodation for 20 chairs. The Members of the staff attend every morning and afternoon to give demonstrations and otherwise assist students in their work in the Conservation Room and Prosthetic Laboratory. The Probationers' Laboratory is supervised by the Director of the Conservation Room assisted by the Staff Demonstrators, and instruction is given in operative dentistry on a "mannikin" to students during their first three months of clinical study. Students in Dental Prosthetics are received, and a graded, systematic, and full course of instruction, extending over two years, is carried out under the supervision of the Director of the Prosthetic Laboratory, assisted by four demonstrators, a house surgeon, and skilled mechanics.

Dental students have the opportunity of attending at this hospital the whole course of instruction required by the examining board for the B.D.S. Lond. or L.D.S. Eng.—viz., the complete course in dental prosthetics, the special lectures and practice of the Dental Department, and the general lectures and practice of the Medical School. Students who enter for a medical as well as a dental course are allowed to pursue their study of Dentistry during any period of their medical course most convenient to themselves without further charge.

Fourteen house surgeons, 20 assistant house surgeons, and 4 student demonstrators of Dental Histology are appointed annually. The following appointments are held by students: Full surgeon's dresser, assistant surgeon's dresser, dresser in the children's department, casualty dresser, dresser to the director of the conservation room, probationary dresser, clerk to the anæsthetist and dresser in the general anæsthetic and local anæsthetic rooms. Two Entrance Scholarships are awarded annually in April as follows: (1) A War Memorial Scholarship in Arts of the value of £40 per annum for four years, open to students under 19 years of age. Candidates are required to take English and any two of the following subjects: French, German, Latin, Greek, and Mathematics. (2) A Science Scholarship of the value of £40 per annum for four years, open to students under 20 years of age. Candidates are required to take two of the following subjects: Chemistry, Physics, and Biology. Further information will be supplied by the Dean of the Medical School.

King's College Hospital

The *Dental School* is part of the Medical School of King's College Hospital, and was opened in November, 1923. The Dental Out-patient Department of the Hospital is used for the performance of dental extractions. A large Conservation Room with provision for 40 dental chairs has been equipped. Smaller rooms are used for clinical teaching and administrative requirements, and a specially equipped laboratory for training in the art of dental mechanics. An X ray apparatus has been installed for use in dental skiagraphy. The Dental museum contains a large number of specimens illustrating oral, buccal, dental, and other diseases. The library, lecture theatre, lecture rooms, common rooms, and the refectory are all available for the use of students. Courses of study, including practical work, are provided for the degree of Bachelor of Dental Surgery of the University of London, and for the Diploma in Dental Surgery of the Royal College of Surgeons of England. Special arrangements are made for those students who wish to take a medical degree or qualification in addition to a degree or diploma in Dental Surgery.

The following salaried appointments are open to qualified members of the School: Registrar, Resident House Surgeon, Non-Resident House Surgeon, and Tutors in Dental Mechanics, Operative Dental Surgery, and Dental Materia Medica.

Full particulars of the Dental School may be obtained on application to the Dean, or to the Secretary of the Medical School, King's College Hospital, Denmark Hill, London, S.E.5.

London Hospital

This school is a part of the London Hospital and Medical College, and is fully equipped on the most modern lines and with the latest appliances. It provides a complete curriculum in all subjects for the B.D.S. Degree and for the L.D.S. Diploma, and is admirably adapted for the purpose of teaching. The Conservation Room is well lighted and ventilated, and fitted with pump chairs of the latest pattern; the fountain spittoons at many of the chairs have been specially designed. Each spittoon has attached to it a saliva ejector, hot and cold water, compressed air, gas and electric current, also a swing bracket to carry the student's cabinet. Electric sterilisers are supplied in each department and motor engines where required. The school possesses, in addition to the Theatres, Laboratories, and Museums in the College, a special Museum of Dental Anatomy and Surgery, Operative Dentistry, Prosthetic and Extraction Rooms, an X Ray Room, and Laboratories for Practical Metallurgy and Prosthesis. A systematic course of instruction is arranged for pupils. The up-to-date Laboratory contains every modern apparatus, and is in charge of a skilled curator and his assistants. Entrance Scholarship: Francis Farmer Entrance Scholarship in Science, value £25; no age limit. Subjects: Chemistry and Physics. Prizes: The Harold Fink Prize in Operative Dental Surgery, value £8 8s.; the "London" Prize in Dental Prosthesis, value £6 6s. Prizes are also offered for competition at the end of each of the courses of lectures in the curriculum. Connected with the Medical College and Dental School are a Library, Athenæum, Clubs' Union, Dining Hall with moderate tariff, and an Athletic Ground. A new Residential Hostel has been opened, and provides accommodation for 50 students. For full particulars as to Scholarships and Prizes, fees and course of study advised, apply to the Dean of the Medical School.

TEACHING INSTITUTIONS OUTSIDE LONDON

Birmingham Dental Hospital

The Dental Hospital in Great Charles-street has accommodation for 100 students. The equipment is in accordance with the most modern requirements for the efficient teaching and practice of Dental Surgery, including Radiology and a department for Practical Pathology and Bacteriology. The hospital, both internally and externally, has been renovated, and several departments have been reconstructed. The operations performed annually average 70,000, including gold and other fillings, crowns, bridges, porcelain inlays, jacket crowns, and injections for block and infiltration anæsthesia. The orthodontic department is one of the foremost in the country. The prosthetic and mechanical department is large and well lighted and two highly skilled instructors are always present, while two honorary officers give daily demonstrations. Application for information as to fees and scholarships must be sent to the Dean of the Medical Faculty, Birmingham University, or the Dean of the Dental Hospital, Birmingham.

Leeds University School of Dentistry

The School of Dentistry is adequately equipped to provide for the complete training of the dental student. It forms a part of the Leeds School of Medicine whilst the instruction in clinical and mechanical dentistry is carried out in the Dental Hospital. The School is now in occupation of a spacious new building especially designed to the requirements of modern dental teaching. The School is also the dental department of the General Infirmary, and its close association with the work of that institution ensures an adequate supply of clinical material, and enables a fuller insight into the position dental surgery holds in relation to general medicine and surgery, especially with regard to the major diseases and injuries of the head and neck. The courses of study are mainly designed to meet the requirements of the B.Ch.D. and L.D.S. Leeds, but every opportunity is afforded to students preparing for the degrees or diplomas of other licensing bodies. Full-time teachers give the instruction in clinical dental surgery, prosthetic dentistry, and mechanics, which is carried out under the supervision and direction of the Professor of Clinical Dental Surgery and members of the Honorary Staff. Special facilities are provided for instruction in Orthodontia, Radiography, Local and General Anæsthetics, and Bacteriology. Prizes are offered for competition to students in their respective years of study. Post-graduate clinical courses are arranged in collaboration with the Dental Board of the United Kingdom, and facilities exist to meet the requirements of dental surgeons desirous of obtaining special post-graduate instruction. Communications should be addressed to the Warden, School of Dentistry, Leeds, from whom a prospectus may be obtained.

University of Manchester School of Dental Surgery

Courses of study are provided to meet the requirements for the B.D.S. Degree and the L.D.S. Diploma of the University of Manchester, and for the L.D.S. Diploma of the Royal College of Surgeons of England. At the Dental Hospital instruction is given in practical Dental Mechanics, Operative Dentistry, Diagnosis and Extraction, Orthodontics, Dental Prosthetics, Anæsthetics, and Radiography by specially appointed Clinical Teachers. All the courses of instruction are open to women students. Copies of the prospectus may be obtained on application to the Dean.

Newcastle-upon-Tyne Dental Hospital and Sutherland Dental School

This institution is a component part of, and constitutes the Dental Department in, the University of Durham College of Medicine. A new dental hospital, erected within the grounds of the Royal Victoria Infirmary and equipped with the most modern apparatus, was opened in 1932, and it is possible to undertake the whole of the dental curriculum—i.e., systematic lectures, dental and general hospital practice, together with the mechanical pupilage—at the College. The Dental Board of the United Kingdom recognises the school for the purpose of granting its bursaries to students who are able to comply with the conditions laid down by the Board. The composition fees payable by dental students are £90 for all systematic lectures and laboratory work at the College for the B.D.S. (or £85 for the L.D.S.), £50 for dental hospital practice for B.D.S. (or £40 for L.D.S.), £16 16s. for general hospital practice, and £80 for pupilage in mechanics. A dental prospectus and any other information may be obtained from the Dean, University of Durham College of Medicine, Newcastle-upon-Tyne.

SCOTTISH TEACHING INSTITUTIONS

Edinburgh Dental Hospital and School

The Edinburgh Dental Hospital and School is located in spacious and well-equipped buildings at 30, 31, and 32, Chambers-street, and offers special advantages to dental students. The General Courses required for the Dental Diploma may be taken in the Medical School of the Royal Colleges of Physicians and Surgeons or in the University schools. The general hospital attendance and clinical instruction are taken at the Royal Infirmary. The University, Medical Schools, and Royal Infirmary are within three minutes' walk of the Dental Hospital. The special courses are taken in the hospital. The Dental Hospital practice, extending over two years, affords a student ample opportunity for a full acquaintance with every branch of dentistry. The hospital admits a limited number of indentured pupils. They receive their instruction in Mechanical Dentistry concurrently with the general and special courses. A premium of 60 guineas is payable with each such pupil. The practice and lectures of the hospital are recognised by, and qualify for, all the Licensing Boards. Those students who desire to take a Medical and Surgical Diploma in addition to the L.D.S. have in this school admirable facilities for so doing. The triple qualification of the Royal College of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow is recommended. The Higher Dental Diploma (H.D.D.) of the Royal College of Surgeons affords an opportunity of obtaining a higher qualification subsequent to registration. The Prospectus, with full information, may be obtained by application to the Dean or the Assistant Secretary.

Incorporated Glasgow Dental Hospital

This hospital is located at 211, Renfrew-street, Glasgow. The school is open to Men and Women Students, and Lectures are given on Dental Surgery, Operative Dental Surgery, Orthodontia, Dental Anatomy and Physiology, Dental Histology, Dental Mechanics, Crown and Bridge work, Dental Metallurgy, Dental Bacteriology, Radiology, Anæsthetics, and Dental Materia Medica. Lectures on general subjects required for Dentistry may be taken at the University or at one of the extramural schools where special provision is made for Dental Students. The new Dental Hospital is now open and is equipped with all the modern methods for teaching students. Post-graduate courses will be inaugurated during the coming winter.

Glasgow Royal Infirmary

Dental Department: The following course in the curriculum can be taken at St. Mungo's College: Anatomy, six months; Practical Anatomy, nine months; Physiology, six months; Chemistry, six months; Practical Chemistry, three months; Surgery, six months; Medicine, six months; Materia Medica, three months. Clinical Medicine (three months) and Clinical Surgery (six months) are taken at the Royal Infirmary.

IRISH TEACHING INSTITUTION

Dental Hospital of Ireland

All Dental Students who have passed their Second Dental Examination in the Royal College of Surgeons in Ireland (or an equivalent examination or examinations) are admissible to the Clinical Instruction of the Hospital. In addition to Clinical Instruction and Special Demonstrations, courses of lectures are given at the hospital on Dental Surgery and Pathology, Mechanical Dentistry, the Administration of Anæsthetics, Orthodontia, Dental Anatomy, and Dental Materia Medica, and instruction in Anæsthetics. The course in practical Dental Mechanics can be taken in the Hospital Laboratory. Post-graduate courses are given in Orthodontics. Further particulars can be obtained from the Dean, at Lincoln-place, Dublin.

The Services

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt.-Comdr. S. G. Rainsford to be Surg. Comdr.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. M. O. Wilson retires on retd. pay.

Maj. E. C. Lang to be Lt.-Col.

TERRITORIAL ARMY

Maj. and Bt. Lt.-Col. E. W. Matthews to be Lt.-Col.

James Henry Crawford (late Capt. I.M.S.) to be Capt.

T. A. S. Kennerley and A. Houlbrooke (late Offr. Cadet, Liverpool Univ. Contgt., Sen. Div., O.T.C.) to be Lts.

TERRITORIAL ARMY RESERVE OF OFFICERS

Capt. D. C. Vaughan, from Active List, to be Capt.

INDIAN MEDICAL SERVICE

Majs. to be Lt.-Cols.: P. C. Banerjee, B. Prasad, A. N. Bose, J. M. Mitchell, M G. Bhandari, N. J. Gai, and M. M. Cruickshank.

Lt. C. B. Miller is restd. to the estabt.

To be Lt. (on prob.): E. C. Rowlette.

Lt. W. J. Poole relinquishes his prob. appointment.

Medical Branch.—Flight Lt. (Hon. Squadron Leader) C. A. E. I. Brownlee relinquishes his temporary commission on completion of service and is permitted to retain the honorary rank of Squadron Leader.

DEATHS IN THE SERVICES

Lt.-Col. Edmund Hassell Wright, I.M.S., retd., who died on August 13th aged 72, was a St. Thomas's student who qualified with the conjoint diplomas in 1887. He received his first commission in the Indian Medical Service in 1890 and retired with the rank of Lt.-Col. in 1910. At one time he was District Medical Officer and Sanitary Officer of the Medical School at Tanjore, Madras. He was specially interested in the tropical diseases common to Southern India, and his energetic pursuit of these and other affections of the natives of India impaired his health. On his retirement he went to Switzerland, but some three years ago returned to this country when he went to live at Woking. He had intended to write a treatise on the diseases to which he had devoted his life, but the project was never carried out.

M.D. DEGREES OF SWISS UNIVERSITIES.—The universities of Basle, Berne, Geneva, Lausanne, and Zürich grant the degree of Doctor of Medicine to "medical practitioners from other countries who are legally entitled to practise in their country of origin" under the following conditions: 1. Pursue a course of study in the final subjects of the medical curriculum, and pass a viva-voce examination in such, at the end of one academic year (nine months). 2. Prepare at the same time a thesis for the doctorate, which has to be accepted by the Faculty of Medicine towards the end of the year. The total fees (examination and diploma) amount to Fr.450 Swiss (£25). At Lausanne there is a tutor for British practitioners. At Geneva the laboratory course is so arranged that it provides the subject matter for the thesis, which is prepared during the entire stay. The candidate should make written application to the dean of the Faculty of Medicine, and further information can be obtained in this country from the hon. secretary of the Lausanne Medical Graduates' Association (Dr. Charles Franklyn, The Corner House, Queensway, Lincoln).

INDEX TO "THE LANCET," VOL. I., 1934

THE Index and Title-page to Vol. I., 1934, which was completed with the issue of June 30th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

ADDRESSES AND ORIGINAL ARTICLES

DISTURBANCES OF THE BODY TEMPERATURE *

BY C. E. LAKIN, M.D., F.R.C.P. Lond., F.R.C.S. Eng.
PHYSICIAN TO THE MIDDLESEX HOSPITAL AND THE LONDON FEVER HOSPITAL

EXACTLY 160 years ago Joseph Priestley by concentrating the sun's rays upon a red compound of mercury by means of a burning glass liberated a gas which he called Dephlogisticated Air, or oxygen as we now know it. How little did his friend, Samuel Parker, the London optician, who made and gave him this glass, a foot in diameter, divine the untold development of knowledge which would result from this simple gift!

Combustion and Heat Production: Some Elementary Considerations

When a candle burns in an enclosed space occupied by air the air loses some of its oxygen, becomes richer in water vapour and carbon dioxide, and also becomes hotter. This latter fact is simply an example of the universal law that no change, chemical or physical, can take place without energy being either absorbed or liberated in the process. In the example we have chosen energy is set free in the form of light and heat. Even when iron rusts a little heat is produced, but so slowly that it is dissipated before it can heat the iron. Similarly, when we breathe in air the oxygen is taken up by the hæmoglobin of the blood and carried to the tissues where the oxygen joins with the protoplasm of the tissue cells, with the result that the heat accompanying this chemical change is sufficient to keep our bodies warm even on a cold day. To continue the comparison, the air we breathe out is warmer and more moist and contains less oxygen and more carbon dioxide than the air we breathe in. If this was all that happened the cell protoplasm would soon become deprived of its carbon, but there is a constant supply of fuel in the form of carbon compounds arriving from the alimentary tract derived from the food we eat. The large complex molecules contained in food are broken down in the process of digestion into simpler constituents which, after absorption, are built up into the protoplasm of cells where, again by a process of oxidation, they provide a constant supply of heat and energy. This cellular activity we speak of as metabolism. In states of heightened metabolism more heat is produced, while in conditions of lowered metabolism the production of heat is lessened. The functional activity of the thyroid and adrenal glands plays a further part in influencing metabolism and heat regulation. It may be said that energy is used up every time a muscular action is performed, every time the stomach digests or the brain thinks.

But the generation of heat within the body does not explain the fact of the body temperature being kept constantly at the same level. This fact presupposes that the amount of heat produced is exactly balanced by the sum total of the losses of heat which are constantly going on: at the surface of the body by conduction, radiation, and evaporation; from the lungs by evaporation of aqueous vapour and by the warming of the colder inspired air; in the intestinal canal by the warming of cold food or drink; and lastly, heat is lost by the warm dejecta leaving the body. Any disturbance of this equilibrium must be followed by an increase or a lowering of the body temperature. But there is another factor without which the maintenance of this equilibrium and the equable distribution of heat throughout the body would be impossible and that is the circulation of the blood. By means of this a regulation of the loss of heat may be brought about whenever necessary, the blood-supply to the skin varying as the arterioles dilate or contract under the influence of the vasomotor nerves. Whenever the external temperature would bring about too considerable a loss of heat, the peripheral arterioles contract and the circulation becomes slower and heat is thereby retained in the body; sometimes, as in shivering, the muscles are stimulated to increased action and increased production of heat results. When on the other hand the loss of heat from the surface is prevented, as occurs in a very hot room, the peripheral arterioles dilate, the heart's action accelerates, and a much greater quantity of blood flows through the skin, and the sweat glands pour forth sweat which, by its evaporation, tends to lower the temperature. At the same time the respiration is quickened and further loss of heat takes place by means of the aqueous vapour in the expired air.

Although oxidative processes are taking place in all the tissues of the body, the two chief seats of heat formation are the muscles and the glands. It has been computed that the muscles constitute more than one-half of the total weight of the soft tissues of the body, and even during rest oxidative changes are constantly occurring in them, leading to heat production and the maintenance of muscular tone. It is probable that, weight for weight, the glands are still more effective as heat producers, but they only make up about 4 per cent. of the body-weight. The liver of an adult weighs about 3 lb., and is in constant action even when digestion is not in progress. The kidneys, weighing 5 oz. each, are also in a state of constant activity, and it is said that the urine leaving them is warmer than the blood in the aorta. According to Pembrey,

> "an adult man produces about 1,700 calories in twenty-four hours when he is fasting and remains perfectly quiet in bed. The sources of this heat have been calculated. The heart during its work produces about 70 calories, and the respiratory muscles about 150 calories; the heat due to the activity of the liver and kidneys has been estimated by Tigerstedt at 368 and 74 calories respectively. The sum of these is 662 calories, so that there remains a balance of about 1,000 calories, which must be formed almost entirely in the skeletal muscles. The *minimum* production of heat in twenty-four hours by a man weighing 70 kilogrammes (11 stone) may be estimated at 1,200 calories arising from the muscles and 500 calories from the glands."[1]

It has also been computed that in a man doing a moderate amount of daily work about one-twentieth of his metabolic energy leaves the body as mechanical energy, the rest being evolved in the form of heat. Coming to the question of heat loss, it has been estimated that about 5 per cent. of the total heat loss is expended in warming the food and inspired air, about 15 per cent. in the evaporation of water and CO_2 in the respiration, and about 80 per cent. by radiation and convection and the evaporation of sweat from the skin (Starling). The proportion of the heat lost by the skin will increase very largely in the presence of a high external temperature or of an excessive heat production in consequence of violent muscular exercise.

---

* The first Lettsomian lecture for 1934, delivered before the Medical Society of London on Feb. 19th. Lectures II. and III. will appear in later issues.

[1] Text-book of General Pathology. Edited by M. S. Pembrey and J. Ritchie. 1913.

It is clear that the various processes responsible for the production of heat such as muscular and glandular activity, as well as those concerned with the loss of heat such as vascular dilatation, are all under nervous control. There is, however, great diversity of opinion as to whether special centres for the regulation of temperature exist in the brain, and we shall return later to the consideration of this subject.

Means of Measuring Temperature

Galileo is said to have been the first to utilise the principle of the expansion of bodies when subjected to heat in making measurements of temperature. The year of his invention of the thermometer is given as 1603, and it was his contemporary, Sanctorius, the celebrated Paduan professor, who applied his invention to clinical medicine. Time does not permit us to go into the history of thermometry; suffice it to say that thermometers began to make their appearance in English hospitals about 1866–67, though they had been in use in Edinburgh long before, and came into general use about 1868–70. They were about 10 inches long and, as Brunton relates, so clumsy that they were carried under the arm "as one might carry a gun." Their reduction in size—in fact the invention of the pocket thermometer—was due to Clifford Allbutt (1868). One name we cannot pass over, that of Wunderlich, professor of medicine in Leipzig from 1850 to 1877, whose classical work "On the Temperature in Diseases" was translated into English and published by the New Sydenham Society in 1871. Of Wunderlich it has been said: "He found fever a disease and left it a symptom."

The means at our disposal for registering the temperature of the body are:—

(1) The *mercury thermometer*—either in the form of the clinical thermometer as we now know it or, where surface temperature is being investigated, a mercurial thermometer of special shape in which a long cylindrical bulb coiled up in one plane at right angles to the stem is applied to the skin.

(2) The *electrical resistance thermometer*. This method depends upon the alteration of the electrical resistance of a platinum wire caused by a slight increase in its temperature. The alteration in conductivity is then measured by means of a Wheatstone's bridge or may be recorded photographically.

(3) The *thermopile*. This is based upon the principle that if the junction between two dissimilar metals be warmed a difference of electrical potential is produced and a potentiometer is used to record the current changes.

The two latter methods are employed where great accuracy is desired or a continuous record is to be made.

Two other instruments are in use where the degree of humidity of the air has to be taken into account as in cases where observations have to be made on perspiration. First, there is the wet and dry bulb thermometer, consisting of two mercurial thermometers, the bulb of one being covered with a close-fitting muslin bag which is kept moist by being held in contact with a wick dipping in water. The water evaporates from the bulb at a rate varying with the degree of saturation of the atmosphere with aqueous vapour. If the air is already saturated with moisture and no evaporation is taking place from the wet bulb both thermometers will register identical temperatures. Where the difference in the temperatures of the two thermometers is great, one may regard the air as being dry. The degree of humidity of the air can then be calculated from a formula Valuable as this information is it does not give u a true idea of the cooling power of a particular atmosphere. It fails to register for instance cooling du to air movement. This deficiency is supplied by Leonard Hill's kata-thermometer, whereby the rat of cooling is measured directly. A special type o kata-thermometer, known as a Comfimeter, give an immediate indication of the cooling property o air in rooms.

Normal Daily Range of Temperature

The mean daily temperature in health is usuall said to be 98·4° F. when taken in the mouth. If th whole 24 hours be taken into account this is probabl rather too high than too low a mean. By means of th continuous readings method of recording temperatur it is found that in health the temperature of th body is highest in the evening between the hour of five and eight and lowest in the early hours of th morning. This is chiefly to be explained by th muscular activity which occurs during the day. It i questionable to what degree the increased metabolism resulting from the ingestion of food is also responsibl since a temperature curve similar to the ordinary typ has been observed in fasting men. A reversal the daily routine such as occurs in night worke leads after a few days to a reversal in the temperatu curve. When night duty is first undertaken a overpowering desire for sleep is usually experience about 4 A.M., the hour of the usual minimum. Whe a healthy person is kept in bed, the normal temperatu variations still occur but the evening maximum i not quite so high. During sleep the temperature fall This is to be attributed to the diminished activity the body whereby less heat is produced and also to th relaxation of the vessels of the skin leading to increase loss of heat. It may be said that in health the rang is approximately from 97° F. to 99° F. if the mout temperature be taken. The rectal temperature i usually ½° to 1° F. higher than the temperature a taken in the mouth.

Sustained exercise leads to an increase of bod temperature, the rise being proportional to th exertion made. It may be as much as 3° or 4° F. bu is of temporary duration, and in health is unaccom panied by any feeling of discomfort. During exercis breathing is quickened and the pulse-rate rises and i this way the body gets rid of some of its extra hea by an increase of aqueous vapour in the expired a and by sweating. The increased temperature whic occurs in spite of the increased loss of heat appea to be beneficial to the athlete in that it facilitates th dissociation of oxyhæmoglobin in the tissues, wit the further result that larger amounts of CO_2 ar evolved and the hydrogen-ion concentration tends t go up.

Temperature also varies with age. In infants a hour or two old the temperature may be as low a 93·2° F. It rises gradually during the first few day of life but the infant only slowly develops the pow of maintaining a constant body temperature, an its temperature falls as soon as it is exposed to moderate degree of cold. Heat regulation bein imperfect, a rise or fall of the body temperature i the case of an infant is of less clinical significance tha a similar change in the temperature of an adult. fit of screaming may cause a rise of several degree a fact which may cause concern if this imperfectic of heat regulation is not appreciated. It has bee found that too cold a bath or exposure to cold aft a warm bath may lower the temperature of a healthy infant from 7° to 9° F. In old age the temperature is usually subnormal. Metabolism is much less active and the power of heat regulation becomes enfeebled, so that old people are much more affected by extremes of weather.

When we consider the temperature of the surface of the body it is found that in health it varies in different parts. The temperature of the skin of the trunk is much more constant and uniform than that of the extremities. Absence of uniformity is a sign of vigour and conversely a uniform surface temperature in all parts is a sign of poor health.

In concluding this section I should like to quote from Pembrey's article (loc. cit.) on the Physiology and Pathology of Temperature, to which I am much indebted. He says:

> "There is no uniformity in the temperature of the healthy body; the temperature is not constant in health, notwithstanding the fact that it is often said to be so and clinical thermometers and temperature charts are marked with a line at 98·4° F. for the normal. The absence of uniformity is a sign of health and well-being. We are comfortable and unconscious of the fact that there are local differences of temperature, which at once becomes manifest when we place our hands in succession on the face, chest, abdomen, and foot. As soon as the external conditions, such as heat, moisture and absence of wind, become favourable for the development of a more uniform temperature of the body, discomfort and inefficiency arise. This question is one of the greatest importance in relation to the influence of climate and artificial systems of heating dwellings and work-rooms, and it is unfortunate that many authorities have overlooked the physiological aspect. In living things there is no uniformity, and all attempts to obtain uniformity in religion, politics, work, or social standing, have failed. Uniformity would mean absolute stagnation—death.
>
> "The extravagant and dusty open fire is better than the closed stove or the radiators filled with hot water or steam, for it produces more variations in the temperature of the room and these act upon the skin. Changes in the temperature of the skin stimulate the nervous system, and produce a more steady growth and greater activity of the body and mind."

Pyrexia: Hyperthermia: Aseptic Fever

Before proceeding further it may be well to define the sense in which the words pyrexia, hyperthermia, and fever are used in these lectures. *Pyrexia* is used in the sense of a heightened body temperature. *Hyperthermia* signifies a high temperature produced by causes other than infection, such as, for instance, is seen in heat-stroke or pontine hæmorrhage, or after the injection of drugs such as β-tetrahydronaphthylamine. The last example will in due course be considered under the heading of aseptic fever. The term *Fever* is used in the sense of a complex response of the body to infection in which pyrexia or raised temperature is but one of the manifestations. It is essentially a response in metabolism associated with a toxic disturbance of heat regulation, and it will be shown to be due to an exaggeration of the processes by which the body normally responds to conditions which otherwise tend to lower the body temperature. Before entering upon a consideration of the underlying processes responsible for fever it will be convenient to give some attention to the subject of hyperthermia such as is exemplified in heat-stroke.

HEAT-STROKE AND SUN-STROKE

Divergent opinions have been held as to what happens in death from exposure to the sun. Some have held that this condition is not due primarily to the heat of the sun but rather to its actinic rays, maintaining that a distinction should be drawn between heat-stroke and sun-stroke. Experiments upon soldiers whose clothing was specially designed to prevent penetration of the actinic rays of the sun have disposed finally, I think, of this theory of "sun-stroke" in the strict sense of the term (Jour. Roy. Army Med. Corps, 1911, xvi., 109). That sun-stroke is a fever endemic in certain hot countries and due to a specific micro-organism is another view for which there is no convincing evidence. In some instances it would appear that cases of specific fevers have been mistaken for heat-stroke and conversely some cases of heat-stroke have been erroneously diagnosed as specific fevers. Accumulated evidence points to the fact that sun-stroke is really heat-stroke, and is a disorder of the heat-regulating processes of the body produced by the action of moist heat upon men who are working hard or fatigued and often unsuitably clothed. We have seen that even under favourable conditions muscular work may lead to a rise of temperature to 101° F. or 102° F. Where a man is exposed to a higher external temperature than the body temperature when the air is unduly moist, and especially if it is also stagnant, it becomes difficult for him to regulate his temperature by sweating. It is true that in some cases where he is unsuitably clothed loss of water from the skin has been so great that, before unconsciousness occurs, the clothing is wet with sweat, yet where evaporation from these is slow on account of high atmospheric humidity the body will not be cooled.

We know that the chemical or metabolic processes in the living organism are less active when the body temperature falls below a certain optimum, and that with increasing body temperature these processes are speeded up; in this way with increasing body temperature the production of heat is further increased, and in the case we are considering a vicious circle becomes established. The heat-regulating mechanism of the body is overwhelmed and death will occur unless the temperature be lowered. A temperature of 107·6° F. maintained for some time will coagulate the globulin of the cells, a factor which plays a part in determining death in these circumstances. A writer has well said:

> "Soldiers have been especially liable to 'heat stroke' and many lives have been lost during forced marches, when the air was hot, moist and stagnant. The conditions under which soldiers work are the most favourable for the production of heat stroke; they are unsuitably clothed, heavily laden, and march in such close order that they are surrounded by air saturated with moisture from the sweat and breath of their comrades. They march under orders, and are not free to obey the dictates of their own sensations; moreover, their pride will often make them persist in their efforts to keep up with their more efficient comrades until they fall out of the ranks and become unconscious." (Pembrey.)

The onset of heat-stroke may occur with catastrophic suddenness and death be almost instantaneous, or there may be premonitory headache, nausea, dizziness, and visual disturbance. In a case that was admitted to the Middlesex Hospital the temperature rose to 109° F., the breathing was deep and the pupils dilated, the man being quite unconscious. As he grew worse the pulse became irregular, rapid, and more feeble, the breathing more shallow and of the Cheyne-Stokes type, and he died within a few hours of admission in spite of the most active antipyretic treatment.

There are other cases spoken of as "heat-exhaustion," in which the skin is bathed with sweat, the body temperature raised though much less so than in the form just considered but in which the patient is in a condition of profound collapse. There is rarely loss of consciousness. In such cases the failure of regulation appears to be due to a weak heart and defective vasomotor control. It is difficult to determine whether the weakness of the heart is the cause or the effect of the failure to regulate the temperature, it being a well-established fact that persons with weak or diseased hearts fall easy victims to heat-stroke, while on the other hand the heart is readily injured by a high temperature and a defective supply of blood. There is usually no difficulty in distinguishing clinically between heat-stroke and heat exhaustion, but there is no clear line of demarcation between the two conditions and cases of heat exhaustion may pass on to heat-stroke. In the one condition the heat-regulating mechanism is embarrassed, in the other it is overwhelmed.

There is another condition to which passing reference may be made, known as "heat cramps," met with more especially in stokers, miners, steel-workers, and others exposed to intense heat. Cronin in 1892 was one of the first to study this condition. Spasms of sudden onset affecting successive groups of muscles of the limbs or of the abdominal wall occur intermittently over a period of 24 hours or so. They are usually attributed to the loss of blood chlorides, the loss amounting in some cases to as much as 20 g. in the 24 hours. This loss of chlorides is believed by some to be a diffusion effect of taking large quantities of water. Others, in view of the prompt benefit which results from the intravenous injection of sodium bicarbonate, regard the condition as being due to an increase in the blood of toxic elements brought about by profuse perspiration. Heat cramps may be prevented by supplying men exposed to great heat with salinized water containing from 0·25 to 1 per cent. of sodium chloride cooled to about 50° F., and salt tablets are commonly dispensed in industrial works where high conditions of temperature prevail. Cases are usually treated with saline fluids, warm baths, and rest.

I have known death to occur while a patient suffering from renal dropsy was having a hot-air bath. Such deaths appear to be due to heat-stroke. If sweating fails to take place the temperature of such a patient rapidly rises. A nurse in charge of such a patient should be told to take the temperature of the person subjected to such treatment every two minutes till sweating occurs. If no beads of sweat are seen and the temperature progressively rises the bath must be brought to an end without further delay. In a healthy person the secretion of sweat commences as soon as the temperature of the body has attained a height of 0·2° to 0·5° C., that is roughly ½°-1° F. above the normal.

In guarding against sun-stroke it is necessary to wear light loose clothing to favour the evaporation of sweat, and a good supply of drinking water must be available. On a march frequent halts must be called. The most successful treatment of sun-stroke is the internal and external application of cold water and, if available, ice. Cooling the head and effusions of cold water to the neck so that the temperature of the blood in the carotid arteries may be affected is often followed by improvement. In severe cases ice water enemata are called for, as where the circulation is depressed the application of cold to the surface may fail to be transmitted through the feebly circulating blood to the internal parts of the body. Even in cases of recovery from heat-stroke abnormal nervous symptoms may occur for years after the stroke whenever the external temperature of the air rises above a certain point.

We have seen that sun-stroke is due to inability of the body to lose heat by sweating, and before leaving the subject of heat-stroke, an experiment of Leonard Hill's is so illuminating in this connexion that it must be quoted.

> A number of healthy young men were crowded into an airtight compartment provided with necessary apparatus for sampling the air for analysis. After 44 minutes the dry bulb thermometer registered 87° F. and the wet bulb 83° F.; the CO_2 had risen from 0·04 per cent. to 5·26 per cent., while the oxygen had fallen from 21 per cent. to 15·1 per cent. Great discomfort was experienced and the skin of all was flushed and drenched with sweat. The talking and laughing of the occupants had gradually become less and finally ceased. Long before the discomfort had become extreme the oxygen percentage became so low that matches would not burn, yet the disinclination to smoke cigarettes was not noticed till some time after it was impossible to light them. On whirling the air in the chamber by means of an electric fan immediate and great relief was felt in spite of the fact that the temperature continued to rise. On turning off the fans the discomfort returned and the occupants cried out for the fans to be restarted. Hill then allowed the occupants of the compartment to breathe fresh air through tubes provided with mouthpieces piercing the walls of the chamber, but they received practically no benefit from the fresh air. The starting of the fans, however, brought relief as before. Persons outside the chamber whose bodies were cool then breathed in the vitiated air from the compartment. No discomfort was experienced, nor did they suffer from headache or any of the effects popularly supposed to be due to inspiring vitiated air.

It is clear, from this experiment, that neither the lack of oxygen nor the presence of a high percentage of CO_2 or other excreted substance has any influence on the "badness" of the air of a room. Discomfort is due to the loading up of the air with moisture, making it impossible for the occupants to lose sufficient water from the skin.

PERSPIRATION AND SWEATING

Reference may here be made to the distinction which can be drawn between perspiration and sweating. By perspiration, or insensible perspiration as it is called, is meant the escape of water vapour by osmosis through the skin. It is thought that the sweat glands play no part at all in this process. The amount escaping will be proportional to the heat production of the body and to the external temperature, will be greater when the air is dry and less if the air be stagnant. It is diminished in places where the skin contains much fat and is not greatly influenced by alterations in the amount of fluid drunk. If the body be enclosed in a vessel through which a regulated current of air is passed and the temperature of the air be gradually raised it is found that the amount of water given off from the skin rises slowly up to a certain point and then suddenly mounts rapidly. This sudden increase is due to a new process coming into play—namely, the activity of the sweat glands. Beads of sweat appear and there is a great increase in the discharge of CO_2 from the skin. Prof. Kuno of the Manchurian School of Medicine has shown that, except in the case of the palms and soles, the sweat glands of the body are almost entirely concerned with the regulation of the body temperature. He has shown by means of absorbent paper that sweating is not uniform in different parts of the body.

Curiously enough, the palms and soles, where the sweat glands are most closely crowded, respond little if at all when the temperature of the body is raised; profuse sweating in these parts occurs in response to any intense sensory stimulation and in states of mental stress. Kuno has shown that the head, neck, dorsal and ventral aspects of the upper part of the body sweat most, while the axillæ and femoral regions participate to a slighter degree. Thus it will be seen that sweating principally occurs in those parts which by reason of their being more exposed in a hot climate offer the best opportunity for evaporation to occur. Those parts of the skin in which there is little chance of evaporation sweat least—namely, the armpit, perineal region, inguinal and femoral regions. This seems contrary to our usual experience, because those parts of the body are very likely to become clammy in hot weather, but they become wet not because sweating is especially abundant but because sweat, once discharged, evaporates with difficulty.

Under normal circumstances in temperate climates the greater part of the water imbibed in the course of the day is excreted by the kidneys, a smaller portion leaving by the lungs and by the surface of the skin in the form of insensible perspiration. The amount of water lost by the lungs and by the skin is about equal and varies with the metabolism of the individual and with the temperature and humidity of the air. Benedict estimates that in the case of a man with a basal metabolism of 1700 calories 430 g. (roughly 15 ounces) are lost by the lungs and a like quantity from the skin in the form of insensible perspiration in 24 hours. The sweat is the most dilute of all the body fluids and contains 99 per cent. of water. It is, of course, hypotonic as compared with plasma, and this contributes to its efficacy as a cooling medium, since the more dilute a solution the higher is its vapour pressure and consequently the more rapid its rate of evaporation. Of its solid constituents about three-quarters consist of sodium chloride and about half the rest of urea. In cases of renal insufficiency sweat becomes more concentrated and it is said that its urea content is increased. The secretion of sweat is under the control of the sympathetic nervous system, and may be induced by warming the arterial blood flowing to the brain in the carotid arteries even when the temperature of the body is otherwise unchanged. Though usually associated with an increased blood flow in the skin capillaries sweating is not dependent upon this, for stimulation of the sciatic nerve results in sweating in the leg in spite of the fact that vasoconstriction is also produced. Moreover, the perspiration of syncope, fear, and death is associated with pallor of the skin (Bayliss).

ASEPTIC FEVER

This term has been employed to denote the pyrexia which results when certain chemical substances are introduced into the body either by ingestion or injection. Among such substances may be mentioned β-tetrahydronaphthylamine, dinitro-o-cresol (the drug recently introduced for the treatment of obesity), atropine, cocaine, caffeine, and the injection intravenously of very strong sugar solutions. Another form of what may be termed aseptic fever is sometimes seen in prolonged thyroid feeding. If a few milligrammes of β-tetrahydronaphthylamine (which we may abbreviate to T.H.N.) be injected into an unanæsthetised rabbit (Elliott: Jour. of Physiol, 1912, xliv., 374) and the animal be examined after the lapse of half an hour, its temperature is found to have risen, respiration is panting and rapid, there is protrusion of the eyes and dilatation of the pupils. There is erection of its fur accompanied by intense constriction of the arterioles of the skin, readily observed in the ears, which feel cold to the touch. The pyrexia and the changes in the vascularity of the skin produced by the injection of T.H.N. have been compared to the changes taking place during the rigor state of an attack of malaria, and further reference will be made to this form of aseptic fever when we enter upon a consideration of the processes underlying fever. Prolonged thyroid feeding produces an entirely different type of pyrexia, not very unlike the so-called hectic type encountered in tuberculous infections. Experimental pyrexia cannot be produced in a warm-blooded animal if the spinal cord be divided in the cervical region or the mid-brain removed.

THE TEST-MEAL IN THE DIAGNOSIS OF GASTRIC DISEASE

By N. F. Maclagan, M.B., M.Sc., M.R.C.P. Lond.

WHOLE-TIME WORKER FOR THE MEDICAL RESEARCH COUNCIL

(From the Courtauld Institute of Biochemistry, Middlesex Hospital, London)

THERE is at present no general agreement on either of the two principal questions which may be asked about test-meals—namely, what is the best form of test-meal to use and what information of diagnostic value may be obtained by its use. Much has recently been written by Bloomfield and Polland [1] in favour of the histamine test, but while one may agree with its theoretical advantages it appears that from a clinical standpoint the final decision should rest upon proved utility rather than upon these. If any other form of test-meal can be shown to be of more service in distinguishing a benign from a malignant gastric lesion, that one should be used in preference. We may, however, anticipate the results of this analysis to the extent of saying that the histamine test compares very favourably with its rivals in this respect.

The present paper gives the results of an attempt to compare the different types of test-meal now in use, and to assess the value of each, on the basis of some of the statistics which have recently been published. The Ewald (one hour) meal and the histamine test appear to be most popular in America, and the Rehfuss type of fractional test-meal in England. Reports on large series of patients are available on each of these, but many do not give the figures necessary to this type of analysis, so that only one suitable series for each type could be found. It is particularly unfortunate that the results recently reported from the Mayo Clinic by Vanzant et al.[2] do not contain full details of the cases. While their data for normal persons are admirably tabulated they have omitted the actual means and standard deviations of the pathological ones, so that although their method is well adapted to the demonstration of changes of acidity in disease it does not permit a critical inquiry into the diagnostic value of the Ewald meal. It appears, however, that they do not claim very much in this direction (see Comfort and Vanzant [3]).

THE DATA TO BE OBTAINED

The total information which may be obtained from a test-meal may be considered under four heads.

(1) *Examination of the resting juice.*—The value of this procedure is too well known to require emphasis here. Its value in the diagnosis of gastric carcinoma has been stressed particularly by Bennett,[4] and it is sufficient to say that most physicians, at least in this country, would consider it an essential

part of the test. In the fractional and histamine tests the resting juice is first removed, and although this examination can easily be combined with the Ewald meal, as suggested by Harrison,[5] this is apparently not the practice in America.

(2) *Emptying time, or volume of residue.*—The histamine test alone fails to give any information on this point. It is questionable whether this is a serious criticism, for the motility of the stomach under the conditions of the test-meal is well known to be extremely variable (Bloomfield and Keefer [6]) so that minor alterations are of doubtful importance. Most of the cases of early pyloric stenosis which can be detected in this way will show the presence of charcoal in the resting juice or will be demonstrated by X rays.

(3) *Presence of blood in the test-meal.*—Traces of blood are a normal finding in the histamine test, and although of greater significance in the fractional test are easily produced by trauma. Gross hæmorrhage will be detected by any test.

(4) *Height of acidity reached.*—Most recent publications have been concerned with this point almost exclusively, and sufficient figures have now been published to warrant a first attempt at comparing the three methods in this respect.

Degree of Acidity and Deductions to be Drawn from it

The basis of this branch of test-meal diagnosis rests upon the association of hyper-acidity with peptic ulcer, and of hypo-acidity with gastric cancer. These associations appear to be best explained by the theory of Hurst,[7] who postulates the existence of a "hypersthenic gastric diathesis" prone to peptic ulcer, and a "hyposthenic gastric diathesis" prone to gastric cancer,* but an alternative explanation of the frequency of hyper-acidity in peptic ulcer is concerned with the theory of duodenal regurgitation (Boldyreff,[8] Bolton and Goodhart [9]). This is a much disputed point which I have discussed elsewhere,[10] but it need not be considered here as it will not affect the subsequent arguments.

(*a*) *Demonstration of achlorhydria.*—The significance of achlorhydria varies with the type of test-meal, but there is now almost general agreement that histamine should be used if the demonstration of achlorhydria, or the presence of Castle's intrinsic factor, is the principal object of the examination. This is both because pure undiluted gastric juice can only be obtained in this way, and because histamine is the most powerful stimulant of gastric secretion, so that many persons who fail to secrete hydrochloric acid with gruel or alcohol produce average amounts with histamine.

(*b*) *Significance of different levels of acidity.*—It is generally agreed that absolute indications are rarely forthcoming, but that the matter resolves itself into one of relative frequencies. I am not, however, aware of any previous attempt to express these frequencies in numerical terms or to compare the usefulness of different test-meals in this way. Certainly the existing data are all too scanty to permit any very great accuracy in these calculations, but they may nevertheless give comparative results, and may serve to show where further observations are likely to be of value.

One of the greatest difficulties, the lack of satisfactory normal standards, has only very recently been removed by the work of Vanzant et al.[11] on the Ewald meal, and by Polland [12] on the histamine test. Corresponding standards for the fractional test-meal are deficient, being confined to the pioneer work of Bennett and Ryle,[13] Baird, Campbell, and Hern,[14] and Apperly and Semmens.[15] These refer to healthy medical students, mostly male and within a limited age-period, so that they are not of general application.

We may now take two representative cases as a basis for discussion.

CASE A.—The patient exhibits certain symptoms and signs thought to originate in the stomach, and his test-meal shows a certain level of acidity. What is the chance of his having (i) a peptic ulcer and (ii) a peptic ulcer or a gastric carcinoma ?

The mental choice between (i) and (ii) will be largely a matter of age and clinical history. It is not an unimportant choice, for we shall see that while the test-meal may occasionally help in (i) it can never do so in (ii). There may be those who will consider these points too obvious to require mention, but let them reflect upon the large numbers of "routine" tests which are still performed in many general hospitals upon doubtful cases of dyspepsia. It happens not infrequently that the radiological examination is postponed, perhaps for reasons of economy, and a test-meal is substituted, so that it may be of some interest to calculate the chances of gaining useful information in this way.

Now the answer to these two questions obviously depends upon the following: the frequency of ulcer (x %) and of cancer (y %) in the population from which the patient was drawn; the frequency of his particular level of acidity in persons with ulcer (u %), with cancer (c %), and without ulcer (e %), and without cancer (f %). Since in the general population the incidence of ulcer or cancer is not large, we may without serious error take $e=f=n=$ % of normal persons having the required level of acidity. In certain cases this is not accurately known, and we shall have to take instead average figures from a large number of abnormal persons, excluding as far as possible cases of ulcer and cancer.

It is now easy to show that the patient's probability of having ulcer is

$$\frac{ux}{ux+n(100-x)},$$

and his probability of having either ulcer or cancer is :

$$\frac{ux+cy}{ux+cy+n(100-x-y)}.$$

Since we are in doubt as to the diagnosis, we may interpret this as meaning that the patient in (i) has a 50 per cent. chance of having a normal stomach, so that $x=50=100-x$, and our probability becomes :

$$\frac{u}{u+n}.$$

The patient in (ii) also has a 50 per cent. chance of normality and, say, equal chances of ulcer or cancer, so that $x=y=25$, and the probability is

$$\frac{u-c}{u+c+2n}.$$

If gastric (g %) and duodenal ulcer (d %) are to be considered separately, we have in (i) :

$$\frac{g+d}{g+d+2n}$$

and in (ii) :

$$\frac{g+d+c}{g+d+c+3n}$$

as the required probabilities. The difference between these figures and 0·5, the assumed clinical probability, is a measure of the contribution of the test-meal to the diagnosis. If we draw an arbitrary line at the 20 : 1 chance, as is usual in statistical work, we may say that useful information is obtained only if the calculated probability lies outside the limits 0·05–0·95. It must, however, be emphasised that 0 and 1 do not represent absolute certainties, being due partly to inadequate numbers and partly to imperfect statistical technique. In most cases the figures necessary for a fuller statistical treatment are not available.

---

* For present purposes it is immaterial whether this is an inborn condition or the result of gastritis.

CASE B.—The patient has a doubtful gastric lesion, demonstrated by X rays, and his test-meal shows a certain level of acidity. What is the chance of malignancy ?

Probably no one would dispute the importance or the difficulty of such cases as this, so that an examination of the probability is of special interest. This is particularly so on account of the difficulty of deciding at operation whether an ulcer is benign or malignant. According to Stewart[16] a pre-operative diagnosis should always be aimed at. The diagnosis lies usually between gastric ulcer and gastric carcinoma, for duodenal ulcer rarely causes difficulty in radiological diagnosis. Using the same symbols and assuming a 50 per cent. chance of malignancy on clinical grounds, the probability is :

$$\frac{c}{g+c}.$$

One further calculation is concerned with the proportion of cases in which the diagnosis is likely to be helped. If, for example, 0 per cent. and 29·8 per cent. respectively of cases of peptic ulcer and normals come within the useful range of probability,

$$\frac{0}{2}+\frac{29{\cdot}8}{2}=14{\cdot}9\%$$

of our doubtful population consisting of half normals and half ulcers will be helped.

It will be noted that no mention of age or sex has been made in the above discussion. This is a necessary omission on account of the lack of data and will be referred to below. The applications of these methods to the three types of test-meal will now be considered.

THE EWALD MEAL (Table I.)

Sagal Marks and Kantor[17] gave four "Uneeda" biscuits with two glasses of water, without removing the resting juice. A single extraction was made at 45 mins. As normal standards their total figures for both sexes from ages 41–50 have been used, since they state that their percentages were almost unaffected by excluding cases of gross gastric disease.

TABLE I.—*Ewald Meal (Sagal Marks and Kantor)*

No. of cases ..	1461	46	357	41	Probabilities.		
Diagnosis ..	"Normal."	Gastric ulcer.	Duodenal Ulcer.	Cancer of stomach.	Case A. (i)	Case A. (ii)	Case B.
Relative frequency %	n	g	d	c	$\frac{g+d}{g+d+2n}$	$\frac{c+g+d}{c+g+d+3n}$	$\frac{c}{g+c}$
Achlorhydria	10	2	0	45	0·91	0·61	0·96*
Sub-acidity	20	23	3	40	0·39	0·52	0·64
Normal ..	24	26	15	10	0·46	0·42	0·28
Hyperacidity	46	49	82	5	0·59	0·50	0·09

* Probability falls within useful range.

It is apparent by inspection that no help is obtained in Case A. The only diagnostic point is the absence of achlorhydria in duodenal ulcer, and even this is of no use if the possibility of gastric ulcer arises. In Case B the finding of achlorhydria is seen to have some significance, so that 2 per cent. of ulcers and 45 per cent. of cancers will be diagnosed as cancer. This means that 23·5 per cent. of our doubtful cases will be thought malignant instead of the real figure of 22·5 per cent.

There is of course nothing new in this but it is interesting to note the sort of accuracy which may be expected. Perhaps the most important point which emerges is that in the absence of achlorhydria the test-meal contributes nothing to the solution of the diagnostic problem.

The anomalous position of gastric as opposed to duodenal ulcer may be commented upon here. The Ewald, and to a less extent the fractional test-meal, fails to reveal the hyper-acidity in gastric ulcer which in the histamine test is apparently identical with that found in duodenal ulcer. Although this might be thought an advantage in the differential diagnosis of gastric from duodenal ulcer, it is heavily outweighed by the approximation between gastric ulcer and carcinoma, which is a much more vital matter. It is interesting to note that the results recently reported from the Mayo Clinic by Vanzant et al.[2] even show a diminished acidity in gastric ulcer, although on the other hand the incidence of achlorhydria is reduced. Whatever may be the reason for this unusual finding,† it is certainly not an argument in favour of the Ewald meal.

THE FRACTIONAL TEST-MEAL (Table II.)

The data are taken from Koyihar,[18] in which the usual type of gruel meal was used. The "normal" figures are those for 311 cases of multiple diagnosis, excluding ulcer, gastric cancer, and pernicious anæmia. It will be seen that no superiority over the Ewald meal can be claimed. The only significant finding is again that of achlorhydria in Case B, and 2 per cent. of ulcers and 43·5 per cent. of carcinomas are involved. 22·7 per cent. of our doubtful population will be diagnosed as cancer instead of the true 21·7 per cent. There remains of course the advantage of examining the resting juice.

TABLE II.—*Fractional Test-meal (Koyihar)*

No. of cases ..	311	50	100	23	Probabilities.		
Diagnosis ..	"Normal."	Gastric ulcer.	Duodenal ulcer.	Cancer of stomach.	Case A. (i)	Case A. (ii)	Case B.
Relative frequency %	n	g	d	c	$\frac{g+d}{g+d+2n}$	$\frac{c+g+d}{c+g+d+3n}$	$\frac{c}{g+c}$

* Probability falls within useful range.

THE HISTAMINE TEST (Table III.)

Polland[12] examined 988 persons, of whom 654 were found on examination to be free from any disease likely to affect the gastro-intestinal tract.

---

† It may be mentioned in passing that Vanzant et al. calculate the probable error of the difference from the normal mean from the variance of the diseased population only. Although the variance of the normal population is smaller it is not entirely negligible, and it is just possible that the altered acidity in gastric ulcer might fall below the conventional level of significance if allowance were made for this. The figures necessary for the calculation are not given in their paper.

The figures in the Table refer to males of all ages. In Case A (i) 29·8 per cent. of normal persons, or 14·9 per cent. of our doubtful population, are affected; the presence of ulcer in them would be rendered very unlikely by the results of the test. In Case A (ii) the test is of no value. In Case B, 48 per cent. of ulcers and 81 per cent. of cancers, or 64·5 per cent. of our doubtful population, are helped. In the remaining 35·5 per cent. no relevant information would of course be obtained.

TABLE III.—*Histamine Test (Polland)*

No. of cases ..	384	143	46	Case A.		Case B.
Diagnosis.	Normal.	Peptic ulcer.	Cancer of stomach.			
Highest total acidity.	Relative frequency per cent.			(i)	(ii)	
	n	u	c	$\frac{u}{n+u}$	$\frac{u+c}{u+c+2n}$	$\frac{c}{u+c}$
0– 19	10·4	0	68	0*	0·77	1·00*
20– 39	5·0	0	4	0*	0·29	1·00*
40– 59	9·4	2	15	0·18	0·66	0·88
60– 79	14·4	0	9	0*	0·24	1·00*
80– 99	16·0	18	2	0·53	0·39	0·10
100–119	18·5	32	2	0·63	0·48	0·06
120–139	19·8	36	0	0·65	0·48	0*
140–159	6·5	12	0	0·65	0·48	0*

* Probability falls within useful range.

As a more qualitative deduction we may say that the cases overlap principally in the zone of total acidity from 80–119, which includes 52 per cent. of ulcers but only 4 per cent. of carcinomas. Ulcers are very rare below these limits and cancers very rare above them.

These deductions are obviously affected by errors of random sampling. A more correct approach to the problem consists in the calculation of the means and standard deviations of the acidity in cases of ulcer and cancer, when a better estimate of the distribution is obtained. This has been done in Table IV. from Polland's data. It is evidently necessary to consider separately cases with total acidity below 20, since they form a discontinuity in the data. Unfortunately only 15 cases of cancer with free hydrochloric acid are thus available for analysis, but although this number is small the assumption of a normal distribution appears to be preferable to the alternative of ignoring sampling errors.

TABLE IV.—*Histamine Test (Polland). Males with total acidity above 20 units. Calculated from Fisher's* [21] *table of the normal distribution*

No. of cases ..	15	135	
Diagnosis	Cancer of stomach.	Peptic ulcer.	—
Mean	54·3	116·9	
Standard deviation	23·6	18·8	Probabilities.
	Relative frequency per cent.		Case B.
Internal.	c.	u	$\frac{c}{u+c}$
20–40	20·0	0·002	1·000*
40–60	32·2	0·2	0·99*
60–70	15·3	0·5	0·97*
70–80	11·5	1·7	0·87
70–100	11·1	16·0	0·41
100–110	1·7	17·4	0·09
110–120	0·6	21·0	0·03 *
120–140	0·4	32·6	0·01 *
140–160	0·02	9·5	0·002*

Accepting 70–110 as the doubtful range, it will be seen that only 1·0 per cent. of cancers are likely to lie above and only 0·7 per cent. of ulcers below these limits. Expressing these in relation to the cases which fall within the useful range 1·3 per cent. of cancers and 1·1 per cent. of ulcers will be incorrectly diagnosed.

* Probability falls within useful range.

It will be seen from the Table that this method indicates a further improvement in the separation of the two diseases. 24·3 per cent. of carcinomas and 35·1 per cent. of ulcers fall within the zone of overlapping, so that the diagnosis is helped in the remaining 75·7 per cent. of cancers and 64·9 per cent. of ulcers. Further, in only 1·3 per cent. of these cancer cases and 1·1 per cent. of ulcers will the diagnosis be incorrect. Since the range from 0–20 represents a virtual certainty‡ (68 per cent. of cancers and no ulcers), we have for the whole group 92·2 per cent. of cancers and 64·9 per cent. of ulcers, or 78·5 per cent. of the doubtful population in which useful indications are obtained.

Discussion

It will be seen that this method of inquiry has demonstrated a substantial advantage of the histamine test over the Ewald and fractional tests, which were found to be of equal utility. The results may be summarised thus:—

CASE A.—(i) Histamine gives useful indications in 14·9 per cent. of doubtful cases. Ewald and fractional test of no value. (ii) No test of any value.

CASE B.—Histamine useful in 78·5 per cent. of doubtful cases. Ewald in 22·7 per cent.; fractional in 21·5 per cent. (both of these confined to achlorhydria).

These conclusions are of course based only upon the height of acidity reached and do not take into account the value of examining the resting juice and of detecting blood in the specimens. On these two points the fractional test is superior to the Ewald. The only drawback to the histamine test is its failure to demonstrate gastric motility, which is probably of minor importance

These results are strongly in support of the claims of Bloomfield and Polland, whose arguments need not be recapitulated here in detail. It is becoming more and more obvious that in attempting to differentiate between two diseases associated respectively with a high and a low gastric secretion, the most serviceable test is that which gives most information about gastric secretion as such. The histamine test is the only one in which the actual volume of pure gastric juice secreted within a measured time under the influence of a standardised stimulus is made available for direct examination.

I am therefore inclined to accept the arguments in favour of the histamine test, and also Polland's remark to the effect that further modifications of technique are not likely to be of much value. The only suggestion one can make is that further tabulation of the volumes of acid secreted (=concentration of acid × volume of juice) should be undertaken as they appear to show a wider divergence in ulcer and cancer than either volumes or concentrations alone. It also appears unwise to take the greatest 10 minutes volume as the secretion index, for it is too liable to be affected by difficulty in emptying the stomach. In the course of work now in progress on normal students, Lander and I [19] have taken instead the volume secreted from 10–50 minutes, multiplied by

---

‡ According to Palmer and Heinz [22] no undoubted case of benign peptic ulcer associat [illegible] after histamine has been recorded. Dr. F. [illegible] state that he has seen such a case, pr [illegible] on. There is, however, no doubt as to [illegible] association.

1·5, to give a rate of secretion per hour. This should reduce the errors of volume estimation to one quarter.

Some opposite conclusions of Comfort and Osterberg[20] must be noted here. These workers made a direct comparison of the Ewald and histamine tests on 120 patients, and could find no advantage in the use of histamine. Their results with histamine were, however, strikingly different from those of Polland in several respects, noticeably in the greater overlapping of cancer and ulcer cases and in the difference between gastric and duodenal ulcers. Since Polland's series contains a much larger number of cases it would seem that we must accept it in preference pending further confirmation by others.

In conclusion, some obvious criticisms of the methods of calculation may be anticipated. It must be freely admitted that a number of assumptions have been made which are not strictly accurate, and that a number of relevant facts have been ignored owing to poverty of data. The inquiry may perhaps be considered to have served a useful purpose if only to expose the lack of existing knowledge on these points. The fact that the same assumptions were applied to each of the three tests still leaves some justification for drawing conclusions as to their relative value.

The principal flaws in the method lie in the following considerations :—

(1) Age and sex have been largely neglected. We now know, thanks to the work of Vanzant et al.[11] and of Bloomfield and Polland,[12] that gastric acidity decreases with age and is higher in the male sex. What are required, therefore, are detailed standards for each sex and for each decade, to include ulcer and cancer as well as normal persons. When these become available the accuracy of test-meal diagnosis will be materially increased. Polland's normal standards fulfil a long-felt want but he has not tabulated in detail the volumes of acid secreted. Since it is hardly likely that any one clinic will have sufficient material to establish satisfactory pathological standards, it is to be hoped that future publications will give full details of the age and sex of their patients so that their results may eventually be pooled.

(2) We have assumed the same distribution of acidity in doubtful carcinomas and ulcers as in carcinomas and ulcers in general. Further data are certainly necessary on this point. It has previously been supposed that the test-meal *failed* in just these cases, for malignant ulcers are frequently accompanied by the presence of free hydrochloric acid, and, as we have seen, the older test-meals cannot then give any additional information (unless of course characteristic signs are present in the resting juice). Bloomfield and Polland,[1] however, claimed to find a low output of acid in such cases by the histamine test, and certainly they have recorded many cases of carcinoma with free acid present but yet well outside their ulcer range. If this finding be confirmed the histamine test should prove of the greatest value in these cases.

The question of malignant degeneration in a simple ulcer is not so hopeful, and we can hardly hope at present that any assistance will be forthcoming in these cases, which are likely to show an acidity within the ulcer range.

(3) Only in one case has the attempt been made to allow for errors of random sampling, and this can only represent a first approximation owing to the inadequacy of the available data.

Conclusions

(1) A new method has been developed by means of which the efficacy of the test-meal in the differential diagnosis of ulcer and cancer of the stomach may be tested. This has been applied to typical data from the Ewald, fractional, and histamine tests with the results given below.

(2) The test-meal is of little value in cases of suspected ulcer.

(3) In the differential diagnosis of doubtful gastric lesions demonstrated by X rays, the test-meal may be of considerable value in a proportion of cases. This proportion is much the highest in the histamine test.

(4) The histamine test is superior to the other two. The Ewald and fractional tests are about equal except that the examination of the resting juice gives an advantage to the fractional test.

(5) The limitations and possibilities of this method of calculation are discussed, and the need for further data is emphasised.

It is a pleasure to express my thanks to Prof. E. C. Dodds for his advice and criticism.

TETANUS TREATED WITH CURARE

BY LESLIE COLE, M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE

CURARE is an arrow poison used by the natives of South America to paralyse their game. They prepare it in the form of a black resinous extract from the bark of plants of the genus strychnos, which they store in gourds, earthenware pots, or bamboo sticks. A number of plants may be used in preparing the extract, and the strength of the crude preparation varies considerably in different samples. Boehm[1] found that different preparations might contain different alkaloids, most of which have a paralysing action and are typified by curarine. Their action is similar to that of the crude drug. One of them, however, curine, is a weaker poison and has an entirely different effect, for it acts upon the heart.

The chief effect of curare is to paralyse voluntary movement by blocking the passage of impulses from the peripheral nerves to the muscles. The point of action is thought to be the end-plates of the motor nerves. The voluntary muscles are first paralysed and later the respiratory muscles, death taking place from asphyxia.

The idea of using curare to control the spasms of tetanus is not new, for it is mentioned in several older medical text-books. Hunter[2] used it in a few desperate cases, but apart from this, accounts of cases in which it has been used are difficult to find.

Hartridge and West[3] have used curare to control tetany in parathyroidectomised dogs. They found considerable variation in strength of different samples and that two specimens out of seven possessed the power of removing tetany in the dog without causing paralysis. West[4] used one of these two samples in the treatment of 17 cases of muscular rigidity, resulting from diseases of the pyramidal and extrapyramidal motor systems. In doses which caused no detectable weakness or loss of power there was considerable reduction of rigidity while under the influence of the drug. He suggests that some samples of curare may contain a second active principle which has a selective action in that it can abolish rigidity in certain rigid states without causing paralysis, and mentions the possibility of using curare in tetanus. These observations show that different samples of curare vary considerably both in strength and action, and the dose is therefore a question of difficulty.

The sample used in the case here described was given me by Dr. J. F. Gaskell[5] and was of the "gourd" variety. It was the most potent of ten samples whose paralysing power had been compared by injection into leeches. Doses up to 32 mg. had been given to a patient with pyramidal rigidity, and this observation formed the basis of dosage in these cases. Prof. Hartridge tested the potency of this sample for frogs and found that 0·005 mg. is the lethal dose for a frog weighing 26 g., and that it paralyses frogs from that amount to 0·0025 mg.

THE FIRST CASE

A labourer, aged 39, in the afternoon of Monday, Jan. 15th, while cutting reeds, cut the tip of the second finger of the left hand on a reed. The wound was a deep one. He treated it by soaking it daily in hot water. On Monday, Jan. 22nd, he found difficulty in opening his mouth, and his throat felt stiff on swallowing. On the 23rd the stiffness of the jaw and the difficulty with swallowing were much worse and he had spasms of pain in the neck and back. On the 24th all these symptoms were worse, and he was admitted to Addenbrooke's Hospital at 1 P.M.

State on admission.—Severe spasm of masseters. Risus sardonicus. Back arched and rigid, abdomen boardlike. No relaxation between spasms. Some stiffness of arms and legs but no local tetanus. Whitlow of tip of second finger of left hand, fluctuant and full of pus. Scar of wound on lateral aspect of finger. No œdema of hand or lymphangitis. No teeth present in upper jaw.

Treatment on admission.—200,000 units of antitoxin were given intravenously and 2000 subcutaneously on either side of the infected finger. Half an hour later the whitlow was incised and washed out with hydrogen peroxide. No further antitoxin was given.

Progress.—Spasms began shortly after admission and increased rapidly in severity. By the evening the patient was having severe spasms which were brought on by the slightest sound or movement, and these occurred every minute or so. Opisthotonos occurred during the spasms, the back was rigid and arched between spasms, and the abdomen boardlike.

The sedatives used during the course of the illness were avertin and paraldehyde given rectally and occasional small doses of morphia. 7·3 c.cm. of avertin (full dose for basal anæsthesia) was given every night for eight nights. From three to five drachms of paraldehyde were given rectally dissolved in normal saline every day for ten days. Food in the form of glucose lemonade, milk, and egg and milk were given hourly when the patient was awake. The fact there were no teeth in the upper jaw made feeding a good deal easier.

By Jan. 26th, however, the spasms were getting more frequent and severe, and the patient was showing signs of exhaustion. Treatment with curare was therefore begun. Four doses of 32 mg. were given subcutaneously at six-hourly intervals beginning at midday on the 26th. Within two hours of starting this treatment the spasms were less severe, the rigidity of the arms and abdomen was less, and the spasm of the masseters was less, so that feeding was made a good deal easier. The patient had less pain and was more comfortable. He complained of no abnormal sensations after injection and there was no evidence at any time of difficulty in breathing. The pulse-rate however continued to rise. Observations on the blood pressure and reflexes could not be made. This improvement continued for 48 hours, but on the 29th spasms and rigidity began to get worse again. He was therefore given three more injections of 32 mg. of curare at six-hourly intervals. Following this the same effects were observed and the same improvement occurred, but the pulse-rate still remained rapid. On Feb. 1st spasms and rigidity again began to get worse, and so one more injection of 32 mg. was given. Following this there was steady improvement and the spasms gradually became less and ceased on Feb. 6th. The rigidity of the abdomen and back and the opisthotonos gradually passed off and had disappeared by Feb. 17th. No abnormal symptoms were observed during convalescence, but the wasting and weakness of the forearms and legs were very marked. Before discharge on Feb. 28th the patient could walk about the ward and the central nervous system showed no abnormality. One month later he was perfectly well but for some weakness of the arms and legs.

THE SECOND CASE

The patient, a boy aged 7, on July 12th fell off his bicycle and grazed his left elbow, knees, and right heel on the road. The wounds were slight and superficial, except that on the heel which was rather deep. No treatment was given. On the morning of the 14th he seemed out of sorts and complained of stiffness of the jaw on trying to eat, and pain in the neck, shoulders, and left side of the chest. These symptoms grew steadily worse and he was admitted to hospital on the 15th.

State on admission.—Continuous rigidity of the abdomen and back with stiffness of the jaw and risus sardonicus. The stiffness was made worse by noise or manipulation, and occasional slight spasms with opisthotonos occurred. The wounds had scabbed over.

Treatment and progress.—100,000 units of antitoxin were given intravenously and the wounds were cleaned. Rigidity and spasms became more severe and frequent. At 10.30 P.M. the jaw was continuously clenched, the back arched and rigid, the abdomen boardlike, and the limbs stiff. Spasms of the most intense severity occurred every 30 seconds and were caused by the slightest sound or touch. The attempt to give water with a spoon brought on severe spasms, swallowing was impossible, and attempts to suck fluid through a tube had the same effect. Perspiration was profuse, temperature 104° F., and pulse-rate 140–50.

At 11.30 P.M. 7·5 mg. of curare were given subcutaneously. Five minutes later the spasms were less severe, the reflex excitability was less, and the limbs were less rigid. At 11.40 7·5 mg. were given; at 11.50 15 mg.; and at 12.10, 15 mg., with progressive improvement. After the last injection of curare the rigidity of the abdomen had disappeared between spasms, the limbs were relaxed, the mouth could be opened, and fluid could be sucked and swallowed without bringing on spasms. Reflex excitability had almost disappeared, and the arms and legs could be manipulated freely. Only occasional slight spasms occurred throughout the night. At 1 A.M. there was some respiratory difficulty, but this improved. The pulse, however, grew weaker and more rapid, and the temperature rose steadily to 108° F. at 5.30 A.M. The respiration then began to fail and the child died at 6.20 A.M.

DISCUSSION

These cases of tetanus are 2 of a series of 19 cases I have treated during the last six years. Of the 19 patients 11 recovered. All of them, including the two which received curare, were treated on the same general lines, each being given a large dose of antitoxin by the intravenous route as early as possible and before the wound had been touched. The first case treated with curare and described above was certainly the most severe of those which recovered.

In both cases here described, curare seemed to reduce the continuous rigidity of the limbs, abdomen, and jaw muscles, to lessen reflex excitability, and to lessen the frequency and duration of the spasms. In Case 2 the severe spasms, induced by attempting to suck fluid and even by the sight of fluid, were stopped and swallowing was made possible. In Case 1, in which the dose was relatively small, the action of the drug was first apparent about two hours after the first injection. The effects appeared to last about forty-eight hours. In Case 2 the effects first appeared five minutes after the injection.

It is possible that in Case 1 the action was sufficient to tide the patient over the critical period of the illness by preventing exhaustion and by allowing more food to be given. No unpleasant symptoms were observed while the drug was being given and respiration did not appear to be effected in any way. No serious after-effects were noted, though it is possible that the rather prolonged weakness and wasting of the muscles of the arms and legs may have been due to the curare.

The second case was of such rapid onset (incubation period 48 hours) and intense severity that there was no chance of recovery. Treatment might have been more effective in prolonging life if it had begun a few hours earlier. Given however when rigidity was continuous, and reflex spasms of the most intense severity were occurring every thirty seconds, curare checked the spasms, stopped the reflex excitability, and made the rigidity very much less. Respiratory failure only occurred seven hours later when the heart had begun to fail.

Observations on these two cases are encouraging and confirm the suggestion that curare or its alkaloids will be useful in the treatment of tetanus. Dosage however is at present a difficult problem, and will remain so until standardised preparations are available and more is known of the particular actions of its various alkaloids.

I am indebted to Dr. Gaskell for the curare used in these cases, and for allowing me to treat Case 2, and to Prof. Hartridge for testing the potency of this sample on frogs.

SPINAL MANIPULATION

WITH SPECIAL REFERENCE TO LUMBOSACRAL STRAIN AND BRACHIAL NEURITIS

By Thomas Marlin, M.D. Glasg., D.P.H., D.M.R.E.
MEDICAL OFFICER IN CHARGE OF THE MASSAGE, LIGHT, AND ELECTROTHERAPEUTIC DEPARTMENTS OF UNIVERSITY COLLEGE HOSPITAL

In a study of the methods commonly used for manipulating the spine, whether it be by the "osteopath's twist" or by the forcible movements under an anæsthetic as practised by orthopædic surgeons, one cannot help feeling that generally an unnecessary amount of force is used. This does not mean necessarily that the operator uses too much force to gain his end by his particular technique, or that no benefit accrues from such manipulation. But it seemed that it would be a great advantage if a method could be devised, which, while still effective in producing the movement, would be more pleasant to the patient and produce less reaction in the surrounding tissues. This is important, for a patient who has once been hurt naturally resists if the manipulation be attempted on a subsequent occasion. Hence we desire a movement which can be done with the minimum amount of force. Then certain parts of the spine are difficult to manipulate. Different workers, using different techniques, and many of them displaying much ingenuity, have managed to produce a movement at practically every intervertebral joint, but two regions for various reasons have always presented difficulties. These two regions are the lumbosacral junction and the first dorsal segment including the first rib. Accordingly it would be an advantage in devising any new method if such technique could embody a principle which would make it effective for those two regions.

Working in collaboration with H. Goehring of Pennsylvania I have developed a method which apparently meets the case. It is not unpleasant to the patient, does not cause much discomfort or reaction afterwards, and can be used effectively for the whole spine except the cervical region, where several other methods are in vogue. We early came to the conclusion that of all forms of forcible movements, traction or extension was the least disagreeable to the patient. In our own fingers, for example, we could produce a separation of the joint surfaces of the inter-phalangeal or metacarpo-phalangeal articulations by flexing those joints and then forcibly pushing them a little further into flexion. Such a proceeding caused considerable discomfort, whereas the same result could generally be attained by pulling on the digits, and this was not in the least degree painful.

Now most spinal manipulations rely for success on such movements as flexion or extension, rotation or twisting, or on thrusts of various kinds, and it occurred to us that, taking a lesson from what we had found in our fingers, we might try to exploit the principle of traction; but the difficulty was to be able to fix the spine at any given level.

For instance, with a patient on his back, if we took hold on of his head, one hand beneath the occiput and the other under his chin, and made traction, it was possible by giving little tugs on the head to produce movement at various levels of the cervical spine. With this procedure, however, we were not able to control the exact level at which movement took place.

A similar problem arose with respect to the rest of the spine. If the patient were on his back and we tugged on the feet, sometimes movement might take place at the ankle or the knee, very often it occurred at the sacro-iliac joints, and sometimes at the lumbars or lower dorsals. The site at which movement took place probably varied with the point of friction between the patient and the couch, and the height at which the feet and legs were held when the tug was administered, but certainly was not within the control of the operator.

Various methods and devices were tried with a view to fixing the spine at different levels while the pull was being administered. The body was put into different positions, the trunk held at varying angles to the horizontal, and straps applied in a number of ways, but nothing appeared to fulfil the purpose till the idea suggested itself that the end might be achieved if two operators took part in the manipulation. Each operator must be capable of doing either part of the manipulation, and each should know exactly what the other is expecting to do or feel. Once this absolute understanding has been established between them the method is simplicity itself.

A strong couch is required, suitably padded, and with detachable pillow, so that the patient can lie quite flat. It is essential to have the covering of the couch of some material other than leather, and for this purpose a corduroy cloth is recommended, so that the friction between the patient and the couch should be as great as possible. For a physician of average stature a convenient height for the couch will be about two feet, which is somewhat lower than couches are generally made, but it is easy to have the legs cut down to the required height.

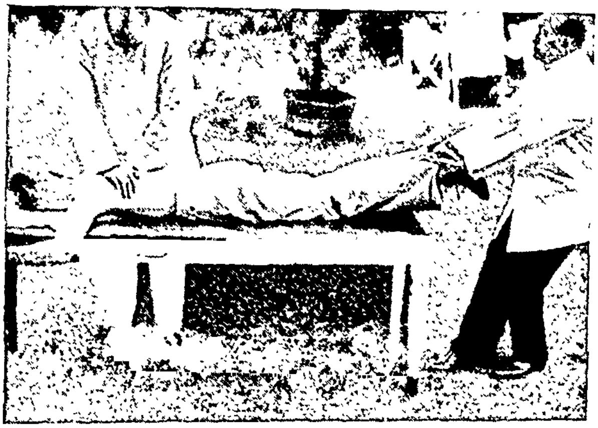

FIG. 1.—Manipulation of upper dorsal vertebræ.

The patient lies on his face, head turned to either side, and grasps the two top corners or legs of the couch, while the operator at the foot of the couch takes hold of the ankles. An assistant bends over the patient with his hands on either side of the spine, and exerts a considerable pressure vertically downwards on the patient's back at any desired level (Figs. 1 and 2). The first operator, raising the patient's feet, legs, and part of his body off the couch, gives a steady pull, and if necessary augments this with a tug. Success of this team manipulation depends on the coöperation between the two operators, and though one of them is designated the assistant, this is for purposes of description. The assistant may nod or use some prearranged signal to show that he is making his pressure. and the operator at the feet, who meanwhile has been awaiting the signal, pulls at exactly the correct instant. The assistant indicates whether the desired movement has taken place, then another attempt may be made if necessary, or a tug administered. If the assistant's pressure is made at the level of the fifth dorsal vertebra (Fig. 1), then the spine from that vertebra upwards will be fixed, so that the movement will tend to be at the articulations between the fifth and sixth dorsals. By suitably altering his hands the movement can be directed to the lumbosacral (Fig. 2), or any other level as the assistant wishes.

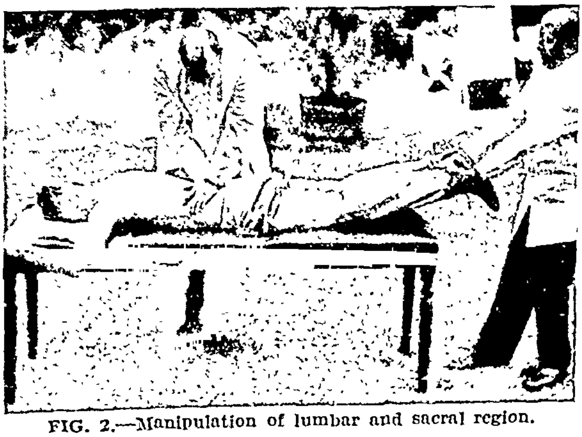

FIG. 2.—Manipulation of lumbar and sacral region.

Certain points should be noted. In this method of manipulation no loud snap takes place. There may be a soft noise, not easily heard, so the operator pulling on the ankles is generally not aware whether he has produced movement. The movement, in fact, is only slight, and only detected when the assistant is carefully watching for it. He must keep a very steady pressure and not allow his hands to slip over the patient's skin while his fellow worker makes the pull; hence it is practically impossible to carry out this treatment over a silk garment, for this slips readily under the fingers.

Another point is that in most cases only slight traction on the ankles is sufficient. The movement seems to take place almost before we are ready to appreciate it. If that is so without having the patient anæsthetised, then is it not possible that many people suffer injury to their spines as they lie stretched out completely relaxed under deep anæsthesia on the operating table, and even if they get over that ordeal, are they always treated with due respect as they are hoisted from table to trolley and from trolley to bed by people who do not realise the delicate task they are performing?

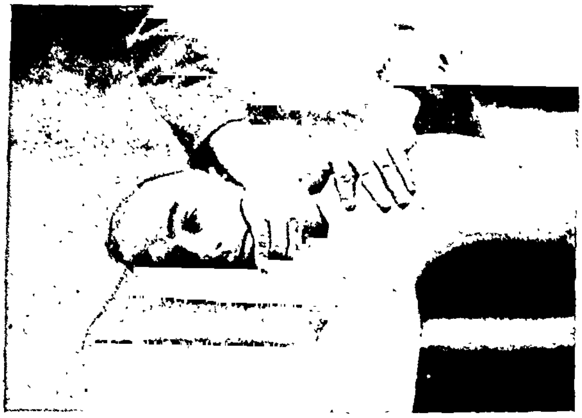

FIG. 3.—Manipulation of the left first rib, showing position of the operator's hands.

BRACHIAL NEURITIS

When we come to consider brachial neuritis certain points stand out. Along with the weariness and aching in the arm complained of by the patient, we may detect tenderness on pressure alongside the vertebral border of the scapula and in the prescapular tissues. There is often pain on pressure at the insertion of the levator anguli scapulæ, perhaps spasm in the muscle itself, and not infrequently pain in the side of the neck corresponding to the insertion of this muscle. These are accompanied by limitation of movement of the scapula or of the cervical vertebræ, and various methods are adopted for freeing up these structures. But the important thing which may be overlooked is the part played by the first rib. It is not uncommon when palpating in the supraclavicular region to find the first rib sensitive and slightly more prominent than its fellow, as if pulled up on the affected side. Perhaps such a condition could be initiated by such an act as sneezing, when, owing to the peculiar attachment of the scaleni muscles, the first rib might be drawn up and cause interference with part of the brachial plexus. Accordingly, treatment should be directed to freeing-up the first rib, and this, as was pointed out, has always been one of the difficult problems.

A single operator, trying to manipulate, say, the first left rib, might proceed in the following manner. The patient lies on his face, no pillow, head turned to the left, and arms hanging down over the edge of the couch. The operator, standing on the right side, places the heel of his left hand against the angle of the rib under consideration, then with his right hand he grasps the patient's chin and rotates it as far as possible to the left and holds it in that position (Fig. 3). With his left hand he now delivers a downward thrust —i.e., in a postero-anterior direction—against the angle of the rib, and this sometimes gives the desired movement. Now this thrust is not at all pleasant to the patient, and in rough hands a great deal of pain may be inflicted without producing any beneficial result. The team technique, however, overcomes all this discomfort. The operator, taking his hold as above, draws the chin to the limit of rotation, and makes a steady pressure over the first rib, but avoids making any thrust. Then the assistant, also standing on the right side, grasps the patient round the thighs, and raises the legs, pelvis, and trunk off the table, at the same time making traction on the thighs. When the trunk is raised to a particular height a distinct movement of the rib will probably be felt, without any discomfort to the patient.

When this has been done strapping should be applied for a few days to take the weight of the arm off the shoulder. Naturally, other factors such as septic foci or dietetic errors would be sought for and corrected, but the intention of this article has been to draw attention to, and describe, a part of the treatment which is not generally understood—namely, the production of those movements which have been mentioned.

REGIONAL DISSOCIATIONS IN BLOOD PRESSURE

(CIRCULATORY ANISERGY)

By Maurice Villaret
PHYSICIAN TO THE HÔPITAL NECKER; PROFESSOR IN THE PARIS FACULTY OF MEDICINE
L. Justin-Besançon
PHYSICIAN OF THE PARIS HOSPITALS; AND
René Cachera
INTERN OF THE PARIS HOSPITALS

In cardiovascular physiology the centre of interest has shifted; for it is now understood that the importance of the peripheral circulation has been underestimated.[1] Using the term in its widest sense, the peripheral circulation includes not only the superficial vascular supply of the extremities, but also the vascular supply of the deep viscera. Functionally, but not topographically, therefore, it is separate not only from the heart but also from vessels directly depending upon it, such as the large arterial trunks in the limbs.

Until recent years the attention of clinicians and physiologists seems to have been directed almost solely to cardiac function and circulatory conditions in the larger arteries. This outlook is unduly centralised; it tends to reduce to a simple problem in hydraulics all the conditions, admittedly very complex, which govern the distribution of the blood throughout the organism. Some writers have even attempted to express the laws governing circulatory equilibrium in a few mathematical formulæ. The heart was regarded as the only motor organ, and the arteries were regarded as simple, elastic, inert tubes. These structures were thought to be the only ones worthy of study, and agencies concerned in propelling the blood were considered negligible. The idea of vis a tergo was so simple an explanation of the facts that it was naturally regarded as final. It left conditions in the capillaries and entire venous system comfortably obscure, but this part of the circulation constituted only a degraded reflection of the central energy derived from the cardiac pump and merited no special attention.

Interest thus became wholly concentrated upon precise laws conforming to mechanical principles supposedly controlling the circulation within the principal arteries; and the success of this conception gave it sanction, since in practice the measurement of arterial pressure was alone considered fundamental. It was soon apparent, however, that the circulation could not be satisfactorily reduced to a problem in hydraulics. It was found, for instance, that the capillaries have an active rôle, together constituting a true peripheral heart; that there are peripheral autonomous vasomotor centres; and (most important) that reflexogenic vascular regions provide for the automatic regulation of arterial pressure which operates independently of the heart in very large degree.

The attention of clinicians was simultaneously directed to the desirability of measuring venous pressure and its pathological variations and to the part played by the peripheral circulation in phenomena of shock. Lately the importance of modifications in the equilibrium of the return circulation has been stressed anew, hypotonus existing in syncope and hypertonus in acute pulmonary œdema.

From the group of facts from which these few examples are drawn it is clear that classical views on circulatory equilibrium need revision. The decentralising of the cardiovascular system was considered by one of us in a recent paper,[2] in which experimental findings were presented and the following comment was made:—

> We believe it instructive to group together the facts which we are about to present, because they all support the same idea—namely, the existence of relative autonomy of the several circulatory sectors and their mutual independence of each other, permitting simultaneous regional conditions to occur in which the blood pressure is very different, both in arterial territory and the venous system. This fact shows us not only the decentralisation which is necessary, but the necessity of accepting a regional division, local or visceral, of vascular action. These simultaneous differences or oppositions, this multiplicity of reactions and their unequal character, have been designated by us, for greater convenience, as "circulatory anisergy."

PHENOMENA OF ANISERGY

We may now rapidly review the more distinct phenomena of anisergy which we have been able to show objectively in graphs simultaneously recording, in dogs, the figures of arterial pressure in different regions; also by comparing variations in arterial pressure with concomitant variations in the calibre of a visceral artery (the retinal artery, viewed with the ophthalmoscope); and still further by comparing tracings showing arterial and venous pressures.

The first procedure consists in comparing variations in general arterial pressure, as recorded at the central end of an artery, with those occurring at the same time in recurrent arterial pressure. The so-called "recurrent" pressure is that obtained by the aid of a cannula introduced into the peripheral end of an artery. The cannula, connected with an ordinary kymograph, measures the blood pressure maintained in the peripheral part of the limb through the existing anastomoses. This local pressure evidently reflects most notably the peripheral vasomotor actions present, but it reflects other conditions as well, since it communicates by the anastomoses with the general pressure, upon which it consequently must depend in some degree. Curiously enough François-Franck, who used this technique, rejected it for this very reason, saying that "the peripheral segment of the artery presents pressural variations which are the same as those present in the general arterial pressure, on account of anastomoses, which render the peripheral system merely a diverticulum of the aortic system." It seems to us that this difficulty may be easily overcome and all sources of error avoided if the interpretation of variations in the recurrent arterial pressure be observed in relation with those in the general pressure. Under these conditions all modifications in recurrent pressure which are relatively greater than the simultaneous general arterial pressure, or which occur apart from variations in the general pressure, or, a fortiori, which are inversely related to variations in the general pressure, must evidently be due to local vasomotor action.

By this method we have observed considerable differences and dissociations in regional variations in arterial pressure. During constriction, as well as during dilatation, of the peripheral vessels produced by suitable pharmacodynamic agents, the recurrent pressure has risen or fallen in a degree not in proportion with concomitant fluctuations in the general pressure. For example, in one case the variation in the recurrent pressure was five times as great as that in the general pressure. Here we stress the thought that this is no ordinary phenomenon. It might, in fact, be objected that an agent stimulating peripheral vasomotor action should, logically, modify peripheral pressure first of all and principally, affecting the general pressure in a secondary and lesser degree, and that our tracings could merely show, in a distinct manner, a fact which might be predicted by common sense.

We have shown, however, that it is possible to vary the recurrent and the general pressures, in relation with each other, in widely differing ways according to the dose of the medicinal agent, the manner of introducing it, and consequently the addition of a cardiac to a vascular effect, and especially according to the intensity with which certain vascular sectors respond. Still further, one of our graphs showed a tracing in which the recurrent-pressure curve was opposite, point by point, to the general-pressure curve. Each ascent in one was contrasted by a perfectly symmetrical descent in the other.[3] In this connexion we said, "We do not think it possible to present a more striking example of circulatory anisergy than this one, showing two arterial pressures measured in two distinctly different regions and simultaneously affected by changes occurring inversely and symmetrically."

In the second procedure ophthalmoscopic examination of the retinal artery was associated with record of the general arterial pressure. We have thus been able to show that the state of dilatation of the retinal artery is relatively independent of the degree of the general arterial pressure, whether high or low. This fact was demonstrated by various methods utilising different medicinal agents, in different doses, and in different combinations. Collaborating with Mrs. Schiff-Wertheimer, we obtained the following findings:—

(*a*) In man the subcutaneous injection of 20 cg. of acetylcholine dilates the retinal artery, even in the absence of any decline in the general arterial pressure.

(*b*) In dogs, inversely, different doses and the use of methyl-acetylcholine produced arterial hypotension persisting for a long time after cessation of dilatation in the retinal arterioles.

(*c*) Again, and as in our most striking example of peripheral circulatory anisergy shown by contrary variation in two different pressures, dilatation of the retinal artery, actively produced in the presence of well-developed arterial hypertension, constitutes a most striking splanchnic circulatory paradox. We obtained it by simultaneously or successively injecting adrenaline and acetylcholine into dogs.

These different examples justify the conclusion that arterial hypotension or hypertension and dilatation of the retinal artery are two easily dissociable phenomena.

In a third series of studies we examined comparatively variations in venous, general arterial, and recurrent pressure under various influences. The variations in the three different pressures were recorded simultaneously, the test animal being the dog. Just as we observed distinct regional dissociation in changes in the arterial pressure, we were able here to show the extreme freedom existing in reciprocal variations in the venous and arterial pressures. Under certain conditions these pressures may be totally independent of each other, rise or fall in one being unaccompanied by any modification in the other.

Loeper, Lemaire, and Patel have previously reported similar facts.[4] They showed that during a period in which arterial pressure rises in the normal dog under the action of adrenaline or falls in dogs previously treated with yohimbine, the effect of adrenaline on venous pressure remains unchanged, consisting of venous hypertension, both after and before treatment with yohimbine. The phenomenon which we observed was an inverse one, but had similar significance from the viewpoint now concerning us.[5] In exploring the peripheral circulation we observed that adrenaline either raises venous pressure or leaves it unaffected, according to whether the vagi are intact or divided, while the general arterial and the recurrent pressures are considerably raised in all cases. The same result is produced by using atropine instead of vagal section.

Consequently the two examples selected show total absence of parallel action in variations, in no wise reciprocal, occurring in arterial and venous pressures.

True, the causation of the pressural variations is here more complex, the venous pressure being closely related to the cardiac output. Whatever the intimate mechanism of the phenomenon may be, however, and even if the peripheral vascular factors are not the only ones present, it is none the less suggestive to show objectively that the arterial and venous pressures are in fact mutually independent under certain conditions. This fact particularly emphasises the relative autonomy of the return circulation and the importance of examining it.

These data usefully supply precise facts and concrete examples supporting a new view of circulatory equilibrium. This newer conception tends to become ever more widely extended, but is too often considered only in a vague and general way. The applications of these theoretical ideas are very extensive in clinical practice. Before rapidly reviewing these applications and to avoid any exaggerated interpretation of the tendency just mentioned, we disclaim any suggestion that examination of the heart and of its functional condition and measurement of blood pressure are no longer of value. On the other hand, we do not think that these factors supply all the data which are important as to the condition of the cardiovascular apparatus, as hitherto considered. In fact, one of us combated this exclusive view long ago in calling attention to the clinical importance of measuring peripheral venous pressure. As present ideas trend, they only confirm the sound basis of this view, which is by no means new.

CLINICAL APPLICATIONS

A knowledge of the regional dissociations in blood pressure, both in the arterial and the venous systems, allows of many deductions of pathological and diagnostic value.

1. *Pathological inferences.*—There is no need to recall the many pathological conditions modifying, within a limited vascular territory, the local arterial condition by vasomotor action occurring in different directions, but localised within a limited region. In the peripheral domain, erythromelalgia and Raynaud's syndrome constitute the two most representative examples. Although more difficult to recognise, deep and visceral vascular spasm limited to restricted areas is becoming more generally known. Some of the grave disturbances present in ophthalmology and otology are assigned to localised vasoconstriction. A case of lead colic recently published by one of us [6] should probably be interpreted as an effect of localised hypertension not affecting general blood pressure.

In neurology the growing importance of spasm limited to the cerebral arteries in causing motor effects, of deficiency or of stimulation, is a familiar fact. Four cases recently reported to the Société médicale des Hôpitaux de Paris by de Gennes [7] and by Pagniez, Plichet, and Decourt [8] show decisively the rôle of localised vascular spasm in producing subpermanent epileptic attacks, and also show the possibility of abolishing the spasm by means of acetylcholine. Finally, are not anisergical conditions in the greater and lesser circulation causative of certain forms of pulmonary œdema or infarct, of certain forms of syncope and even of some of the cases of cardiac failure, as reported by Lian, Laubry, and Tzanck, Gallavardin and Dumas?

2. *Diagnostic inferences.*—From these experimental and clinical examples an important practical idea follows—namely, that one cannot depend upon measurement of the arterial pressure in a large artery of a limb to ascertain the general state of the circulation. We do not minimise the primary importance of this measurement, but suggest that large inferences from data so obtained may be inappropriate. Findings in one part of the body are not necessarily applicable to the whole of it, as is too often assumed. Such generalisation implies uniformity in the vascular system, whereas all the facts presented here show there is a great deal of regional variation in the circulation.

One might, of course, go so far as to say that the measurement of blood pressure is valid only for the arterial sector examined. This is by no means our opinion. We nevertheless call attention to the fact that the degree of pressure present in the brachial artery is valueless for indicating the pressure present in a visceral territory, or even in the arteries of the fingers. We have emphasised the complexity of the various factors concerned in circulatory equilibrium. These factors appear largely autonomous, each with respect to the others and with respect to the heart. If this be true, it is easily evident that the knowledge of a single one of the entire group of factors, such as the degree of pressure present in the larger arteries, is not sufficient to supply information about the entire circulatory system.

Such are the conclusions derived from the experimental studies just reviewed. These studies show the relative independence of function in the different elements of the circulatory system. They reveal this system as an infinitely complex whole, in which the various parts operate in different ways.

THE TREATMENT OF DEAFNESS

By D. F. Fraser-Harris, M.D. Glasg., D.Sc. Birm., B.Sc. Lond., F.R.S.E.

LATE PROFESSOR OF PHYSIOLOGY, DALHOUSIE UNIVERSITY

Strange as it may appear, there is no body of persons qualified to interpret an aurist's prescription for a deaf patient, and to supply the appropriate deaf-aid instrument, as there are opticians able to read an oculist's prescription and to provide the spectacles specified. Just as it requires a specialist —the oculist—to ascertain the precise nature and amount of departure from normality in vision, so it requires a skilled person to ascertain the precise kind and degree of deafness from which a deaf patient may be suffering. There are types and degrees of deafness just as there are types and degrees of departure from normal visual acuity.

The reason for this difference is that the science of optics has been developing for about the last two hundred and fifty years, while the great advances in the precision of electrical instruments for amplifying and transmitting sounds have all been made since the War. Especially is this true of the refinements that enable a specialist in acoustics to interpret an aurist's prescription, and so provide the deaf person with exactly that type of instrument which will compensate or correct his or her particular kind of deafness.

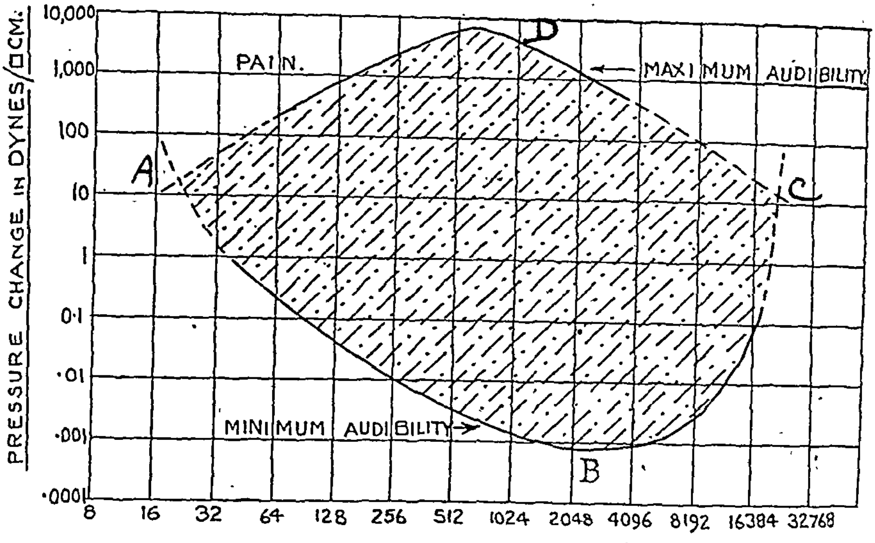
THE AUDIOMETER AND AUDITION CURVES (AUDIOGRAMS)

To understand the great advances recently made in the diagnosis and estimation of deafness we must refer to an instrument, the audiometer, by which the deaf person is tested. One of the first descriptions given in this country of the instrument was in The Lancet in 1925—"The Audiometer and its application to Medical Research" (C. M. R. Balbi: The Lancet, May 2nd, 1925). The audiometer is in essence an instrument to which one listens through an ear-piece to a series of musical notes which can be varied in frequency and intensity. In the form developed by Radio-Aid Limited it has frequencies of 125 to 4000 cycles per second in eleven and a half octaves. The intensity can be adjusted from zero to 20 units of the scale which is in absolute units of air-pressure—i.e., dynes per square centimetre.

The audiometer will undoubtedly be used universally for all hearing measurements. It is operated by merely turning a dial to select the desired note, and by turning another dial to modify the sound intensity. The patient holds the telephone-receiver close to his ear and signals when the sound being listened to is only just audible. This intensity can be recorded on a suitable chart, and it gives the threshold of audibility for the ear at this particular frequency.

From Fig. A we may learn several facts about normal hearing. In the first place we see that the range of normal audibility is through nearly 11 octaves. In the next place, it is evident that a note of frequency about 16 cycles per second is the lowest audible pitch, and that the intensity of the first audible note is of the order of ten dynes per square centimetre. Compare this with the note of about 2000 cycles frequency which can be heard when of an intensity so small as 0·0007 dynes per square centimetre. In other words, in normal hearing, the lower the pitch of the note below 2000 cycles the greater must be the intensity for the note to be heard.

FIG. A.—*Audition area for the normal ear*



Further, the curve A.B.C., which is the graphic expression of the threshold of *minimum audibility*, shows that notes of all pitches below the intensities marked on this curve are inaudible.

The upper limit of hearing, or *maximum audibility*, as expressed by the curve A.D.C. requires some explanation. This curve does not mean that notes of intensities greater than those on the curve are inaudible but that such notes have acquired a loudness which renders them disagreeable as music or unintelligible as speech.

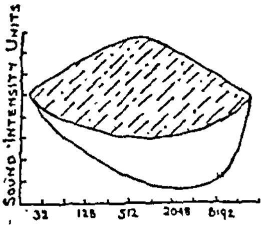
Notes of extreme intensity are believed to be the means of reflexly inducing the stapedius muscle to go into a state of spasm whereby the stapes is jammed in the fenestra ovalis and so prevented from vibrating in unison with the membrana tympani. This reflex action is regarded as a protective mechanism whereby injurious violence on the part of the stapes is prevented. The condition of spasm of the stapedius has been likened to pin-point contraction of the iris in an excessively bright light which is also a protective mechanism.

At all events, extremely loud notes are very disagreeable æsthetically so that the region beyond the curve A.D.C. has been called that of "auditory pain." It clearly corresponds to painfully bright lights which blind the eye and convey no intelligible visual information whatsoever.

EXAMINATION OF PATIENTS

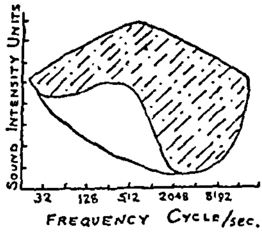
Suppose that we have tested a deaf patient, Mr. X, and obtained his audiometer chart (Fig. 1). It is evident that his deafness may be regarded as the *subtraction* of a certain intensity from the value of the notes as audible to a person with normal hearing. Mr. X's chart indicates some form of obstructive deafness, since it shows that his deafness is "uniform" or uninterrupted by any zones of hearing throughout the deaf area.

FIG. 1



Mr. X's audiometer chart.

FIG. 2



Mrs. Y's audiometer chart.

FIG. 3

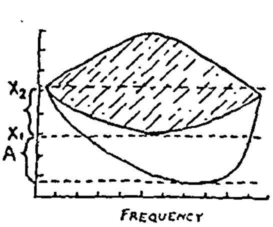


FIG. 4

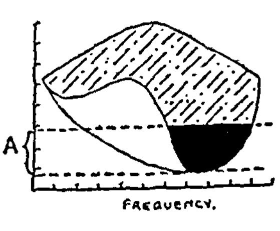

FIG. 5

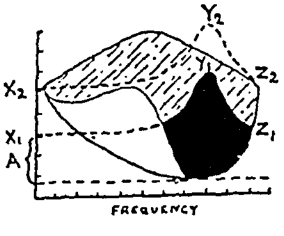

FIG. 6

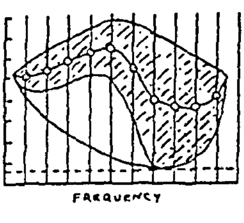

An inspection of Mr. X's audiogram will also indicate that a hearing aid whose *amplification* is uniform throughout the musical scale is the kind of device applicable to his case, for we shall thus be amplifying all the notes to which Mr. X is deaf. In other words, we shall have brought his abnormally high minimum threshold of audibility *down to the normal level* so that by the deaf-aid he is enabled to *hear a sound which, without amplification, would be inaudible to him.*

Thus, referring to Fig. 3, if we amplify the intensities of the sounds by a constant amount A, a sound of intensity X_1 (just otherwise inaudible) will now be heard as though it were of the sound intensity level of X_2.

In the next place let us consider a patient, Mrs. Y, whose audiometer chart is as in Fig. 2. An inspection of her chart shows that this patient is deaf chiefly to the lower notes of the scale, but has normal hearing for the higher notes. In other words, Mrs. Y has non-uniform or irregular deafness. This region-deafness has been called "aural astigmatism" (Balbi).

Now clearly it will not do to give Mrs. Y a deaf-aid which amplifies equally at all frequencies, because if this were done she would not even hear like a normal person in her region of deafness (the lower notes), the amplication A not being sufficient, but she would perceive sounds of high frequency (black area in Fig. 4), such as squeaks and scratches, with a distressing degree of distinctness. We may refer to the black areas in Figs. 4 and 5 as "super-sensitive" areas.

If non-uniform amplification were applied (as in Fig. 5) we might intensify the notes in this region to a loudness which was more distressing still, because even sounds of small intensity at this frequency would, on account of the peaked amplification applied, be brought up to a loudness which lies within the pain-area to which we have previously referred. Mrs. Y, in fact, needs *selective or differential amplification* in which sounds only in the region of the lower notes to which she is deaf are amplified leaving unamplified the upper frequencies where hearing is normal.

This kind of amplification suitable for aural astigmatism is provided by what is known as "filter circuits" and "automatic volume control." The principle of this is that the amplification provided shall be maintained so that the intensity shall always lie half-way between the thresholds of maximum and minimum audibility for the person concerned, as indicated in Fig. 6. These electrical corrections by "filter circuits" are now made by various arrangements of capacities, inductances, and resistances. It is a highly technical affair, but the problem of differential amplification has been elegantly solved.

The principles of prescription and of differential amplification were conceived some time ago by Mr. C. M. R. Balbi, who for a number of years was honorary consultant to the National Institute for the Deaf. Mr. Balbi wishes to put the treatment of deafness on a scientific basis, and at the same time prevent deaf persons falling into the hands of the quack as has unfortunately happened so often in the past. He has, moreover, demonstrated its utility by putting the invention on a practical footing, and is successfully operating it under a Limited Company called "Radio-Aid Ltd."

However, it is obvious that it is not for any one firm or individual to organise a controlling body, so this article has been written to make the suggestion that the time has come for a concerted effort to be made to form in this country a body of "auricians" (shall we call them?) to correspond to the opticians. Opticians are registered after passing a qualifying examination; and analogously there should be a register of qualified auricians, who should organise themselves on the model of their brethren, the opticians, obtain their Charter of Incorporation, define the qualifications of membership, and in fact acquire for themselves that professional status to which they are now fully entitled.

Clinical and Laboratory Notes

AN INFLATABLE INTESTINAL BAG IN URETERO-COLOSTOMY*

By JOHN EVERIDGE, F.R.C.S. Eng.
SENIOR UROLOGIST AND LECTURER ON UROLOGY, KING'S COLLEGE HOSPITAL

THE operation designed by Stiles [1] and the modifications of Coffey have given results so satisfactory as to make others hesitate to offer further modifications or additions. Grey Turner [2] demonstrated the effectiveness of the original Stiles operation in a series of 17 cases. Coffey's [3] main principle of technique differs in the method of emplacement of the ureter; he prefers to embed its length of contact within the muscular layers.

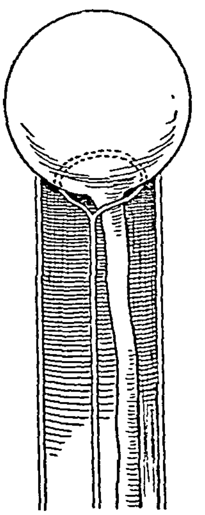

FIG. 1.—Shows bag projected beyond open end of sigmoidoscope.

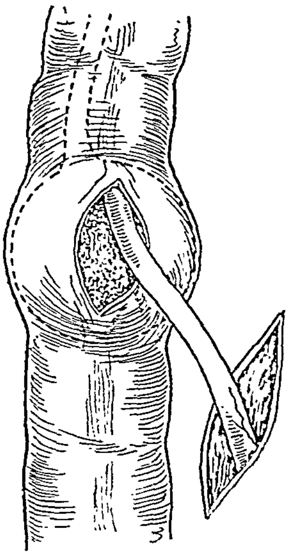

FIG. 2.—The bag in situ during Coffey No. 1 operation.

The technique now suggested has only been used in connexion with Coffey operations, and the primary reason for its introduction was to assist in that rather troublesome step, the formation of the musculo-submucous bed. Rugosity and vascularity of the bowel wall encountered as soon as the serous coat is penetrated render difficult a clean incision, since there is no firm surface to cut upon. In one of my cases I actually entered the bowel lumen before meaning to, oozing from minute vessels rendering recognition of individual layers difficult.

Material and technique.—Special material required: (1) A soft rubber bag equipped with a fairly thick-walled filling tube, at least 2 ft. in length. The bag when distended should be rather under 1½ in. in diameter. It may be stained with indigocarmine and is lubricated with liquid paraffin before introduction. (2) The introducer, an 18-in. length of rigid wire, at the distal end of which is a loop set at an angle. (3) A large graduated filling syringe—e.g., the Thomson-Walker bladder syringe.

Technique.—Having passed the sigmoidoscope to the pelvic colon, the filler tube is threaded through the loop of the introducer and the bag emptied of air. The end of the tube is clamped, and the bag is carried up beyond the open end of the sigmoidoscope and inflated with a known quantity of air. The sigmoidoscope and introducer are withdrawn, leaving the bag in situ. The proximal end of the tube and syringe are handed to an assistant to deflate or inflate, as may be necessary in the subsequent steps of the operation.

---

* A note on the subject has been read before the section of urology of the Royal Society of Medicine (Proc. Roy. Soc. Med., 1934, xxvii., 951).

At the laparotomy the bag is usually found in the ideal position for the anastomosis. If not, it can easily be manipulated up or down. The remaining general steps of the operation require no separate description. References to the publication of Stiles, Grey Turner, and Coffey give full details. The bag is, of course, deflated before the sutures burying the ureter in the bowel wall are tied.

The advantages claimed are the following:

(1) By providing a firm, flat, tense surface a clean incision is more easily made the depth of which may be controlled with precision.

(2) Stretching of the bowel by the bag inflated to the optimum renders the area of incision ischæmic; only the large vessels will bleed, thus the field is less obscured.

(3) The blue stained bag shows up well and thus it is easy to recognise the smallest penetration of the mucosa.

(4) The size and disposition of the stoma may be most accurately controlled, since fixed tissues are being handled.

(5) Distension of the bag renders the operative field, and especially the region of the stoma, less liable to contamination, since fæces (from imperfect preparation) are displaced, mucus in the bowel is kept away, and the mucous coat is squeezed and flattened out. A clamp on the bowel is thus unnecessary if this technique is adopted. Should the other ureter already have been implanted infecting urine is prevented from contaminating the field.

(6) If Coffey No. 1 be adopted the needle bearing the stitch on the ureter is easily insinuated between the bag and the mucous coat and brought back through the bowel at the chosen spot and tied.

(7) If Coffey No. 2 is used a ligature is tied to the end of the catheter and threaded to a curved cutting needle, which transfixes a small knuckle of the bag allowed to collapse for the purpose. The bag is now withdrawn by traction on its tube and so the catheter, bringing the ureter neatly into position for the usual sutures.

This technique of delivery of the catheter appears simple and easier than other methods in use in Coffey No. 2—i.e., by attachment to gauze packing in the bowel, or manipulation of the catheters through a sigmoidoscope or other rigid tube, as suggested by Nitch [4] and Green-Armytage,[5] which remain in situ during the operation.

(8) If both ureters are transplanted simultaneously one or two bags may be used, depending upon the mode of implantation.

ADMINISTRATION OF ANÆSTHETICS TO CHILDREN DURING SLEEP

By W. R. Somerset, M.B. Edin.
HONORARY ANÆSTHETIST, THE ROYAL HOSPITAL, WOLVERHAMPTON

In 1902 I wrote a short note [1] on the administration of chloroform to children during sleep. Since that time I have given anæsthetics to scores of sleeping children without any of them being aware of it, and I have found this method extremely useful for nervous children.

Every experienced practitioner knows that there are many children to whom the administration of a general anæsthetic is a very serious and difficult matter. Their horror of all things medical is so deep-rooted as almost to merit the term iatrophobia. They are terrified if taken to a hospital or nursing-home, and if they are given an anæsthetic the psychological effect may be so great that the results are life-long. Consequently only operations of the most pressing character are carried out, and those which are less urgent have to be postponed or even abandoned. There are also many minor operations which would be done if only there were some way out of the difficulty, and it is for such cases that the following method is especially useful.

The child is put to bed at its usual time and receives a dose of luminal gr. ½–1. At least two hours is then allowed to elapse before anything is done, so that the child may fall into a sound sleep. Three people are required, one to give the anæsthetic, one to hold the child's hands, and a third to turn on the light. For induction I always use ethyl chloride, which is sprayed liberally on an open mask outside the room. As soon as the door is opened an assistant grasps the child's hands and the mask is placed firmly on the face. There is always a struggle, but this is of short duration and the child soon goes under. As soon as the struggling ceases the light is turned on. After ethyl chloride I follow with C_1E_2 mixture or open ether, and the rest of the anæsthetic is uneventful. Next morning the child is not questioned, but I have never known one who stated that anything unusual had happened. Some have been surprised to find their head or a limb covered with bandages, or that some teeth had fallen out, but none have shown the slightest sign of alarm, or any suspicion that an anæsthetic had been given.

I have used this method for all kinds of conditions—e.g., extraction of teeth, dressing and sewing up wounds, setting fractures, and various minor operations—with the most satisfactory results. I have often found it to be a way out of a real difficulty, and I think it might with advantage be more widely used, especially in general practice.

NEW INVENTIONS

A NEW RUBBER PROCTOSCOPE

The necessity of applying diathermy through the sigmoidoscope, as well as the usual diagnostic and therapeutic value of this instrument, has suggested a short rubber proctoscope as convenient for different practical purposes, the ordinary sigmoidoscopes and proctoscopes in general use having certain disadvantages. The rubber proctoscope (here illustrated) is handy to use, simple in construction, and can be of great service for diagnosis and diathermy rectal work. The tube, which is six inches long, is made of vulcanised rubber. It has the advantage of being less rigid and cheaper than the ordinary metal one. It can be sterilised in formalin solution as a rubber catheter. If it is boiled it softens but regains its rigidity in a few minutes. As in other proctoscopes it has the further advantage of bringing the mucous membrane nearer to the eye. The knee-chest position

---

[1] THE LANCET, 1902, i., 992.

is the one of choice for introducing the proctoscope. The buttocks should be raised high to a level with the examiner's face, the shoulder low and the back well hollowed. This position helps the passage of the instrument, no inflation being required. It has also the advantage of not allowing any fluid coming from the intestine to dribble out through the instrument. Any electrical light device can be used with the instrument. The internal illumination as used in Dr. A. F. Hurst's short proctoscope, and supplied by Messrs. Down Bros., London, is very convenient for this purpose. Also the simple head mirror used by the throat specialists, or a head lamp, can be employed. In addition, many of the diathermy apparatus, now on the market, are fitted with external illumination. The commonest site for dysenteric and ulcerative conditions of the large bowel, as well as carcinoma and polypi, is within reach of the proctoscope, which may thus be of service for diagnostic and therapeutic measures.

I wish to express my thanks to the dean of the faculty of medicine, Dr. Ali Ibrahim Pasha, as well as to Prof. H. B. Day, the director of our medical unit, Cairo, for their encouragement and help. The proctoscope is supplied by Messrs. Moring and Co., 2, Soliman Pacha-street, Cairo.

M. A. ARAFA, M.R.C.P. Lond.

Kasr-el-Ainy Hospital, Cairo.

REVIEWS AND NOTICES OF BOOKS

l'Epiphyse (glande pinéale)

By Dr. JEAN CALVET, Professeur agrégé à la Faculté de Médecine de Toulouse. Paris: J.-B. Baillière et fils. 1934. Pp. 148. Fr.45.

THE mysteries of the pineal gland, which have formed a subject for speculation from the dawn of science up to the present day, are still unsolved. But it seems clear from the facts which Dr. Calvet has lucidly marshalled in this monograph, that the pineal plays an intricate part in the endocrine balance of the body, being particularly concerned with the rate of growth and sexual development. The author has been led, through his own histological and experimental observations, to suppose that the pineal body is a glandular organ and that it belongs to the endocrine system. In assembling the data which lead him to this conclusion he is at all times scrupulous in paying regard to the conflicting observations of other workers. After summarising in a series of short chapters the historical, embryological, anatomical, histological, and physiological aspects of his subject, Dr. Calvet outlines the clinical disturbances that are correlated with pineal tumours. The best known of these is the so-called Pellizzi syndrome, or precocious macrogenitosomia which occurs in childhood and is characterised by exaggerated growth, premature development of the sex glands and secondary sex characters and, inconstantly, by psychical disturbances. This syndrome is regarded by many authors as a result of pineal destruction with the consequent removal of pineal control. On the other hand, a similar kind of disturbance has been reported in cases in which the region of the mid-brain or the interpeduncular space has been occupied by a tumour and the pineal has been intact. The syndrome has not been observed when a pineal tumour is manifested in adult life. It is readily distinguished from the precocious sexual development that is associated with suprarenal tumours by the concomitant neurological signs and symptoms, and by the presence, in the suprarenal type of disturbance, of normal stature and an abdominal tumour.

A full bibliography enhances the value of this monograph.

Gonococcal Infection

By ROBERT V. STORER, M.R.C.S. London: John Bale, Sons and Danielsson, Ltd. 1934. Pp. 91. 7s. 6d.

IN writing about gonorrhœa Dr. Storer pays special attention to bacteriological diagnosis. His work is therefore more suited to the practitioner who makes his own films and his own diagnosis as to the presence or absence of the gonococcus, than for the medical man who is too busy to carry out his own bacteriology or else does not feel equipped for the task. In his preface the author states that his monograph "is intended to explain the principles which should guide the general practitioner in his management of those cases of gonococcal infection which come under his care." We doubt whether he has fully achieved this purpose. It is with the complications of gonorrhœa and with its symptoms that the general practitioner is chiefly concerned, and to these Dr. Storer gives little attention.

His book is clearly written; it is both interesting and suggestive.

Manipulative Treatment for the Medical Practitioner

By T. MARLIN, M.D., Ch.B., D.P.H., R.C.P.S. Eng., D.M.R.E., Medical Officer in Charge of the Massage, Electrotherapeutic and Light Departments, University College Hospital, London. London: Edward Arnold and Co. 1934. Pp. 133. 10s. 6d.

IN this small book Dr. Marlin sets out the technique which he has adopted successfully in various forms of manipulation, hoping that the descriptions, which are clear, terse, and accompanied by informative photographic reproductions, will lead readers to try out the movements recommended. Useful notes as to the apparatus necessary are given, and wise hints on the attire to be adopted not only by the patient but by the operator. The book closes with two interesting chapters, one setting out the reasons which should lie behind the choice of cases for manipulative treatment and the other pointing out that in spinal manipulation team technique or assisted technique may be of great value. Dr. Marlin in another place in this issue of THE LANCET (see p. 477) expounds this subject, using illustrations from his book.

The Healthy Infant

By E. R. C. WALKER, B.A. Camb., M.B., F.R.C.P. Edin., Clinical Assistant, Royal Aberdeen Hospital for Sick Children. With foreword by Prof. CHARLES MCNEIL. Edinburgh: W. Green and Son, Ltd. 1934. Pp. 137. 3s. 6d.

WHETHER it is that the modern parent prefers reading about healthy children to bringing them up, or whether it is simply that smaller families make the former diversion possible, it is certainly the case that the annual output of books concerned with the normal infant has increased enormously of recent years. Dr. Walker's little book is an admirable example of a non-technical presentation of his subject by a doctor for laymen, or more particularly laywomen. It is written clearly and pleasantly, and if much of it appears to be the emphasis of commonsense principles, it will be agreed that it is exactly the neglect of these that provides the pædiatrician with the bulk of his work. The illustrations are well chosen and reproduced. We see the hero of this saga in his bath, breaking wind, imbibing his meals comfortably and uncomfortably, and in a number of other situations dear to biographers. We do not know how Dr. Walker would face the acid test that should be applied to all professing pædiatricians—namely, the question "How many children have you got yourself?" but on internal evidence there is nothing to suggest a lack of sympathy with the difficulties of the harassed parent.

An Epitome of Obstetrical Diagnosis and Treatment in General Practice

By BETHEL SOLOMONS, M.D., F.R.C.P.I., F.C.O.G., Master, Rotunda. London: John Bale, Sons and Danielsson, Ltd. Pp. 138. 2*s.* 6*d.*

THE relatively small amount of information which this book contains severely limits its value. Dr. Bethel Solomons' use in some places of numbered lists and in others of a rather bleak narrative is rather disturbing. His short sentences are sometimes a little obscure in meaning; he would have done well to abandon them entirely in favour of tabulated information. Moreover, valuable space is occasionally wasted by the repetition of information already given in "summing up" paragraphs which are hardly required in a book which is itself a summary.

Except in one or two places the treatment recommended is in accord with that usually practised in London. We think Dr. Solomons' advocacy of non-control of the fundus in the third stage of labour is unsound, and we are sorry to see the term sapræmia appear in the section on puerperal sepsis. On some important subjects very little help is given—notably, in the chapter on general diseases in pregnancy. The section on obstetric operations is good.

Anatomy of the Rhesus Monkey

By Nineteen Authors. Edited by CARL G. HARTMAN, Department of Embryology, Carnegie Institute of Washington; and WILLIAM L. STRAUS, Jr., Department of Anatomy, Johns Hopkins University, Baltimore. London: Baillière, Tindall and Cox. Pp. 383. 27*s.*

THE macaque monkey has been fated to be the victim of research in an increasing degree in the last few years, and to a less extent has been a subject for dissection in comparative anatomy rooms. Nevertheless, so far as we know, this is the first effort to provide a comprehensive "anatomy" of the animal for the benefit of these workers. The book consists of 18 chapters, each by a different author, and covers not only the zoological status of the monkey but all the various systems which make up his body, to which Prof. Carl G. Hartman adds a chapter on housing and care. Every chapter is well and clearly written, with excellent illustrations; we hope these will be increased in number in a future edition. This is, of course, a book for specialists, but everyone working with these monkeys will find useful information therein.

Quarterly Journal of Medicine

THE July issue (Vol. III., No. 11) contains the following papers: (1) Calcinosis, by W. D. W. Brooks (London). The results of investigation of a case of this rare disease, in which calcareous deposits occur in subcutaneous and other tissues chiefly of the limbs. It appears to have a close connexion with scleroderma, and metabolic studies on a patient with this condition are also reported. A marked tendency to calcium and phosphorus retention was revealed in the case of calcinosis, but not in that of scleroderma; and histological study of a calcareous nodule from the former suggested that the calcium was deposited in degenerate fibrous tissue.—(2) A Statistical Analysis of 389 Fractional Test-meals, with special reference to Duodenal Regurgitation, by N. F. Maclagan (London). The results are opposed to the views that duodenal regurgitation is responsible for the fall in acidity in the later stages of the test-meal, and that pyloric irritation is responsible for the climbing type of curve.—(3) The Hæmopoietic Activity of the Normal and Abnormal Human Liver, with special reference to Pernicious Anæmia, by J. F. Wilkinson and L. Klein (Manchester). Liver extracts were made from (*a*) normal human livers; (*b*) from the livers of patients with pernicious anæmia undergoing active remission and dying of other diseases; from the liver of (*c*) one partially treated case and (*d*) one untreated case of pernicious anæmia; an extract was also made from the liver of a case of polycythæmia rubra, and a control extract of calf liver. Tested on patients with pernicious anæmia, the extracts in groups (*a*) and (*b*) were found to be hæmopoietically active; that in (*c*) was partially active; and that in (*d*) inactive. The extract from the liver of the polycythæmia case was unusually potent.—(4) The Alleged Pituitary Origin of the Eclamptic and Pre-eclamptic Toxæmias of Pregnancy, by F. B. Byrom and C. Wilson (London) (see p. 490).—(5) The Respiratory Exchange during Exercise in Heart Disease, by Maurice Campbell (London). The pulmonary ventilation on 16 cases of heart disease was found to be rather greater at rest, during, and after exercise than in normal subjects; also in the patients the respiration-rate was faster, and the effective alveolar ventilation formed a smaller percentage of the total ventilation. Elimination of CO_2 was less, and in spite of shallow breathing a much greater proportion of the vital capacity was called upon in the patients. This last appeared important in the production of dyspnœa.—(6) The Effects of Bodily Rest, Muscular Activity, and Induced Pyrexia on the Ventricular Rate in Complete Heart-block, by A. R. Gilchrist (Edinburgh). Investigation of a series of cases of complete heart-block showed that on exercise the ventricle was capable of substantial increase in rate in some, slight in others. A labile ventricular rate accompanied a stable auricular rate and vice versa. Pyrexia produced by protein shock also accelerated the ventricle.—(7) Massive Atelectatic Bronchiectasis, by W. P. Warner (Toronto). Five cases of bronchiectasis involving a whole lung are reported; all were due to atelectasis of the lung, congenital in 1 case, in 1 due to central bronchial obstruction, and in 3 due to the obstruction associated with infection. No fibrosis of lung parenchyma, nor pleural adhesions were present in these cases; the distinctive radiograms are reproduced.—(8) The Treatment of Muscular Dystrophy with Glycine, by D. P. Cuthbertson and T. K. Maclachlan (Glasgow). Experiments are recorded on 7 cases of muscular dystrophy and 2 of muscular atrophy to determine the effect of injected glycine. There was a temporary increase in urinary creatine in all cases, and at the same time the majority benefited generally and by improved power in the affected muscles.—(9) Prolonged Residence in High Oxygen Atmospheres, by D. W. Richards and A. L. Barach (New York) (reviewed in THE LANCET, August 18th, p. 371).—(10) Lung Abscess, with special reference to Causation and Treatment, by James Maxwell. Analysis of 315 post-mortem notes.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 1, 1934

RAIN AND STORAGE

LONDON is dependent for most of its water on two rivers, the Thames and the Lee, neither of them with very large watersheds. Nevertheless, the amount of rain that falls in any year on these watersheds would be amply sufficient to supply man, woman, and child with enough water all the year round if the rain were to fall evenly. Unfortunately, as we well know, this is not the case, and long periods of drought are not compensated by intervening periods of heavy rainfall, because the flood-water, after doing harm to low-lying crops and riverside dwellers, is allowed to reach the sea as quickly as can be arranged. The situation is described in a caustic remark from America quoted in the recent report[1] of the Metropolitan Water Board, "It soon will be four years since 'the drought of 1930' began—and it is still going strong: meantime every human effort is being put forth to shunt available rainfall off to the sea as rapidly as possible." The recent report of the Ministry of Health considers the dangers of flood in the tidal reaches of the Thames almost in the same breath as the drought higher up.

The necessity of pure water was of course not foreseen by the early settlers on the Thames estuary any more than it was in the case of the Hansa towns of North Germany which are for the most part equally badly situated for obtaining a sufficient supply. The Metropolitan Water Board is responsible for supplying a population of 7½ millions, more than equal, as HOUSTON used to say, to the combined populations of Australia and New Zealand. Each of these persons requires on the average a little more than 40 gallons of water a day, the average daily quantity of water distributed being about 293 million gallons—and still going up, for last year there was an increase of more than 28,000 in the number of premises supplied and 5 per cent. more water distributed than in the previous year. Normally of these 300 million gallons daily 200 are taken from the Thames and 50 from the Lee. The Thames should itself be sufficient for the purpose, for even last year more than 1300 million gallons of water a day passed Teddington weir; the Water Board is entitled if it wishes to take all of this except the comparatively trifling amount of 170 million gallons to keep the Pool of London flowing—and even this small obligation has been reduced to 50 million gallons in the present emergency. But the drought during the six months around last Christmas created a situation without parallel in recent times, for the rainfall was something like six inches below the average and actually only 79 million gallons passed Teddington weir on Sept. 4th and no water at all passed Feilde's weir on the Lee during two days of the same month, and only 2 millions on one December day. Obviously without some storage the position would be impossible, and it has been the policy of the Water Board since 1902 steadily to develop the storage capacity. At the appointed day in 1904 when the old water companies were amalgamated there were only the Staines reservoirs with a capacity of 3380 million gallons; Walton reservoir opened in 1907 gave another 1200 millions, King George's reservoir in 1913 more than 3000 millions, and finally in 1927 the Littleton reservoir, built two years earlier, was brought into general use, bringing up the effective storage to a total of 19,000 million gallons.

A striking illustration of the value of storage is to be found in the newly completed Sösetal dam in the Harz mountains, designed to provide a supply of drinking water for a number of important towns in the Province of Hanover, including Hildesheim and Bremen. The Harz being densely wooded and rising sharply to a height of 4000 feet out of the North German plain, induces the copious precipitation which results in devastating flooding of the river Leine, one of the large tributaries of the Weser. In January, 1932, 1500 million gallons of water fell in this small watershed within a period of 60 hours instead of so many days; 15,000 gallons per second were retained by the dam and only 700 were allowed to pass, with the result that this valley was the only one entirely unharmed by flooding. The yearly total of water entering the dam will vary in dry years (such as 1911 and 1921 were) from 6000 million gallons to 11,000 in wet years, averaging about 8000. The total content of the reservoir will be 5500 million gallons, making it possible to deliver 7000 millions in the year at a controlled rate of flow, approximately 220 gallons in the second. By keeping back flood-water and delivering a regular supply of water into the Leine, the needs of agriculture will be met all along the course of the river, while the use of the reservoir as a supply of drinking water will have no drawback, since the 2000 million gallons a year which will enter the supply pipes are no more than the flood-water which normally romps down to the sea, doing nothing but harm in its course.

These facts and figures from Hanover bring out the prime value of storage, if anyone had doubts on the point, but the advantages of storage are not exhausted by the equalisation of supply. Storage has its own virtue. It is, as HOUSTON again remarked, nature's own way of purifying water and the mere lag of water in storage reservoirs produces results of importance. The sedimentation of suspended solids carries down a large proportion of the bacteria present in the raw water; a reduction of 72 per cent. occurred last year in the Littleton reservoir. Excremental microbes are reduced by 92–97 per cent. by storage alone, and the bacteriological standard reached after filtration of the sedimented water is very high. On the other hand, storage may lead to the growth of algæ and related organisms, which clog the filter-beds, and these have not been kept entirely in check with copper sulphate. There is room here for further study of algicidal agents and indeed of the whole sequence of biological changes in river water before and after filtration. The minor problems of storage must be solved, for certain it is that only a large increase in storage capacity will prevent recurrence of the present anxious situation. If all the storage reservoirs of Thames and Lee were full there would be no more than 66·6 days' supply available. If there were a year's reserve the Water Board need not pass sleepless nights in the driest summer. The initial expense of installation would no doubt be great, but the running cost need not go up materially, and London would regain its position of premier city in the provision of healthy amenities. Moreover, every gallon of water stored in flood-time would benefit the riverside dwellers.

---

REGIONAL BLOOD PRESSURES

MORE and more interest is being taken in the peripheral circulation, not only in the limbs but also in the viscera. It is now recognised that there are peripheral vasomotor centres, which act apparently in independence of the heart and big vessels, and it has also become clear that the venous system plays an important part in the general circulation. In these circumstances dissatisfaction is often expressed with the present methods of measuring blood pressure, and it is realised that false conclusions may sometimes be drawn if readings from the brachial artery are taken as a guide to the state of the general cardiovascular system. It has been pointed out [1] that the pressure in the two arms may differ by as much as 10 mm. systolic and 5 mm. diastolic; E. J. STIEGLITZ and D. W. PROBST found differences of this kind in 15 per cent. of cases, and concluded, with justice, that no single reading from one arm could be considered satisfactory. Recently BRODIN and JOSEPH [2] have examined and compared the arterial tension in the legs and arms of elderly people, using a Pachon's manometer, and here again a good deal of variation has been found between the two sets of readings, the systolic pressure in the lower limbs being higher than in the upper. At the Mayo Clinic another significant inquiry on similar lines has been made by VOLDENG,[3] who has investigated the feasibility of ascertaining clinically the blood pressure in arteries of different sizes in the same subject. In normal persons of various ages mean pressures were estimated in the brachial artery, in a digital artery, in an arteriole, and in a capillary. In this normal group he found stability of the blood pressure gradient even when the effects of cold air and cold water, warm air and warm water were tested. On the other hand, when similar observations were made on ill people—including cases of essential hypertension, arterio-sclerosis, polycythæmia, and anæmia—much variation was noted. For example, in essential hypertension the resistance was found to be mainly in the arterioles; whereas in severe generalised arterio-sclerosis, although raised in the larger vessels, the pressure was actually below normal in the arterioles and capillaries. In polycythæmia the pressure in the minute vessels was found to be much reduced and it tended to return to normal as the condition of the blood improved under treatment.

It is clear again from all this work that estimates of the brachial pressure alone do not necessarily give adequate information about conditions elsewhere in the vascular tree. Prof. VILLARET, Dr. JUSTIN-BESANÇON, and Dr. CACHERA have pressed this conclusion even further, and have shown "the existence of relative autonomy of the several circulatory sectors and their mutual independence of each other, permitting simultaneous regional conditions to occur in which the blood pressure is very different." Their observations and deductions, as published in our present issue, are of no little importance in the way they bear on some of the problems of medicine, especially those associated with an arterial spasm and shock. And although they do not regard our present methods of estimating blood pressure as valueless, it is impossible to read their paper without realising that these methods leave much to be desired. The time can hardly be far distant when we shall look back on them as regrettably crude.

LESS NOISE

SINCE last Monday motorists in London have been forbidden, on penalty of forty shillings, to sound their horns after 11.30 P.M. within five miles of King Charles's statue at Charing Cross. This is the latest result of an agitation that has been going on now for some little time: in Queen ELIZABETH'S reign street noises, including horn-blowing, were forbidden in London at night on pain of imprisonment; a hundred years ago the inhabitants of a city church were complaining that the noise of stage coaches drowned the voice of the preacher. No one will readily believe, however, that the auditory sufferings of our forbears were anything to be compared with our own, and Dr. KINNIER WILSON reflects the general opinion when he says that noise "is noisier to-day than it used to be—much." [1] There is as yet no proof, he admits, that even so it is really producing neurosis; indeed it is clear that on the whole people suffer from noise because they are nervous—not suffer from nervousness because of the noise.[2] Nevertheless there are certainly such things as vicious circles, and there seem to be many weaker brethren to whom noise is an abounding source of irritation. Moreover, it has no countervailing advantage to justify its infliction on the sick and sensitive; and when the secretaries of hospitals are protesting right and left about the din outside their wards the time has undoubtedly come to deal with a genuine nuisance. Any sound made by somebody else is liable of course to be regarded as objectionable; but there are many which the majority will agree to condemn as excessive or inappropriate, and the Minister of Transport's experiment on nocturnal horn-blowing is pretty generally welcomed. If the results of similar steps in Paris and other continental cities are any guide the silent zone in London is likely to be a success and we may look forward to similar arrangements in other parts of the country.

[2] THE LANCET, 1932, i., 995.

A second step which the Ministry has taken is the formation of a traffic noise committee with very wide terms of reference. Its personnel includes Sir **Henry Fowler**, a past president of the Institute of Mechanical Engineers, who will be chairman, and Mr. G. W. C. **Kaye**, D.Sc., and Mr. H. F. **Gough**, F.R.S., of the National Physical Laboratory at Teddington, the resources of which are to be placed at the committee's disposal by the Government. In a broadcast address on August 23rd the Minister said his object in appointing the committee was to discover the means of manufacturing motor vehicles with as silent a mechanism as possible so that noisy machines would no longer be allowed on the road. Though there are few people who would object to the average motor-car of to-day on the score of noise, a strong indictment can be framed against the average motor cycle and what is termed the sports car. The committee will clearly find plenty of material to work on if it wants to earn the gratitude of those who live on the King's highways, and the new acoustical laboratories at Teddington seem to have been erected at just the right moment. The National Physical Laboratory has for some years given close attention to the problems of measuring and abating noise, and it appears that while a noise may have several disturbing features, the actual loudness may be measured by both subjective and objective means. This is of importance because the adoption of standards of noise may have to be envisaged by the committee. Its composition should enable representatives of science and industry jointly to tackle such problems as inefficient silencers, engine noise, excessively loud or offensive hooting, the "revving up" of cold engines, and unsuitable street paving.

The action of the Ministry of Transport reflects a growing public sensitiveness to noise—a sensitiveness which has found expression in the birth of the Anti-Noise League of which Lord **Horder** is president. The League is to interest itself in much beyond disturbing sound on the roads; it is not above considering banging doors, aeroplanes, or wireless loud-speakers. In all these directions there is much to be done. From the scientific standpoint, however, the most constructive work on noise and its effects has been in relation to industry, and particularly useful data may be found in two studies published by the Industrial Health Research Board.[3] One of these suggested that even after years in a noisy environment the worker does not become completely adapted or acclimatised to noise, but goes through the process of adaptation daily. The other, by Mr. K. G. **Pollock** and Prof. F. C. **Bartlett**, F.R.S., while concluding that the psychological and physiological effects due directly to loud noise have been greatly exaggerated, agreed that in general it is prejudicial to efficiency, and found that its harmfulness is roughly proportional to the difficulty of the work on hand.

BRITISH ASSOCIATION AT ABERDEEN

The 103rd meeting of the British Association for the Advancement of Science opens at Aberdeen on Wednesday next with a presidential address in the Capitol cinema by Sir **James Jeans**, entitled "The New World-picture of Modern Physics." An evening discourse in the MacRobert Hall on the following Monday on the Storage and Transport of Food, by Sir **Frank Smith** will take the form of a memorial lecture for Sir **William Hardy**, who was president of the Association at the date of his death in January last. The proposed evening symposium on the general relation between science and the community has dropped out of the programme, and there will be no set general discussion on this topic, but anyone who gives even a casual glance at the programme of the meeting must become aware of the extent to which the Association is becoming an effective mediator between science and the public. The sectional presidential addresses are particularly designed to this end, and as we have already announced some of them bear closely on matters related both to the student of medicine as well as to the student of life in general. Prof. H. E. **Roaf** on colour vision, Dr. **Shepherd Dawson** on psychology and social problems, Dr. E. S. **Russell** on the study of behaviour, are all good evidence of this. Those who would listen to experts discussing some of the more engrossing scientific problems of the moment may attend on Friday in the section of chemistry a discussion on ascorbic acid (vitamin C), or in the combined sections of physiology and agriculture a symposium on nutrition in relation to disease. On Monday those interested in water—and who is not?—must choose between a discussion on underground water-supply, in the section of geology, and a symposium on bacteriological problems of fresh water, in the combined sections of zoology and botany. Similarly, on Tuesday morning a choice must be made between a discussion on the chemistry of milk (chemistry and agriculture combined), one on the interpretation of animal behaviour (zoology and psychology combined), and a symposium on food preservation (physiology). Probably many of those who visit the meeting for social comradeship and quiet study will want to hear Sir **Henry Fowler**'s summary on Monday morning of the report of a committee on the reduction of noise, and even to take part in the afternoon excursion to the Bridge of Dee for a demonstration of successful reduction of the exhaust noise from the motor bicycle.

ANNOTATIONS

ECLAMPSIA AND THE PITUITARY

THE intermediate lobe of the pituitary gland secretes a hormone, or a mixture of hormones, known as vasopressin, which exerts two very characteristic pharmacological effects—namely, vasoconstriction and postponement of the excretion of water but not salt through the kidneys. The effect of lack of this hormone, or at least of its antidiuretic moiety, is seen clinically in the picture of diabetes insipidus. Yet the clinical counterpart of excessive secretion of vasopressin, which surely must occur, has never been defined. If a pharmacologist were invited to speculate on the probable nature of this imaginary syndrome, he might well predict a rise in blood pressure and a tendency towards an accumulation in the tissues of œdema-fluid which would be rather poor in salt. In extreme cases he might foresee a degree of vasoconstriction intense enough to cause focal ischæmic necrosis in various organs. Furthermore, knowing that pituitrin combined with a high water-intake can cause convulsions in normal animals and precipitate fits in epileptic subjects, he might also anticipate convulsions. In other words, he might postulate a syndrome which would tally fairly closely with the pre-eclamptic and eclamptic toxæmias of pregnancy. It is not surprising then that the idea that these toxæmias are due to overactivity of the pituitary —by no means a novel one—is attracting considerable attention at a time when new facts about that gland are coming to light almost every week, and if the hypothesis can be translated from speculation to demonstrated fact most of the mystery surrounding eclampsia will vanish.

Such direct evidence as has so far accumulated is not entirely convincing. Prof. Harvey Cushing's [1] recent observation that the posterior lobe of the pituitary is invaded by basophilic cells from the more anterior parts of the gland in eclampsia is suggestive, but unfortunately he found the same change in two normal control glands. Many attempts have also been made to isolate pressor substances from toxæmic blood, but the technical difficulties are great, the results obtained have been equivocal, and a pressor effect is by no means peculiar to pituitary extracts. On the other hand, the antidiuretic property of pituitrin is unique, for no other known pharmacological agent will suspend excretion of water while allowing free passage of salt through the kidney. For this reason the statement of K. J. Anselmino and F. Hoffman [2] that ultrafiltrates derived from toxæmic blood cause postponement of diuresis when injected into rabbits is of considerable importance. These workers claim to have demonstrated that toxæmic blood contains a principle identical with vasopressin, in concentrations ranging from 0·002 to 0·008 units of pituitrin per c.cm. and depending on the severity of the clinical manifestations. F. B. Byrom and C. Wilson [3] have recently attempted to confirm these conclusions, but without much success. Finding that they were unable to obtain consistent results with rabbits, they employed instead a method devised by J. H. Burn [4] for the quantitative assay of the antidiuretic principle, in which the rat is used as the experimental animal; and their first step was to justify this change in technique by demonstrating that the rat method was sensitive enough to reveal the presence of pituitrin in the minimum dilution mentioned above. They then performed 38 experiments with ultrafiltrates derived from blood in 13 cases of toxæmia, but found evidence of vasopressin in only four instances, as compared with five instances in a control series of 44 experiments in which normal ultrafiltrate or saline was used as the test solution. Byrom and Wilson conclude that if an excess of pituitrin is present in the blood in eclampsia its concentration is considerably lower than Anselmino and Hoffman suggest. This does not necessarily imply that the pituitary hypothesis of eclampsia is untenable, but it suggests that further evidence is urgently needed before the hypothesis can be accepted as proven.

APTITUDE TESTS FOR MEDICAL STUDENTS

FOR some years a Committee of the Association of American Medical Colleges has been experimenting with tests for picking out those applicants who have the ability to complete successfully the medical school course. The form of the test as at present used includes seven parts: (1) comprehension and retention; (2) visual memory; (3) memory for content; (4) logical reasoning; (5) scientific vocabulary; (6) ability to follow directions; and (7) understanding of printed material. During the past year it was applied to as many as 9000 students. A detailed study of the results of this work has been made, and was presented by the secretary to the committee, Dr. F. A. Moss, at the forty-fourth annual meeting of the Association held in Rochester and Minneapolis in 1933.[1] A considerable degree of correlation is shown between success in the aptitude test and success in the medical schools. For instance, in the school-year 1929–30 the test was given to some 5000 freshmen medical students. Of the 10 per cent. who made the highest scores in the test no man failed to graduate and their average medical school grade was 86·0 for the four years' course. Of the 10 per cent. who made the lowest scores in the test, 54 per cent. failed to graduate (40 per cent. failed in the first year), and their average grade for the four years was only 71·4. On the other hand, these tests resemble those developed by industrial psychologists for detecting the accident-prone, in that while they are successful in broadly separating the sheep from the goats they cannot be confidently relied upon to place every individual in the right category. The correlation between success in the test and success in the medical school is certainly not absolute, or anything approaching the absolute. The more serious discrepancies—students who score highly in the test and do poor medical school work, and students who fail at the tests but succeed in the schools—have been specially examined by Dr. Moss. By a questionnaire addressed to the deans of various medical schools he sought to discover whether personal factors were the responsible agents. The chief reasons advanced for the unexpected failures were ill-health, financial worries, too little study, or too many outside interests. Even the best aptitude tests must "gang aft agley" when the would-be physician is "a 'play boy' with many love affairs," or is unable to resist the "social distraction" of the athletic team; while "incompatibility with certain professors" was too much of a handicap to one. The unexpected successes, on the other hand (those who did badly in the test), were composed mostly of ard workers—the "plugger type" Dr. Moss calls hem—together with students of "particularly pleasng personality" or with "close relatives who are physicians." Perhaps in future the aptitude tests might award a few extra marks for these latter haracteristics leading to unlooked-for success! Thus, although the test may be of considerable use n eliminating undesirables, yet so long as some men who do badly in it do creditable work in the schools, it is difficult, as Dr. Myers of Indiana University points out, to "convince fathers and mothers, who are interested in having their sons accepted, that this test should be used in accepting or rejecting students." Dr. Moss rightly emphasises that such a test, even if much improvement in it is found possible, can be only one criterion in selecting medical students.

THE INCISION IN APPENDIX OPERATIONS

THE various ways of approaching the diseased appendix, and the various objections to them, are reviewed by E. H. Fiske and H. E. Rhame,[1] who point out that an ill-planned incision may cost the patient his life. The methods of exposure may conveniently be divided into (1) those in which the rectus sheath is opened by a vertical incision, with retraction of the muscle inwards or outwards as necessary, and (2) abdominal section, either oblique or transverse, lateral to the outer edge of the sheath. Fiske and Rhame condemn the rectus incisions: first because they permit of only an indirect approach to the appendix through uncontaminated tissues, and encourage excessive handling of the intestines; secondly because the drainage they allow must often be against gravity; and thirdly because they leave a scar at right angles to the line of skin cleavage, and cause injury to vessels and nerves, all of which increases the liability to post-operative hernia. With the lateral incisions, on the other hand, although many of these objections are obviated, the exposure tends to be incomplete. The incision they themselves have planned is one that allows of almost indefinite extension, either medially or laterally, depending on the findings at operation. It is slightly oblique, somewhat in the position of McBurney's, but the muscles are not split in the fashion of the gridiron. It starts from a point midway between the umbilicus and the symphysis pubis and at the outer third of the rectus, and passes obliquely outwards and upwards two fingers-breadth above the anterior superior spine—running parallel with, and one finger's breath above, the iliac crest. The external oblique aponeurosis is divided in the direction of its fibres, and the incision carried down through the internal oblique; the transversalis is split in its line of cleavage and retracted; the transversalis fascia and the peritoneum are then cut in the line of the previous incision. If necessary the incision can be carried as far laterally as the reflection of the peritoneum on to the ascending colon. Medially the fibres of the external oblique muscle can be divided by an extension of the incision in the aponeurosis, or the rectus sheath can be opened, allowing inward retraction of the rectus muscle. By vertical incision up or down the rectus sheath even wider exposure may be secured. Its authors claim that by using this incision they have lowered their operative mortality, and have also much decreased the incidence of hernia. It is unlikely, however, that surgeons in general will agree with all the premisses of the argument against the more usual methods of access. When the diagnosis of an inflamed retrocæcal or retrocolic appendix is assured, the incision must of course be made with a view to easy exposure of the outer side of the cæcum; but does not the lateral rectus incision of Battle ensure such an exposure? There do not seem to be any very good grounds for the great fear of hernia following its use, which is felt by Fiske and Rhame. The original gridiron opening did perhaps give an unduly small exposure, but as employed by many surgeons to-day it can be extended considerably at either extremity. The incision to the inner side of the rectus sheath is also popular still with many operators, although here it must be allowed they have to count on anæsthesia deep enough to render outward traction of the rectus muscle easy, and may have to make a fresh one for lateral drainage. Where special difficulties are anticipated in the operation, or where postero-lateral extension is likely to be helpful, the incision suggested by Fiske and Rhame is one to consider.

CARDIAC SYMPTOMS OF ANXIETY

IT has long been recognised that cardiovascular symptoms readily arise in the absence of organic heart disease. Such symptoms have been studied more particularly in war time, and have received the name of "irritable heart of soldiers" (Da Costa, 1871), disordered action of the heart, and effort syndrome. In the United States the term neurocirculatory asthenia is favoured because it is noncommittal, and the condition thus defined is distinguished on the one hand from organic heart disease, and on the other from psychoneuroses as such, in which anxiety, hypochondria, or hysteria predominate. Of true neurocirculatory asthenia, as thus circumscribed, the principal symptoms are palpitation, shortness of breath, precordial pain or discomfort, and exhaustion. The borderline between normal and abnormal is ill-defined, but "neurocirculatory asthenia may be said to be present when the symptoms appear during such customary physical activities and excitements of daily life as previously caused no symptoms or which in the average person produce no symptoms." This quotation is taken from a paper in which Dr. Henry C. Craig and Dr. Paul D. White analyse 100 cases,[1] and further particulars may be found in a study of the condition in its relation to organic heart disease, which Dr. White has written in collaboration with Dr. Joseph C. Edwards.[2] As in former papers he draws particular attention to the sighing respiration often complained of; indeed, "sighing respiration and precordial tenderness," he says, "are almost pathognomonic of neurocirculatory asthenia."[1] Dr. Doris Baker reported on this symptom in our columns not long ago,[3] and it has also been studied for some years by Dr. C. K. Maytum and Dr. F. A. Willius[4] at the Mayo Clinic. These last workers point out that the "sighing" may be so pronounced as to wake the patient from an apparently sound sleep—a possibility that should be kept in mind when considering nocturnal dyspnœa. They also describe attacks of panting respiration in which the rate of breathing may reach 100 a minute, and manifestations of tetany may develop through over-ventilation of the lungs.

These and other symptoms of "neurocirculatory asthenia" might strongly suggest the presence of true called in when members of such a family fall sick and if these get well the bills are sent in and duly paid. If they die as a rule the bills are not sent in. This accounts for the statement that doctors get paid while members of the family are well and not while they are sick; but the real fact is that the doctors are paid if the patients get well but not if they die." Thus it will be seen that there is substance for the popular statement of the position, while the method of remuneration is a variant of the insurance system. Dr. Wu Lien Teh closes an interesting letter with a reference to the steady publication from his bureau of the National Quarantine Service Reports, and registers his belief that medical work in China is progressive in spite of troubled political conditions.

WEST LONDON HOSPITAL: PROPOSED MEDICAL SCHOOL FOR WOMEN

As was briefly announced in the Students' Number of The Lancet last week a scheme for establishing a school of medicine for women at the West London Hospital is under consideration. For many years there has been a post-graduate medical college at the West London Hospital, but the approaching centralisation of post-graduate medical instruction at the new British Post-Graduate Medical School at Hammersmith has suggested to the medical staff of the West London Hospital that th[illegible] activities might be more usefully directed. It [illegible] ell known that the facilities for the instruction of w[illegible] students in clinical medicine and allied subjects a[illegible] sufficient for the present demand, and it seems [illegible] excellent idea for one more London hospital to give opportunities to women undergraduates. The proposal has not yet received the sanction of the board of the hospital, nor has any official approach yet been made to the University of London in whose province the activities of such a school would lie. The whole question is being given very careful consideration, but the announcement in the public press was premature, and no official statement has been made. The publicity given to the idea, however, should obtain both for the medical staff and lay authorities of the hospital practical arguments for the support of the scheme; and the more it is remembered that it is embryonic the more is it clear that suggestions will have a wide range within which to operate.

LEAD POISONING AND ITS RECOGNITION

Of late years there has been a revival of interest in lead as a poison. Not only have its clinical effects been reinvestigated but it has been suggested as a cause of various unexplained diseases—including, for example, nephritis in children [1] and eclampsia.[2] An understanding of the way in which the poison behaves depends on accurate means of discovering the metal and estimating its quantities in tissues and excreta. Prof. B. Behrens, of Berlin, has lately published [3] conclusions which he bases on a method of estimation devised by H. Fischer. None of the ordinary methods are, he holds, capable of giving trustworthy information about the very minute quantities of lead that one can expect to find in doubtful cases of chronic poisoning. In his experiment Behrens has used the radio-active form of the metal which enables him to estimate exactly quantities as small as 0·0001 mg. He is impressed by the [illegible] that very little is absorbed of any given dose administered by mouth; once taken up by the red blood-cells, however, lead is readily passed on to the tissues, and the bones especially form a depôt where it remains. Excretion, through intestine or kidney, is very slow, and the result is that years after absorption has ceased large deposits may remain in the bone and by suitable measures may be recovered from the fæces. In a paper on lead poisoning in children which appeared in our columns about a month ago, workers at the London Hospital [4] described a case in which the lead was found in the fæces after injection of parathyroid extract—a procedure whose use in this connexion we owe to Donald Hunter and J. C. Aub. Parathormone mobilises the lead in bone, just as it mobilises calcium, and thus increases the amount excreted, and it may be employed in this way, for diagnostic purposes, wherever there is a suspicion that stunted growth, renal rickets, or other abnormality is due to the action of lead. As was first demonstrated by Park [5] in 1930, characteristic appearances can also be recognised—at any rate in advanced cases—on radiographic examination. In illustrating their paper with radiograms showing these appearances, Dr. Jupe and his colleagues pointed out that very few cases of poisoning in children have been reported in England; and they must be right in thinking that others would be recognised if practitioners were more closely on the watch and could apply the proper methods of detection.

The British Pharmaceutical Codex, 1934, is to be published on Sept. 28th.

Sir George Newman has been appointed to serve for a further five years as a Crown nominee on the General Medical Council.

Dr. James Collier will deliver the Harveian Oration before the Royal College of Physicians of London on St. Luke's Day, Thursday, Oct. 18th, at 4 P.M., his subject being Inventions and the Outlook in Neurology.

Sir George Seaton Buchanan has been appointed Master of the Society of Apothecaries for 1934–35. Sir William Willcox and Dr. J. S. Fairbairn again serve as senior and junior wardens.

We regret to announce the death on August 24th, after a short illness, of Dr. Eric Danvers Macnamara, consulting physician for psychological medicine at Charing Cross Hospital, and a psychiatrist of great experience and insight.

The theatre has obviously been at some pains of late to become better acquainted with the medical profession—at work, at play, and at the bar of judgment. Those of the profession who wish in turn to learn something of the theatre (not of acting alone but also of stagecraft and playwriting) are invited to join the autumn courses which are being arranged at the Everyman Theatre, Hampstead, by the Little Theatre, Citizen House, Bath. Details of the enterprise will be found in our advertisement columns.

Traffic Accidents at Walsall.—It is officially stated that one reason for the heavy pressure upon Walsall General Hospital (which is being enlarged) is that the town stands highest but one on [illegible] street accidents [illegible] 0. [illegible] n towns with pop[illegible]

PROGNOSIS

A Series of Signed Articles contributed by invitation

XVI.—PROGNOSIS OF ACNE VULGARIS

ACNE VULGARIS is so well known as hardly to require definition, but perhaps one should say that it is a disease of adolescents and young adults of which the characteristic lesions are comedos, papules, and pustules, that it occurs commonly on the face, back, and chest, where it frequently leaves scars, and that the acne bacillus is found in the lesions with or without *accompanying staphylococci.*

DIFFERENTIAL DIAGNOSIS

Before discussing its prognosis it will be as well to make clear the limitations of the subject. The term acne vulgaris does *not* include acne rosacea, better termed simply rosacea, which is a disease of middle life nearly always associated with digestive disturbances and only secondarily affecting the sebaceous glands. Neither does it include acne necrotica (acne frontalis), which is probably a staphylococcal infection of the hair follicles of the forehead and scalp, and sometimes of the back; acne scrofulosorum, better termed papulo-necrotic tuberculide; nor acne agminata, which some hold to be the same as acne scrofulosorum. The grouped comedones of infants are typically acneiform in appearance but contain no acne bacilli, only spores of Malassez and staphylococci. This condition seems always to be brought on by external irritation or infection—e.g., by the application of camphorated oil or "Russian" tallow to the chest, or contact of the child's head with a dirty greasy cap, or the dirty greasy clothes of the mother. It does not come under the heading of acne vulgaris. Other conditions which are apt to be confused with acne vulgaris are bromide and iodide eruptions, which may very closely resemble pustular acne and occur on the same situations, but never produce comedos. Finally there are the acneiform lesions produced by chlorine, tar, and mineral oils, which may show comedos, but are found on areas not usually affected by acne vulgaris—e.g., the forearms, penis, and scrotum.

INCIDENCE AND TREATMENT

Some degree of acne vulgaris seems to be the common lot of young people between the ages of 12 and 20. According to Bruno Bloch (Brit. Jour. Derm. and Syph., 1931, xliii., 61) out of over 4000 boys and girls examined in Zurich only 0·6 per cent. of the boys of 18 and 3·4 per cent. of the girls of 17 were entirely free from comedos. Severe grades of the affliction were found in 57 per cent. of boys of 19 and in 22 per cent. of girls of 18. Bloch published curves showing a very high degree of correlation between the time of appearance of the signs of puberty and the development of the severer grades of acne. There is a strong hereditary element in acne, or rather in the greasy skin which predisposes to acne, and in some families scarcely any members escape.

It is common knowledge that the great majority of those who suffer from acne in their youth eventually cease to be troubled by it (generally between the ages of 20 and 30), and unfortunately many medical men in general practice who have other and more serious diseases to think about are inclined to pooh-pooh "a few spots," and to advise no treatment as the sufferer "will grow out of it." No doubt he will, but perhaps not before he is permanently scarred and has suffered damage that may have far-reaching effects on his or her future life. Not only so but many girls, and some boys, become morbidly self-conscious about their spotty appearance, which casts a shadow over their lives. On all grounds therefore it is most important that acne vulgaris should be treated, and treated as early as possible, preferably before it has become pustular.

It is impossible to discuss prognosis apart from treatment. Many popular methods of treatment appear to be completely inert and therefore without influence on the prognosis. Such are purgation by salts, the eating of yeast and its extracts or preparations of tin, dieting (except for avoidance of chocolate and, in a few cases, of cheese), and the injection of manganese and of vaccines, except in rare cases of pustular acne. I can remember two cases and two only in which vaccines really had a dramatic effect, one being a staphylococcus vaccine and the other an autogenous acne bacillus vaccine. When the patient who had the latter vaccine relapsed in due course the pathologist was never able to prepare another vaccine which had any effect on the disease. With regard to intestinal antiseptics I have hitherto been a sceptic, but having regard to Arthur Whitfield's strong views on this point (Brit. Jour. Derm. and Syph., 1934, xlvi., 257) it is necessary to preserve an open mind.

What, then, is the prognosis in the ordinary case of moderately severe acne in an adolescent patient? I have found that with the liberal use of soap and water (to which some patients have an astonishing aversion) and of sulphur applications, the avoidance of greasy creams, and the omission of chocolate from the diet, combined with the methodical expression of comedos and the careful use of small doses of X rays, almost all cases of ordinary acne, whether punctate or pustular, can be cured. The methodical expression of comedos should be carried out with the appropriate instrument and under reasonably aseptic conditions. It should *not* be done by the patient spending every spare minute in front of her looking-glass "squeezing spots" with her nails. Comedos should be expressed before they have given rise to pustules. Ultra-violet light treatment is also helpful but it has not the permanent effect of X rays.

Cures brought about in this way seem to be permanent provided that the patient keeps the rules, continues to apply a sulphur lotion a few times every week, and does not allow his or her head to become scurfy. The only cases of relapse which I have seen took place in patients who after remaining well for some months gave up the prophylactic use of the lotion, or allowed their heads to become scurfy, or were persuaded by advertisements to use cold cream on their faces instead of soap and water, or applied oil when sun-bathing. The latter practice I regard as pernicious in any patient with a tendency to acne, for I have seen several women of ages between 25 and 35 who, having long since grown out of their acne, had a relapse following the application of oil when sun-bathing.

The scarring which is the end-result of severe acne may be due to atrophy caused by the pressure of the comedo on its surroundings, and in such cases it often produces a "worm-eaten" appearance on the cheeks. The damage produced by pustular lesions takes the form of more or less round, depressed, white scars. On the back these may be so numerous that practically no normal skin is left.

There is a popular idea that X ray treatment causes or increases scarring. That this is not the case was called in when members of such a family fall sick and if these get well the bills are sent in and duly paid. If they die as a rule the bills are not sent in. This accounts for the statement that doctors get paid while members of the family are well and not while they are sick; but the real fact is that the doctors are paid if the patients get well but not if they die." Thus it will be seen that there is substance for the popular statement of the position, while the method of remuneration is a variant of the insurance system. Dr. Wu Lien Teh closes an interesting letter with a reference to the steady publication from his bureau of the National Quarantine Service Reports, and registers his belief that medical work in China is progressive in spite of troubled political conditions.

WEST LONDON HOSPITAL: PROPOSED MEDICAL SCHOOL FOR WOMEN

As was briefly announced in the Students' Number of THE LANCET last week a scheme for establishing a school of medicine for women at the West London Hospital is under consideration. For many years there has been a post-graduate medical college at the West London Hospital, but the approaching centralisation of post-graduate medical instruction at the new British Post-Graduate Medical School at Hammersmith has suggested to the medical staff of the West London Hospital that their activities might be more usefully directed. It is well known that the facilities for the instruction of women students in clinical medicine and allied subjects are insufficient for the present demand, and it seems the excellent idea for one more London hospital to give opportunities to women undergraduates. The proposal has not yet received the sanction of the board of the hospital, nor has any official approach yet been made to the University of London in whose province the activities of such a school would lie. The whole question is being given very careful consideration, but the announcement in the public press was premature, and no official statement has been made. The publicity given to the idea, however, should obtain both for the medical staff and lay authorities of the hospital practical arguments for the support of the scheme; and the more it is remembered that it is embryonic the more is it clear that suggestions will have a wide range within which to operate.

LEAD POISONING AND ITS RECOGNITION

OF late years there has been a revival of interest in lead as a poison. Not only have its clinical effects been reinvestigated but it has been suggested as a cause of various unexplained diseases—including, for example, nephritis in children [1] and eclampsia.[2] An understanding of the way in which the poison behaves depends on accurate means of discovering the metal and estimating its quantities in tissues and excreta. Prof. B. Behrens, of Berlin, has lately published [3] conclusions which he bases on a method of estimation devised by H. Fischer. None of the ordinary methods are, he holds, capable of giving trustworthy information about the very minute quantities of lead that one can expect to find in doubtful cases of chronic poisoning. In his experiment Behrens has used the radio-active form of the metal which enables him to estimate exactly quantities as small as 0·0001 mg. He is impressed by the fact that very little is absorbed of any given dose administered by mouth; once taken up by the red blood-cells, however, lead is readily passed on to the tissues, and the bones especially form a depôt where it remains. Neither does it include acne necrotica (acne frontalis), which is probably a staphylococcal infection of the hair follicles of the forehead and scalp, and sometimes of the back; acne scrofulosorum, better termed papulo-necrotic tuberculide; nor acne agminata, which some hold to be the same as acne scrofulosorum. The grouped comedones of infants are typically acneiform in appearance but contain no acne bacilli, only spores of Malassez and staphylococci. This condition seems always to be brought on by external irritation or infection—e.g., by the application of camphorated oil or "Russian" tallow to the chest, or contact of the child's head with a dirty greasy cap, or the dirty greasy clothes of the mother. It does not come under the heading of acne vulgaris. Other conditions which are apt to be confused with acne vulgaris are bromide and iodide eruptions, which may very closely resemble pustular acne and occur on the same situations, but never produce comedos. Finally there are the acneiform lesions produced by chlorine, tar, and mineral oils, which may show comedos, but are found on areas not usually affected by acne vulgaris—e.g., the forearms, penis, and scrotum.

INCIDENCE AND TREATMENT

Some degree of acne vulgaris seems to be the common lot of young people between the ages of 12 and 20. According to Bruno Bloch (Brit. Jour. Derm. and Syph., 1931, xliii., 61) out of over 4000 boys and girls examined in Zurich only 0·6 per cent. of the boys of 18 and 3·4 per cent. of the girls of 17 were entirely free from comedos. Severe grades of the affliction were found in 57 per cent. of boys of 19 and in 22 per cent. of girls of 18. Bloch published curves showing a very high degree of correlation between the time of appearance of the signs of puberty and the development of the severer grades of acne. There is a strong hereditary element in acne, or rather in the greasy skin which predisposes to acne, and in some families scarcely any members escape.

It is common knowledge that the great majority of those who suffer from acne in their youth eventually cease to be troubled by it (generally between the ages of 20 and 30), and unfortunately many medical men in general practice who have other and more serious diseases to think about are inclined to pooh-pooh "a few spots," and to advise no treatment as the sufferer "will grow out of it." No doubt he will, but perhaps not before he is permanently scarred and has suffered damage that may have far-reaching effects on his or her future life. Not only so but many girls, and some boys, become morbidly self-conscious about their spotty appearance, which casts a shadow over their lives. On all grounds therefore it is most important that acne vulgaris should be treated, and treated as early as possible, *preferably before it has become pustular.*

It is impossible to discuss prognosis apart from treatment. Many popular methods of treatment appear to be completely inert and therefore without influence on the prognosis. Such are purgation by salts, the eating of yeast and its extracts or preparations of tin, dieting (except for avoidance of chocolate and, in a few cases, of cheese), and the injection of manganese and of vaccines, except in rare cases of pustular acne. I can remember two cases and two only in which vaccines really had a dramatic effect, one being a staphylococcus vaccine and the other an autogenous acne bacillus vaccine. When the patient who had the latter vaccine relapsed in due course the pathologist was never able to prepare another vaccine which had any effect on the disease. With regard to intestinal antiseptics I have hitherto been a sceptic, but having regard to Arthur Whitfield's strong views on this point (Brit. Jour. Derm. and Syph., 1934, xlvi., 257) it is necessary to preserve an open mind.

What, then, is the prognosis in the ordinary case of moderately severe acne in an adolescent patient? I have found that with the liberal use of soap and water (to which some patients have an astonishing aversion) and of sulphur applications, the avoidance of greasy creams, and the omission of chocolate from the diet, combined with the methodical expression of comedos and the careful use of small doses of X rays, almost all cases of ordinary acne, whether punctate or pustular, can be cured. The methodical expression of comedos should be carried out with the appropriate instrument and under reasonably aseptic conditions. It should *not* be done by the patient spending every spare minute in front of her looking-glass "squeezing spots" with her nails. Comedos should be expressed before they have given rise to pustules. Ultra-violet light treatment is also helpful but it has not the permanent effect of X rays.

Cures brought about in this way seem to be permanent provided that the patient keeps the rules, continues to apply a sulphur lotion a few times every week, and does not allow his or her head to become scurfy. The only cases of relapse which I have seen took place in patients who after remaining well for some months gave up the prophylactic use of the lotion, or allowed their heads to become scurfy, or were persuaded by advertisements to use cold cream on their faces instead of soap and water, or applied oil when sun-bathing. The latter practice I regard as pernicious in any patient with a tendency to acne, for I have seen several women of ages between 25 and 35 who, having long since grown out of their acne, had a relapse following the application of oil when sun-bathing.

The scarring which is the end-result of severe acne may be due to atrophy caused by the pressure of the comedo on its surroundings, and in such cases it often produces a "worm-eaten" appearance on the cheeks. The damage produced by pustular lesions takes the form of more or less round, depressed, white scars. On the back these may be so numerous that practically no normal skin is left.

There is a popular idea that X ray treatment causes or increases scarring. That this is not the case was shown by experiments made by H. D. Niles in America (Archives of Derm., 1933, xxvii., 89), in which in 40 patients with acne vulgaris only one cheek was treated by X rays and the final appearance of the two cheeks was compared. There was no difference between the scarring on the two cheeks in 32 cases, more scarring on the untreated cheek in 5, and more on the X rayed cheek only in 3.

When acne occurs for the first time in an adult one should make certain that one is really dealing with acne vulgaris and not with one of the other conditions mentioned in the first part of this paper. If the condition proves to be a genuine acne vulgaris it is no more difficult to cure than ordinary adolescent acne.

Acne conglobata.—The type of acne in which the prognosis is definitely unfavourable is that known as acne *conglobata*. In sufferers from this complaint almost the whole skin may be covered with blackheads, many of them of large size, while on the front and back of the trunk are many pustular lesions in which the suppurative process has burrowed more or less horizontally into the skin causing ramifying tunnels of pus which, when they eventually heal, leave extensive and severe scarring. This type of acne is extremely resistant to treatment and may persist throughout the patient's life. Fortunately such cases are rare.

One may say therefore that the prognosis in any ordinary case of acne vulgaris is good provided that the disease is rationally treated and that the patient will coöperate.

YELLOW FEVER IN THE ANGLO-EGYPTIAN SUDAN

SEROLOGICAL AND POST-MORTEM EVIDENCE

By T. F. Hewer, M.D. Brist., M.R.C.P. Lond.
BACTERIOLOGIST, WELLCOME TROPICAL RESEARCH LABORATORIES, SUDAN GOVERNMENT, KHARTOUM

The introduction of air travel has broken down one of the natural barriers to the spread of disease. When travel, in Africa and the Orient particularly, was confined to land or sea there was usually ample time for people to develop recognisable signs of any serious disease before they reached their destination; this was especially true of yellow fever, whose incubation period is only rarely more than six days. It is now possible for a person to be bitten by an infected mosquito in Central Africa and arrive in Cairo before he becomes ill. The recognition of this possibility, even though it be a very remote one, makes it urgently necessary to introduce preventive measures. If quarantine regulations were enforced at every air port, the passengers being kept in mosquito-proof rooms for two days or more on arrival, it would be worth no one's while to travel by air: it is obviously impracticable. Attention must then be directed to the prevention of infection of the passengers in transit and before they embark; and the first requirement is an accurate knowledge of the present geographical distribution of the disease. A few years ago it was thought sufficient to control aircraft coming from West Africa—a known endemic centre of yellow fever—but now there is evidence suggesting that the endemic area is very much larger than this.

SEROLOGICAL EVIDENCE

During the last two years a yellow fever immunity survey of Africa, instigated by the International Health Division of the Rockefeller Foundation, has revealed the presence of silent areas in which the disease appears to have been present without arousing the suspicions of the local medical authorities.

The survey depends upon the mouse-protection test evolved by Sawyer and Lloyd.[1] The test consists essentially of the inoculation of mice intraperitoneally with yellow fever virus, fixed for mice, together with the serum to be tested, and the simultaneous injection of starch solution into the brain to localise the virus. If the serum lacks protective power the mice die of yellow fever encephalitis. There is good evidence for the specificity of the test, and it appears that the protective bodies remain for many years, if not for life, in the blood of persons who have recovered from yellow fever.

Sera have now been collected from representative groups of adults and children in the southern and western provinces of the Sudan and in the central district of Khartoum. They were all sent to New York, where Dr. W. A. Sawyer carried out the tests in the yellow fever laboratories of the International Health Division of the Rockefeller Foundation. The results, which are being published in detail by Dr. Sawyer and Dr. Loring Whitman, indicate that the disease was present in Darfur province about eighteen years ago, 13 out of 61 adults over eighteen years of age giving protection, while not one of 46 children of various ages down to three years was positive. One of the positive adults was found, on subsequent inquiry, to have been resident in French Equatorial Africa for some years.

At El Obeid, in Kordofan Province, there were no protective sera among 52 persons of ages ranging from five to seventy, but in the Nuba Mountains, some eighty-five miles to the south, 7 out of 30 adults were positive, the youngest being thirty years of age; all the 15 children tested were negative.

The largest percentage of positive results was obtained from the Bahr-el-Ghazal province: at Wau 7 out of 27, and at Rumbek 17 out of 30 adults had protective sera. Three out of 24 children at Wau (aged six, six, and nine years), and 1 of 26, aged eleven years, at Rumbek gave positive results. No children, but 5 of 20 adults at Sources Yubo, and 4 of 16 adults at Li Rangu were positive, the youngest being aged thirty and twenty-eight respectively.

In Mongalla province at Juba, the Imperial Airways port on the Cairo to Cape route, out of 28 adults 3 were definitely positive and 3 others gave partial protection, which was considered inconclusive; 3 out of 22 children, aged seven, seven, and eight,[*] were also positive. At Amadi no children but 2 adults, aged twenty and forty, out of 20 tested, were positive.

In the Upper Nile province 19 children at Yirol were negative, no adults being tested; and at Malakal, another Imperial Airways port, among 55 persons, children and adults, there was 1 definitely positive, aged eighteen, and 3 inconclusive, aged eleven, eighteen, and thirty-five.

In Khartoum the only positive result was obtained with the serum of a man who had been resident in the Nuba Mountains. At Kosti, on the White Nile, the only positives were in people who were natives of Darfur, the Nuba Mountains, and the southern Sudan, thus tending to augment the results obtained in those areas.

In summary, from the results of the mouse-protection test it appears that yellow fever was present, probably in endemic form, in the Bahr-el-Ghazal six years ago; in Mongalla seven years ago; in the Upper Nile province between eleven and eighteen years ago; in Darfur eighteen years ago; and in the Nuba Mountains thirty years ago. There is no evidence that the disease was ever present in the desert areas to the north of the Sudan, the sera from El Obeid and Khartoum being entirely negative. It should be noted that in every case great care was taken to make sure that every person tested had lived all his life in the district being surveyed. A further check-up on the positive cases is still in progress in the Bahr-el-Ghazal.

---

[*] The ages of these children were wrongly estimated in the first instance and reported to the Office d'hygiène as 12, 13, and 14.

CLINICAL EVIDENCE

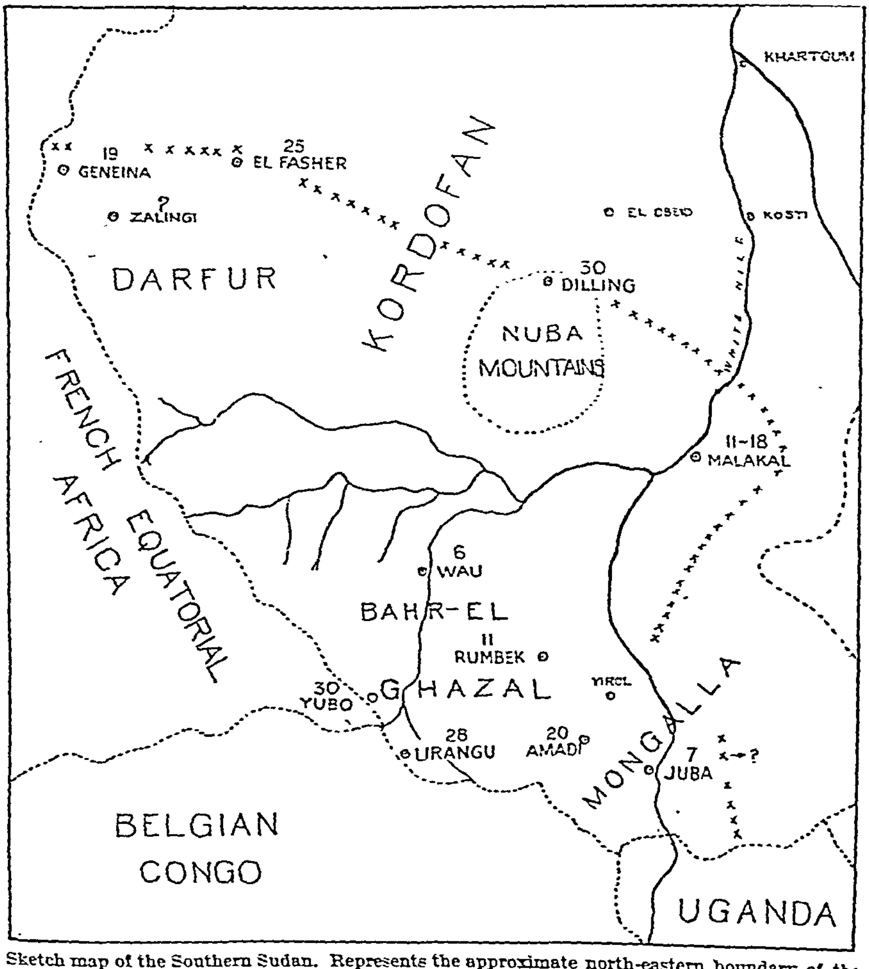
Although the mouse-protection test appears to be perfectly reliable and specific it really only provides data as to the presence of yellow fever in the past. When positive results are obtained in all age-groups of a community from three years upwards, in the absence of a recent widespread recognised epidemic, it is probably safe to assume that the disease is actually present in the locality; but the implications of such a decision are so serious that one must have more conclusive evidence.

Classical clinical cases of yellow fever occurring in epidemics in a susceptible population are generally easy to diagnose, but in the known endemic areas of West Africa and Brazil the classical manifestations of the illness are seldom seen. Soper, Rickard, and Crawford[2] have found the clinical diagnosis most difficult in those endemic regions in Brazil where the disease is most constantly present. In the native population the recovery-rate is high, and even in the fatal cases the classical signs and symptoms are often absent. It seems that any acute febrile disease in an endemic area may be yellow fever.

The issue is further complicated by the presence in Africa of a number of conditions, of unknown ætiology, giving rise to necrosis of the liver. In the Bahr-el-Ghazal province there was a small epidemic of jaundice in 1929; histological examination of the liver was made in a few instances and the disease was definitely not yellow fever. Moreover, the mouse-protection test was done on the sera of two persons recovered from the jaundice disease in this epidemic, and they were both negative. Similar isolated cases of hepatic necrosis and so-called "catarrhal jaundice" occur at frequent intervals in all parts of the Sudan. The spirochæte of Weil's disease has never been found.

Blackwater fever is another Sudan disease which bears certain resemblances clinically to yellow fever. It has, in particular, the common characteristic of occurring most frequently in Europeans who, being highly susceptible to yellow fever, are the very people who are likely to show clinical and classical signs of the latter disease. Blackwater fever is very common in the Bahr-el-Ghazal. The mouse-protection test has been performed on the sera of 7 Europeans, 1 Indian, and 4 Sudanese who had contracted blackwater fever in Darfur, Mongalla, and Bahr-el-Ghazal provinces; none of them gave any protection.

An interesting corroboration of the protection tests in Darfur is provided in a recent article by Prince Omar Tousson.[3] He gives an account of a battalion of 453 Sudanese soldiers in the Egyptian army, recruited from Darfur and Kordofan (in which province lie the Nuba Mountains), who were sent by Said Pasha to the Mexican War in 1863 to render assistance to Napoleon III. African troops were in great demand because they were known to be immune to yellow fever. The mortality from that disease among Europeans at Vera Cruz was alarming. Of these 453 Sudanese only one, their commanding officer, died of yellow fever; it is not clear whether he was Sudanese or Egyptian. It seems likely that this immunity was due to previous infection in the Sudan.



Sketch map of the Southern Sudan. Represents the approximate north-eastern boundary of the endemic area of yellow fever, as suggested by the mouse-protection test results. The figures over the place names are the ages of the youngest people whose sera were positive. The Imperial Airways use aerodromes at Khartoum, Kosti, Malakal, and Juba.

POST-MORTEM EVIDENCE

Since the clinical recognition of mild cases of yellow fever is impossible one must employ some more certain means of diagnosing the disease. This is provided by a routine histological examination of the liver of every person who dies of an acute febrile illness.

In Brazil protection tests gave positive results in some areas in which there had never been any suspicion of the presence of yellow fever. As in the case of the Sudan there were two possible explanations of these findings: either the test was not specific or yellow fever was present in such a mild form that deaths never resulted. Soper, Rickard, and Crawford made routine histological examinations of the livers of all persons dying of any acute febrile disease of less than ten days' duration in these regions and found a large number with definite evidence of yellow fever, thus proving that the "silent" areas are only silent because of the impossibility of recognising them clinically. They have invented an ingenious instrument, called a viscerotome, which can be inserted into the liver of a corpse without the necessity of doing a post-mortem or opening the abdomen. The Rockefeller Foundation has very generously presented the Sudan Government with a number of these instruments, and they have been distributed to the suspected provinces with instructions to the medical inspectors to collect specimens of the liver of every case of fatal acute febrile illness of less than ten days' duration. These specimens cannot be obtained as easily as in Brazil, because of the prejudice of many of the tribes against any violation of dead bodies; and so far very few sections have been examined.

On June 30th, 1934, the following details of a case, which proved to be yellow fever, together with pieces of the liver and kidney for section, were received from Dr. G. C. Cochrane, medical inspector, Wau.

A native of Wau town, 18 years of age, a fisherman by trade, was admitted to Wau Hospital on June 9th, 1934, suffering from fever and jaundice. His illness started, four days before admission, with several repeated chills followed by fever, severe pain in the epigastrium, and bilious vomiting. The jaundice was not noticed till the day of admission.

On examination he was markedly jaundiced, with temperature 100·2° F. and pulse-rate 80; complained of severe epigastric pain. Tongue coated; no vomiting; bowels open. Heart and lungs normal. Liver and spleen not palpable. Reflexes normal. Blood films were examined for malaria and relapsing fever parasites with negative results. The urine was loaded with albumin and contained no sugar. Nothing was found in the fæces.

On June 10th there was marked delirium; temperature 99°–100° F.; pulse-rate 85. Became comatose in the afternoon. One ounce of urine obtained by catheter, heavily laden with albumin. June 11th: deep coma; temperature 101°–102° F.; pulse 85–90. Urine very scanty by catheter. June 12th (eighth day of illness): patient died.

Time has not permitted of getting a more detailed history of the case from Dr. Cochrane; the mail service runs only once a month. His notes on the post-mortem examination are as follows: "No hæmorrhages in the skin. All tissues deeply stained yellow. Liver: normal size, friable, and deeply yellow. Spleen: normal, rather small. Kidneys: enlarged and congested."

The liver showed advanced necrotic changes and Councilman lesions highly suggestive of yellow fever. A section was sent to Dr. G. M. Findlay, of the Wellcome Bureau of Scientific Research, London, who confirmed the diagnosis. In the kidney the outstanding feature was degeneration of all the epithelial cells, including those covering the glomerular tufts and all the tubules; no cellular infiltration. The lumen of the tubules contained hyaline amorphous material.

This is a case whose diagnosis might well be made on clinical grounds, but the heavy albuminuria seems to be the only feature in which it differed from some other very similar conditions which were shown, on section of the liver, to be hepatitis of unknown ætiology.

Such spectacular cases are not very frequently seen, and judging by the results of the mouse-protection tests in Wau and Rumbek districts the majority of the infections must be extremely mild and impossible to diagnose.

DANGER TO FOREIGN RESIDENTS IN ENDEMIC AREAS

One of the first points raised by critics of the protection test results in the southern Sudan has been the apparent absence of any case of yellow fever among the foreign residents. There are several factors which may be adduced to explain this apparent anomaly.

The total foreign population (non-Sudanese) of the Darfur, Bahr-el-Ghazal, and Mongalla provinces, comprising a total area of approximately 293,000 square miles, is only 580 persons. In the Upper Nile Province, where there is much less evidence of the presence of yellow fever, the foreign population numbers 306, mostly in the town of Malakal. In the Bahr-el-Ghazal and Mongalla provinces there are also about 100 natives of the northern Sudan (government employees, servants, &c.) and, as they are undoubtedly susceptible to infection with yellow fever, they should be added to the total of foreign residents. This leaves us with only some 700 persons, in an area of 293,000 square miles, who are definitely at risk and capable, if infected, of being diagnosed clinically. Moreover, a large proportion of the Europeans live in mosquito-proofed houses placed at some distance from the native quarters.

The stegomyia mosquito, which is the chief vector of the disease, is extraordinarily local in its habits. Mosquitoes bred in one house or garden are not at all likely to travel more than a hundred yards in any direction. As they frequent houses they are less likely to be carried far by wind than are the anopheline carriers of malaria. It will be seen that it is therefore possible for yellow fever to exist in the native quarter of a town and for stegomyia mosquitoes to be common in all districts and yet, because the infected mosquitoes do not migrate from one quarter to another, the disease may not spread.

There is some reassuring evidence that the risk is not as great as might be imagined. Protection tests were done on the sera of 7 Europeans, 1 Indian, and 13 natives of the northern Sudan who had been resident for periods between 5 and 30 years in the Bahr-el-Ghazal and Mongalla provinces: all were negative.

Five of the Europeans were Italian missionaries who had lived in houses without any mosquito proofing. The 13 natives of the northern Sudan had lived in native quarters, also without any protection from mosquitoes. On the other hand, this gives no idea of the number who may have been infected with the disease and succumbed. There is still a possibility that some of the deaths attributed to blackwater were in reality yellow fever.

THE MOSQUITO VECTOR

A mosquito survey is still in progress, but the following data, although incomplete, give some idea of the distribution of the important species.

Aëdes (*Stegomyia*) *ægypti*, the acknowledged vector of yellow fever, occurs in Khartoum, but has been found commonly in El Obeid, the Nuba Mountains, and Darfur (Fasher and Geneina). In Juba it is regularly obtained from stagnant water in and near houses. At Wau very little collecting has been done but this mosquito has been recorded. Its presence is also reported from other parts of Mongalla province. In Malakal specimens were collected in 1909 but there has been no subsequent record, and it would not appear to be common.

A few specimens of *Aëdes luteocephalus*, another possible vector, have been found at Juba. *Aëdes apicoannulatus* and *A. africanus* have not so far been found in the Sudan, but *A. vittatus* is abundant in the Nuba Mountains, Darfur, and Mongalla, including Juba. *Mansonia* (*Tæniorhynchus*) *africanus* has been recorded from Fasher, Juba, and Malakal.

Dr. Aldridge and Dr. Stephenson, of Juba, have been very active in collecting mosquitoes, and it is possible that stegomyia may be found elsewhere more commonly than the present records would lead one to suppose.

MEASURES TAKEN AT AERODROMES

The Sudan Government has become signatory to the International Convention for Aerial Navigation. At Juba disinsectisation of all planes is carried out, and the passengers are medically inspected in order that any who have been exposed to a risk of infection may be placed under observation. The hotel where passengers and crew spend the night is mosquito-proofed and the quarters of the local officials of the Imperial Airways are also proofed. Disinsectisation and medical inspection of north-bound planes is repeated in Khartoum.

The aerodromes at Juba and Malakal have been made anti-amaryl to satisfy the rigid regulations of the Air Convention, and the Bahr-el-Ghazal province has been closed to all international air traffic and all aircraft within the Sudan. Article 47 of the International Sanitary Convention for Aerial Navigation has been enforced at Juba and Malakal, and passengers from the Bahr-el-Ghazal province will be subjected to observation for the prescribed period.

DISCUSSION

The reliability of the mouse-protection test for yellow fever has now been established beyond any possible doubt. In Brazil the test gave positive results in previously unsuspected regions, and post-mortem evidence subsequently justified them. Precisely the same sequence of events has occurred in the Sudan.

Positive protection tests were obtained by Dr. Sawyer (unpublished) with sera from French Equatorial Africa and the Belgian Congo, especially high percentages being found in the northern part of the Congo, where it joins the Sudan, and in the adjacent French territory.

The area in which yellow fever is endemic in Africa appears to be roughly triangular in shape, with its base on the west coast and its apex in the southern Sudan. This enormous stretch of country can never be cleared of mosquitoes, and any hope of the final eradication of yellow fever from Africa becomes extremely remote. One must aim at limiting its spread. The exact boundaries of the endemic areas will have to be more accurately defined by further protection tests. We do not yet know how far it reaches to the east of Juba. Mosquito control can be enforced in the chief towns and government stations, but it is impossible in the outlying villages. With greater medical vigilance more cases of the disease will be recognised and proper precautions taken.

It is absolutely essential that all houses occupied by foreigners should be adequately mosquito-proofed.

An additional and effective measure of protection will shortly be available for all persons visiting or residing in the yellow fever zone. In 1931 Sawyer, Kitchen, and Lloyd [4] immunised ten persons with a mixture of neurotropic yellow fever virus, fixed for mice, and immune serum. These workers in New York, and Marshall Findlay [5] in London, have now greatly improved the method of immunisation so that the risks of unpleasant reactions are comparatively slight. It is to be hoped that it will be possible very shortly for all persons flying through Africa to be inoculated; the danger of spreading the disease by air will then be practically eliminated.

SUMMARY

(1) The results of a yellow fever immunity survey by the mouse-protection test of the Anglo-Egyptian Sudan are reported. (2) On the strength of these a wide zone in which the disease appears to be, or to have been, endemic has been defined. The Imperial Airways route to the Cape runs through this zone. (3) A case highly suggestive of yellow fever both on clinical and pathological grounds occurring in a native of Wau is described. (4) The difficulty of diagnosing mild, or even fatal, attacks of the disease in the native population is discussed. (5) Measures adopted for preventing the spread of the disease by air are described and a plan of campaign for combating it is briefly outlined.

ACKNOWLEDGMENTS

The Sudan Government is greatly indebted to Dr. W. A. Sawyer, Dr. Loring Whitman, and the International Health Division of the Rockefeller Foundation for performing the mouse-protection tests, and for their kindness in supplying information as to the results.

My grateful thanks are due to Sir Robert Archibald, director of the Wellcome Tropical Research Laboratories, Khartoum, and Dr. E. D. Pridie, director of the Sudan Medical Service, for allowing the survey to be made and for their advice and assistance. We are also indebted to Dr. G. M. Findlay for confirming the diagnosis of the section of liver from the case of yellow fever.

LONDON LOCK HOSPITAL.—Last year there were 23,369 in-patients, out-patients made 180,000 attendances, and over 18,500 pathological tests were made. It is the only voluntary hospital which admits maternity cases suffering from venereal disease, and in 1933 of 53 deliveries there was only one stillbirth, and no baby born of a treated syphilitic mother bore signs of the disease. Lord Kinnaird, the chairman of the board of management, explains that the hospital is so handicapped by a debt of £20,000 that "unless substantial donations are immediately forthcoming it will be compelled to close down."

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF MEDICINE

At the last meeting of this section the chair was taken by Prof. J. G. Emanuel (Birmingham), vice-president, and Dr. T. Izod Bennett (London) opened a discussion on

Œdema, its Causation and Treatment

In all cases, he said, œdema implied that the passage of fluid into the tissue spaces exceeded the return from them into the lymphatics and capillaries. Attention must be concentrated on the region and boundaries of the tissue spaces. The only two factors of major importance governing the passage of solution from the capillaries to the tissue spaces and back were the intracapillary blood pressure and the colloid osmotic pressure of the plasma proteins. The thin capillary wall acted as a semi-permeable membrane. The intracapillary pressure was probably very difficult to increase at the arterial side, but at the venous side it was easily raised by any condition of back pressure, such as failure of the right heart. The colloid osmotic pressure tended to counteract the intracapillary blood pressure, and was a constant drag on the passage of fluids from the capillaries into the tissue spaces. As transudation took place the forces gradually became balanced, until there was a flow in the reverse direction. The colloid osmotic pressure was diminished by loss of protein from the blood, as in extreme albuminuria—and loss of albumin was more important than loss of globulin. The removal of plasma proteins in animals produced œdema, and a loss of plasma proteins into the peritoneum, stomach, or elsewhere in man had the same effect as prolonged albuminuria. This factor was of extreme importance in the production of œdema. Increased permeability of the capillary wall might be of some importance in acute nephritis, and certainly was important in urticaria, but it would not by itself produce œdema, which was in this case probably due to the resulting transudation of protein through the capillary wall. Sodium chloride was in all cases an important factor in determining chronicity. It would not produce œdema alone, but it tended to hold water in the tissue spaces, and so in almost all cases was of importance as an ancillary; it was the sodium ion that was important and not the chlorine.

Treatment must be based on a consideration of these factors. Anything improving the output of the right ventricle would ameliorate cardiac œdema. Prolonged rest was therefore essential and digitalis was most valuable if auricular fibrillation was present. The progress of œdema could be watched by observing the water balance, all fluids taken during the 24 hours being set out against the total output of urine. The fluid intake should be limited to 25 to 30 oz. daily, and only traces of salt should be allowed in the diet. If, in spite of rest, diet, and digitalisation, œdema persisted, the mercurial diuretics, particularly salyrgan, were often very valuable, and the diuresis produced by them was increased if ammonium chloride was given simultaneously. Acute pulmonary œdema required morphia and immediate venesection. Its onset was signalised by cardiac dilatation, paroxysms of nocturnal dyspnœa, and the appearance of moist sounds at the bases of the lungs. There were two, probably three, varieties of renal œdema. There was a terminal œdema due to cardiac failure in chronic nephritis with high blood pressure; this was not usually accompanied by renal failure, and was no contra-indication to salyrgan. The second variety was seen in so-called "nephrosis," in which long-standing albuminuria had reduced the plasma proteins so much that œdema appeared. There was heavy albuminuria without rise of blood pressure, and without any of the changes characteristic of renal failure. A high protein diet was indicated, vegetable protein particularly being given. Salt should be forbidden and the water intake limited. Salyrgan was not contra-indicated unless there was a progressive renal lesion. The treatment was entirely different in acute and subacute glomerular nephritis. In these cases no strain must be thrown on the kidneys. Starvation must be as complete as possible in the early period, and remarkable recoveries were frequently achieved by restricting food to small amounts of fruit. Subacute and chronic cases were more difficult. A low protein diet was usually indicated, and septic foci must be eliminated.

Dr. A. W. Stott (London) said that a large number of cases of chronic heart disease ultimately died of congestive heart failure, a name which stressed the fundamental feature of the syndrome: venous congestion throughout the body. The clinical features were easily recognisable—orthopnœa, cyanosis, abnormal fullness of the jugular veins, enlarged liver, ascites, and subcutaneous œdema. Mistakes in diagnosis were occasionally made. There must be obvious evidence of venous engorgement, especially in the neck, liver, and lungs. So late a stage of the condition should be prevented if possible, but unfortunately the cause of failure of the heart was not known. Sometimes an infection, even a trivial one, might precipitate it; in others it began with auricular fibrillation. The fact of early myocardial weakness should be recognised if possible, and the cardiac reserves maintained. The danger signal of increasing dyspnœa warned the physician long before signs of congestion appeared. The patient should then be rested and protected as far as possible against infection, and the ventricular rate controlled by digitalis. Even with gross failure, full doses of digitalis would often bring about dramatic results, but there were resistant cases, and few patients suffering from severe congestive failure with a normal rhythm were much helped by this drug. For them there must be complete rest—not such a simple matter as it seemed. A relatively upright position was advantageous to a patient suffering from the severe discomfort of generalised œdema and orthopnœa. Failing a cardiac bed, it was often best to keep the patient in a comfortable chair. Meals must be small, dry, and easily digestible, and only 20 to 30 oz. of fluid should be given in the 24 hours. The xanthine and mercurial diuretics were the most useful. Theobromine and theocin might cause gastro-intestinal disturbance, and should be discontinued if they did not act within a few days. Salyrgan was powerful and practically non-toxic, and rarely caused unpleasant effects. Its results might be increased by producing a preliminary acidosis for a few days, but this was not often necessary. Treatment did not end with relief of œdema; the patient must always thereafter lead a restricted life. A prophylactic injection of salyrgan once or twice a week might prove to be as valuable as its more dramatic use.

Dr. H. Gainsborough (London) confined himself to renal œdema and thought that the condition called nephrosis was really nephritis. There was every conceivable grade between the extremes of acute and chronic nephritis, and a distinction between them was artificial; one cause might produce varying effects. The chronic form showed an insidious onset, a heavy albuminuria and œdema, which might last for months or years, and might come and go. Recovery was, however, rare, and when albuminuria persisted after the tendency to œdema had finished, there was a period of apparent latency, and then the symptoms reappeared. Increasing destruction of the kidney abolished œdema, and possibly the same factor might control œdema in acute cases. Very little advance could be recorded in the treatment of renal œdema. The most effective diuretics were urea, acidosis-producing salts, and organic mercury compounds such as salyrgan. Urea was always indicated, but sometimes failed. The salts sometimes worked excellently but sometimes caused nausea. Salyrgan quite possibly acted by damaging the kidney, and it seemed most unwise to give any drug which might add to the harmful influences affecting that organ. The patient must be treated generally with good food, sunlight, fresh air, and warmth, but the protein of the diet must be kept down to basal requirements. Iron was sometimes helpful; over-hospitalisation was to be avoided, and the patient needed a sanatorium type of life.

Dr. GEOFFREY EVANS (London) said that the œdema of kidney disease might appear in a cardiac form, in a subthyroid form, or, rarely, in an angioneurotic form. There was often a cardiac factor in both acute and chronic nephritis, and digitalis might be of real value. Prompt improvement might follow venesection in acute nephritis, and occasionally thyroid might do good. The toxic factor might be present in all forms of Bright's disease, and starvation might be helpful. In any single case of nephritis the ætiological factors might be varied. Whatever the type of the disease, the physician must look out for the possible presence of any of the known factors producing œdema. Salt restriction might be useful in some cases, and in others might prove intolerable and lead to uræmia. Salyrgan must always be used with caution in kidney disease. Decapsulation was useful in selected cases.

Dr. J. MAXWELL (London) said that the chief factors concerned in the causation of œdema were: (1) increased capillary pressure; (2) increased capillary permeability; (3) alteration in the osmotic balance between the plasma and the tissues, particularly in respect of their protein and sodium contents; and (4) certain little understood factors such as the endocrine system and the hypothetical water-regulating centre.

Increased permeability meant that colloids were passing out of the vessels, which should not normally occur. Certain substances, however, such as alcohol and mercury salts, could bring it about. There was a good deal of protein in the œdema fluid of acute nephritis, inflammation, and heart failure, but very little in nephrosis and nutritional œdema. The chief causes of localised œdema were acute inflammations, urticaria and, rarely, renal conditions. It had been suggested that urticaria was the result of the local release of a substance resembling histamine, rendering the capillaries temporarily more permeable. Injection of adrenaline into the swelling was often very effective, but no known method prevented the attacks. Calcium therapy sometimes relieved the patient and often failed; protein shock had only temporary success, and specific desensitisation unfortunately only rarely gave good results.

Dr. F. BOTTOMLEY (Bournemouth) thought that heat was valuable in certain cases, as shown by an increase in the excretion of urine.

Prof. LANGDON BROWN (Cambridge) said that the value of hot air baths probably depended largely upon the removal of salt from the tissues in the resulting sweat. If the patient was responding well, there would be diuresis, and the sweating would occur at a progressively lower temperature. In the early stages of acute nephritis he recommended a diet of fruit juice and glucose.

Dr. E. L. SERGEANT (Hangchow) suggested that the blood calcium might be examined in the angioneurotic type of œdema, from analogy with rhinorrhœa.

Dr. N. E. WATERFIELD (Great Bookham) regretted no mention had been made of the value of intramuscular inoculation of the patient's own blood, a method of treatment he had often found successful when all other methods had failed in urticaria or angioneurotic œdema.

Dr. W. N. LEAK (Winsford) commented on the possibility of an associated vitamin loss.

Dr. JOHN PARKINSON (London) thought that rest in a chair was not so good as rest in bed. He would not himself restrict digitalis to auricular fibrillation; he had found it useful in œdema when rhythm was normal and sometimes in postponing the onset of œdema.

SECTION OF PATHOLOGY, BACTERIOLOGY, AND BIOCHEMISTRY

A MEETING of this section, with Prof. J. W. BIGGER (Dublin), the president, in the chair, was devoted to the value of

Antiseptics in Control of Bacterial Infections

Prof. C. H. BROWNING (Glasgow) emphasised that, though Lord Lister had left little printed record of his theory or methods, and that little rather a confused record, Sir Hector Cameron, one of his students and friends, had clearly summarised them. Lord Lister did not employ carbolic acid in the treatment of abscesses, although his imitators did. But naturally he was limited in his practice by the antiseptics then available. In the main modern opinion agreed with Lister's opinions on his antiseptics; though there were some, such as boric acid, which he had belauded, which now found little support. The great ambition of Ehrlich, the finding of an antiseptic capable of restraining the harmful action of bacteria while being entirely innocuous to man, was still a legitimate and an increasingly hopeful objective. The older antiseptics were deleterious to living tissue, and were usually ineffective in the presence of serum. New antiseptics, entirely innocuous and little affected by serum, had been found; among others, brilliant green and flavine were particularly worthy of attention.

The power of an antiseptic to kill an organism was usually measured by the Rideal-Walker or Chick-Martin test. But these tests only touched the fringe of the problem. Organisms differed greatly in sensitiveness to the antiseptic; perhaps we should select a specific antiseptic against specific organisms. Moreover, the limitation of virulence of organisms without actually killing them was possible with certain organisms and certain antiseptics. The possible reaction of the host, and its assistance through the stimulus of the antiseptic, must not be forgotten. The study of antiseptics was made easier by the use of actual living tissue, in the animal body or in tissue culture. In one instance a control experiment, on a human being, was possible, and had

Dr. Robert Mells Library

shown the marked benefit of flavine compared with boric acid. In animals the diphtheria bacillus was an exceedingly useful test organism for examining the power of antiseptics to prevent infection and to arrest it in the early stages. Antiseptics must be considered in relation to their action before infection, in early and localised infections, and in generalised infections. Only in the first two cases were they now of proved value. But physicians, surgeons, bacteriologists, and chemical physicists must unite in extending the present boundaries of chemotherapy.

Dr. R. J. V. PULVERTAFT (London) said that Prof. Browning's optimism, as the originator of most that was valuable in chemotherapy, was encouraging and stimulating. The fact that conditions innocuous to man yet harmful to the organism could exist was proven by normal recovery to infection, and supported by the daily practice of housewives, house surgeons, and pathologists when they cut their fingers. He drew attention to the variability of test organisms and in particular of the Rawlings strains of *Bacillus typhosus*, used in the Rideal-Walker test, and described experiments showing how antiseptic values varied with bacterial growth phases. He criticised the use of mercury salts in septicæmia, of urinary antiseptics, and so-called germicidal anæsthetics, and in conclusion asked for entirely new criteria of antiseptic values to be officially laid down.

Dr. G. W. THEOBALD (London) asked for greater consideration to be given to the reaction of the host rather than the bacillus. Life was a complicated biological problem, not to be confined to test-tube experiments. He particularly instanced the possibility of hepatic damage in various conditions and its effect on inflammatory reaction. He described excellent results in midwifery following a careful aseptic and antiseptic routine. Mercurochrome was, he believed, of value, but chiefly in acute infections with *B. coli.* He also believed in the efficacy of brilliant green and acriflavine in localised infection, and mentioned the well-established prophylactic value of gargling in support of chemotherapy.

Mr. ZACHARY COPE (London) thought that chemotherapy was returning to popularity. The newer antiseptics, such as the hypochlorites and flavine, were far better than the older ones, which often even produced pustules on the skin. In general, however, antiseptic treatment was limited to infections under four hours old. Antiseptics could not penetrate into devitalised tissues, and could not touch established and generalised infections. Here the classical surgical weapons of excision and drainage were still supreme. But he thought surgeons and bacteriologists might well revise some of their ideas in the light of Prof. Browning's discoveries and those of his co-workers.

Dr. SYDNEY THOMSON said that antiseptics had a wide use in dermatology. Their specific action was often helped by their solvent action on tissues, such as that of tri-chlor-acetic acid and salicylic acid. The action of ichthyol was difficult to explain on the basis of its antiseptic value. He drew attention to the dangers of mixed antiseptics—of iodine and mercury, causing a biniodide burn, and zinc oxide and eusol. Personal idiosyncrasy to antiseptics such as picric acid made choice of antiseptic important. In agreement with other speakers, he expressed his high opinion of brilliant green and flavine treatment.

Sir ARNOLD LAWSON (London) was more impressed by the value of drainage than antiseptics in the treatment of conditions of the eye. He did not consider the antiseptic action of lysozymes as described by Prof. A. Fleming to be of much importance. The usual rule appeared to be that the worse the eye, the more generous should be antiseptic treatment; the reverse was in fact true, and this often led to corneal ulcers. Silver salts were effective antiseptics, but irritant, and he used acriflavine as the antiseptic of choice in most cases, in a strength of 1 in 2000.

Mr. J. S. WOOD (Parkstone), speaking as a veterinary surgeon, pointed out how differently different animals reacted to infection and antiseptics. The paler the flesh of the animal, the more rapidly it healed; the pig healed very quickly. Flavine was not much used in veterinary surgery, partly because of expense. Glycerin, potassium permanganate, and sea water, which in Bournemouth was laid on in pipes, were the chief veterinary antiseptics.

Dr. L. P. GARROD (London) said there was too much "clinical impression" and too little serious testing in the matter of chemotherapy. Ridiculous claims were made for certain antiseptics owing to the use of inept testing methods. Bacteriologists were not going the right way to impress surgeons; and it was the surgeons who had to be impressed. There were not enough standard and scientifically adapted tests; such tests should be provided.

Prof. BROWNING, in reply, said there was at present no alternative to orthodox surgical treatment of established infection. But much ground had been consolidated, and the antiseptic of the future was likely to be as much better than those of the present day as ours were than Lord Lister's.

Staphylococcal Infections

Dr. H. J. PARISH (London) then read a short communication on new methods in the treatment of staphylococcal infections. He mentioned the older methods of vaccines, bacteriophage, and Besredka's local immunisation. Toxoid and antitoxin were new methods and might sometimes be used together. There were conflicting reports on the value of toxoid treatment. This might be attributable in part to the complexities of staphylococcal toxins; but toxoid treatment undoubtedly raised the antihæmolytic value of the serum and was praised by many workers in the treatment of boils, sycosis, and osteomyelitis. Blepharitis was particularly benefited and certain diabetics with staphylococcal infections ceased to need insulin after its use. Data on the value of antitoxins were less full, but on the whole encouraging. But more knowledge of the nature of staphylococcal toxin was necessary.

The PRESIDENT, as one of the first workers on the toxin, wished to know how many staphylococcal toxins there now were; this Dr. PARISH described as a difficult question. Dr. E. ff. CREED (London) did not believe in a direct relationship between antitoxic value in the serum and general immunity, and Dr. GARROD supported this view and suggested that bactericidal properties of serum were being forgotten. Dr. PULVERTAFT gave some support to the value of toxoid and antitoxin, but suggested that the dosage of toxoid required more study, since increase in the dose did not always give more antihæmolysin in the serum.

SECTION OF MEDICAL SOCIOLOGY

Dr. H. GUY DAIN (Birmingham), president, took the chair at this section, when Dr. G. P. CROWDEN (London) opened a discussion on

Defective Hearing as a National Problem

The national and individual handicap of visual defects had, he said, been very markedly reduced, but the same could not be said of hearing. The special question of the congenitally deaf had been given careful and detailed attention; the problem under discussion only arose with acquired deafness. It was computed that there were approximately 40,000 totally deaf individuals in Great Britain at the present time, but the number of partially deaf or "hard of hearing" was largely a matter of conjecture. It might be estimated at 2,500,000. Many of these, however, were not seriously handicapped. For the remainder, special problems of social life, education, and employment had to be faced. In the majority of cases the cause of defective hearing was disease, and the subject must be approached from the points of view of both preventive and curative medicine. Army statistics were enough to convince anyone of the serious state of the health of young manhood. The chief cause of rejection of men applying for service was middle ear disease. The ratio of rejections for this cause had in recent years increased to over 50 per 1000, and the same condition headed the list of causes of discharge within six months of enlistment. In 1928, out of 53,075 applicants for service in the Army, 2568 had been rejected as physically unfit on account of diseases of the middle ear and deafness. In 1932, 54,159 men were examined and 2993 rejected for the same reason, while a further 290 were discharged as unfit on these grounds within six months of enlistment. Therefore, between 5 and 6 per cent. of the young men of the nation showed evidence of diseases associated with deafness. The problem was, therefore, obviously one of great national importance.

Although disease was the principal cause of defective hearing, deafness might also be caused by noisy employment or accident and advancing age. Before any steps could be taken to prevent and limit the ravages of diseases affecting hearing, it was essential to know the common age of onset and to find a reliable routine method of diagnosis. The returns of the routine inspection of school-children recorded defects of hearing in only 4·2 per 1000. It seemed highly probable that a great deal of minor impairment of hearing in children passed unnoticed owing to the difficulty of testing under the conditions of school medical inspection. The 4a gramophone audiometer was an ideal method for group testing of children and for detection of the early signs of deafness. A hundred children an hour could be tested in groups of 32 or 40. A preliminary survey on children in the Borough of Hornsey had shown that the audiometer picked out all the known cases of hearing defects, and also a large number of previously unsuspected cases, all of whom were found by the aurist to need treatment. The total was 6·6 per cent. instead of the 0·42 per cent. of the annual returns. Subsequent tests have confirmed these findings, and had shown that methods of prevention must be devised to include children of pre-school age. Deafness due to noisy employment was most satisfactorily combated by an ear-stop of cotton-wool and wax, as devised by Mr. W. R. Luxton. The experience of the school medical authorities in Tottenham had proved that it was possible and practicable to detect and treat a very large proportion of cases of early ear disease, and to restore hearing to normal in many cases where the defects were severe. If this could be done locally it could be done generally.

Air Commander A. V. J. **Richardson** described the significance of the hearing problem in admission tests for the Royal Air Force. The boys were enlisted for life and had a fairly stiff examination to pass at the outset. Of 5750 candidates analysed 0·7 per cent. had been rejected for ear disease. In 1925–32 only five apprentices had been invalided (from some 1200 men) for ear trouble. The explanation of the low figures was probably the greater intelligence of the group from which recruits were drawn. Prompt treatment and daily skilled dressing accounted for the low invalid rate. Inner ear deafness, due to testing engines or flying unprotected, was rare and transient. Air Force men were not kept permanently on noisy trades and permanent damage did not occur. Ear-stops and properly fitting helmets were used. Noise had been found to be a factor in inducing fatigue in flying personnel but was not the only factor. The time-honoured tests were used in testing recruits—largely the whispered voice.

Dr. A. R. **Friel** spoke of the prevention of deafness due to middle-ear disease in school-children. Deafness was commoner in the poorer children, middle-ear disease was not unusual in children under 7, and was nearly always secondary to mouth, nose, or throat conditions, which must also be treated. Conservation of time was of great administrative importance and helped to ensure the coöperation of the relatives; therefore every child should have a precise appointment at the clinic. Zinc ionisation was able to save the situation; in most cases the ear was quite well after two or three visits. Acute cases were given glycerin and carbolic mixture to pour into the ear two or three times a day, keeping the ear filled with it for twenty minutes. The commonest cause of discharging ears after otitis media was tympanic sepsis, followed by external otitis, attic, and mastoid disease. Only the last two were inaccessible to zinc ionisation. In the acute stage the nasal or pharyngeal condition could always be found, but might have disappeared by the chronic stage of the ear condition. Children found blowing the nose difficult, and secretion collected at the back forming a mechanical irritant. Diastolisation was a very important method of treating nasal infection; the nurse or the mother could do it and the results were very good.

Dr. A. H. **Gale** (London) said that from the educational point of view deaf children could be divided into totally deaf, partially deaf (i.e., unable to benefit from ordinary education), and those able to join in general classes but perhaps needing special consideration. The definition of the second group was difficult; the latest figure was 1745 throughout the country (0·35 per 1000), but this was said to be too low. Some authorities would put the incidence as high as 5 per cent. of all school-children. From the educational point of view the hearing of the better ear was what mattered. There was a considerable margin of safety between a defect recorded by the audiometer and a social disability. In the third group the medical aspect was more important than the educational. Increased efficiency in routine inspection could be obtained by a brief examination with an electric auriscope. If the school medical officer detected ear discharge he did all he could be expected to do, but at present many cases were missed. A history of ear trouble taken at a school inspection had shown an incidence of 13·9 per cent. The gramophone audiometer was of great value in detecting cases which could not be recognised by inspection.

Prof. A. W. G. **Ewing** (Manchester) observed that audiometer tests of 27,000 children in Rochester, N.Y., had shown that one child in 76 needed medical and special educational attention for ear defect. The implication was that in this country many cases were being missed. Investigations had been made on the relation between hearing for pure tones and hearing for speech, and the gap between routine tests and everyday hearing could now be bridged. Deafness might not be noticeable to the patient, or to his friends or teachers, until hearing had been very seriously impaired. "Problem" children, with no history of deafness, or children adjudged to be mentally defective or retarded, might prove to have undetected hearing defects which accounted for all the trouble, including speech defects. The whole field of auditory defects appeared ripe for a great advance owing to the revolution in the physics of sound.

Dr. PHYLLIS KERRIDGE reported the result of a test of over a thousand adults who had applied to a commercial firm for hearing aids. There were four chief types: 52 per cent. had maximum loss for high tones, only 5·5 per cent. for lower tones, and 5 per cent. approximately uniform loss, the remaining 37·5 per cent. having loss for middle tones. On the average, 50 per cent. hearing loss equalled 60 decibels of hearing loss, or inability to hear loud speech at an ordinary distance. The figures for deaf children were of the same order. The technique of diagnosis of hearing loss was greatly in advance of that of compensation. Deafness with maximum loss in the middle tones was much easier to compensate than the common type of loss of the higher tones. The National Physical Laboratory was undertaking the difficult tests required.

Major-General P. H. HENDERSON (War Office) discussed the problem as it affected recruiting for the Army. Recruits represented every social class and were probably a fair sample to discuss. Ear trouble was now recorded in the Army records as "middle-ear disease," because this had proved to be the commonest cause of deafness though it might not cause it. ("Deafness" was the old formula.) The drum was inspected in every case, hearing tests being given secondary importance only. Electric auriscopes were used. A series of numbers was read out at 20 feet in a strong whisper, including all ranges of pitch, and each ear was tested separately. In the years 1904–13 the average rejection figure was 3·05 per 1000; in the decennium 1924–33 the figure was 45·45 per 1000. The corresponding figures for discharges (i.e. after enlistment) were 0·42 per 1000 and 5·48 per 1000. This indicated a great increase in the incidence of ear disease, and did not include the many applicants who were rejected by recruiting officers without ever getting so far as medical inspection. There had been a similar increase in other causes of rejection, with the sole exception of the chest measurement, which could usually be brought up to standard by a little instruction in breathing. There seemed to be a grave deterioration in the post-war youth. Some authorities thought the change in figures was due to improved examination; with this view Major-Gen. Henderson, as head of the department concerned, could not agree, but believed the examinations to be less thorough now than before the war. He hoped that things would improve when the present school generation came to recruiting age. Ear disease was the chief cause of rejection of recruits and lost thousands of men for the Army, with the result that the general standard of physique for the Army had to be lowered. The subject was, therefore, of great national importance.

Dr. H. M. S. TURNER (Abingdon) described an apparatus like the audiometer that he had devised many years ago, and the difference he had noted between tone deafness and speech deafness. Some people seemed to be deaf to certain vowel sounds, and if these sounds occurred often in a conversation they thought they were getting deaf and became inattentive; he had called the condition "auditory astigmatism." In his apparatus he had had a switch so that the patient did not know which ear he was listening with; this had proved valuable in detecting malingerers. He commented on the extraordinary complacency with which a running ear was regarded by some practitioners.

The PRESIDENT thought that modern apparatus would greatly improve diagnosis, and this led to treatment. Prevention, however, went back to naso-pharyngeal infection, and possibly to diet. More might be done by early correct dieting than by any other means.

Dr. CROWDEN, in reply, said that certain numbers, like three and one and six, tended to be confused by deaf children. The problem, to be tackled nationally, must be tacked in groups and not individually.

Dr. FRIEL, in answer to questions, said he had never seen any untoward results from the introduction of the diastolisation bougie by a mother; the bougie was usually left in for about five minutes.

PARIS

(FROM OUR OWN CORRESPONDENT)

PROF. LÉON BERNARD

THE death of Léon Bernard at the comparatively early age of 62 was as sudden as it was unexpected. The fatal extension of a dental abscess was a matter only of hours. He combined many qualities. Laboratory worker, clinician, administrator, diplomatist, and orator, he excelled in all these fields, and knew how to fuse his many and great gifts in a forceful and convincing personality. He was at one time professor of public health, and some of his friends wondered why he should have abandoned this chair for that of the newly created chair of tuberculosis. On the face of it, he moved from a wider to a narrower sphere, but whatever public health may have lost by this change, it is certain that the cause of tuberculosis in France owes much of the efficient promotion it has enjoyed during the past decade and more to Léon Bernard. He was tireless. Even at table, on the place where others would put their bread, he placed his telephone, and it was a marvel to those who dined as well as worked with him how ceaseless his activities were; for he remained throughout life a practising physician with an influential clientele and with his own clinic.

PROF. LÉON BERNARD

While Grancher blazed the trail for the welfare of the child exposed to infection at home, providing for his adoption by healthy foster parents, preferably in the country, Léon Bernard went still closer to the root of the matter by organising a system by which the infants of a tuberculous parent could be taken into a healthier environment without the home being broken up. He argued shrewdly that if the tuberculous parent instead of the threatened child be sent away, the home was liable to be broken up by the healthy consort forming new ties in the absence of the tuberculous husband or wife. Léon Bernard gave expression to his appreciation of the Papworth system by introducing it, in a slightly modified form, into France. At the Laennec Hospital in Paris he surrounded himself by a distinguished staff of specialists representing every aspect of tuberculosis work. He was an original member of the Health Committee of the League of Nations, and his association with the International Office of Public Health in Paris brought him many international contacts. Although he scarcely understood spoken English, he frequently visited this country and had a French which nearly everyone understood. A few years ago he succeeded Roux of the Pasteur Institute as president of the Conseil Supérieur d'Hygiène Publique—the highest administrative medical honour in France. He was also secretary to the International Union against Tuberculosis as well as the guiding force in the French National Tuberculosis Committee. He was also a close friend of the Red Cross, both at home and abroad, and his services as an administrator were often required by the League of Red Cross Societies. Not exactly a deep thinker, he had an uncanny ability of sizing things up in essentials and of expressing them faultlessly. A bibliography of his publications would run to several pages. Many of his more recent publications were associated with the names of younger colleagues whose work he had done much to inspire.

His funeral on August 22nd was impressive owing to the number of corporate bodies represented there in their last tribute to a great benefactor. A more permanent memorial may be the establishment in Paris of an international school of advanced studies in hygiene maintained by the State but placed under the authority of the health organisation at Geneva. The project has not gone beyond the formalities of precedure and constitution, but one day it may materialise and be a testimony to Bernard's broad international outlook.

PROBLEMS OF FOOD

THE object of the Food Investigation Board is the improvement of our food-supply. In the 1933 report, Sir Joseph Broodbank, the chairman, says that the Board has always attached the greatest importance to investigations which, putting aside immediate practical needs, aim at increasing the present meagre knowledge of the properties of foodstuffs. Much of the work embodied in the latest report,[1] however, has an immediate application, and there is little to be found in it which does not foreshadow practical advantage in the future.

Fish—Fresh, Thawed, and Pickled

At the Torry research laboratory experiments have been pursued into cold storage of different species of white fish. Fillets of haddock, cod, whiting, gurnard, plaice, and lemon sole were sealed in separate cans, frozen in brine at —20° C., and stored at —21° and —12°. After storage for 4, 6, 8, or 12 weeks the fish were thawed and smoked to a "pale" cure; they are fish which, when fresh, give an equally good cure as regards gloss and translucency, and these characteristics were used as criteria in assessing the effects of cold storage. After six weeks' storage at —21° all the cures were as good as fresh cures, but after 8 to 12 weeks there was a noticeable falling off, except on the part of the lemon sole; at —12° the rate of change was more rapid, all the fish—except the indefatigable lemon sole—giving a cure inferior to a fresh cure after four weeks' storage. The lemon sole, after 12 weeks at —12°, gave a cure that was nearly equal to a fresh cure.

Other work of the laboratory included an investigation of the keeping quality of frozen haddock after thawing. The freshly trawled fish were frozen in brine at —21°, and stored at that temperature for varying periods, ranging up to 6 weeks; they were then thawed in ice. It was found that in most cases thawed fish, after freezing in brine, had browner gills, browner blood, and slightly browner flesh than fresh fish; and that the flesh was usually slightly softer than that of fresh fish for the same duration of storage in ice up to 5 days, though after that there was little difference between the two. But these deviations from normal appearance do not indicate an inferior quality, though there might be some difficulty in marketing the fish in the unfilleted state until this has been explained to the buyers. Neither fresh nor thawed fish acquired the putrefactive smell of stale fish until they had been 12 days in ice, when the characteristic odour was observed to the same extent in both. When thawed fish is to be smoked, smoking should follow immediately upon thawing if a first-class cure is to be obtained.

A short section on the curing of herrings deals with the possibility of obtaining a mild cure which will keep. A hard cure is produced by packing herrings in saturated brine and solid salt. The observers produced a lightly salted brand by soaking herrings in brine without the addition of solid salt. They were undeniably palatable, and the flesh was not desiccated as it is in a hard cure, but after 12 days at a temperature of 10° to 15° C. they were also unmistakably sour, and after 28 days putrid. When kept at 0° C., however, they were sound after 12 days, only slightly sour after 28, and uneatable after 39. At —6° C. they remained sound up to 80 days and are being kept for still longer periods.

Experiments on the growth of micro-organisms indicate that temperatures below —6° C. must be employed if fish is to be kept bacteriologically fresh for any length of time. Studies of the vitamin A in halibut-liver oil show a maximum average content in the spring and a smaller rise in the autumn, in each case following, by about a fortnight, a period when diatoms are especially abundant in the sea.

Some Habits of the Apple

Apples have held a reputation as a mystery fruit since the creation, and they evidently appeal to the curiosity of the Board, for a considerable part of the report is given up to their vagaries. Their study is complicated by the fact that no two strains of apple seem to behave alike. At the low temperature research station the influence of the atmosphere composition upon the incidence of the climacteric in apples has been investigated. The climacteric is "the irreversible change . . . which ushers in the senescent phase of life, and which is accompanied by a marked increase in respiratory activity." Post-climacteric apples rather unfairly evolve a substance which induces the climacteric in other apples which have not yet reached the stage at which it is auto-induced; so that when apples are stored together, as soon as one reaches the climacteric the whole company are affected, whereas, if similar apples are stored in separate containers the self-induced climacterics are spread over a considerable period. As an early climacteric is associated with a short storage life it is important to find some method of storage by which the climacteric is delayed. The observers found that when Bramley's seedling apples—the most important English cooking apples—in the late pre-climacteric stage were exposed to an atmosphere of pure oxygen at 18° C. the incidence of the climacteric was considerably accelerated, but that subnormal concentrations of oxygen delayed the climacteric. Studies have also been made of the respiratory activity of apples in the presence of atmospheres containing the normal 21 per cent. of oxygen, but variable quantities of carbon dioxide. Sturmer pippins were used, and it was found that, with apples in the post-climacteric phase, at 10° C., respiratory activity was depressed by a 5 per cent. concentration of carbon dioxide in the atmosphere, and depressed still further by 10 per cent. In the pre-climacteric phase carbon dioxide seemed to exert no marked effect upon respiration, but it had the effect of delaying the climacteric considerably—a finding which naturally has an important bearing on the gas-storage of fruit.

---

[1] Report of the Food Investigation Board for the year 1933. H.M. Stationery Office. Pp. 248. 4s.

Problems of gas-storage are also being studied at the Ditton laboratory, where routine trials have been made with monarch, Cox's orange pippin, Blenheim orange, and Worcester pearmain. The divergent behaviour of different strains of apple may be noticed in their results, but at least there is enough uniformity for the observers to state that for these four varieties of apple the best results were obtained when both the oxygen and carbon dioxide content of the atmosphere were low—usually in the proportions of 2·5 per cent. of oxygen and 5 per cent. of carbon dioxide. In dealing with Cox's orange pippins the development of the characteristic flavour is the chief consideration. The observers found that though gas-storage retards the development of this flavour it does not destroy it; when the apples had been stored under the favourable atmospheric conditions described above, the full flavour did not develop until they had subsequently been kept in air at room temperature for several days. The importance of these gas-storage experiments can be estimated from the fact that there are now 12 commercial gas-stores for apples operative in England, and several more are being built. They have been designed primarily for Bramley's seedlings; with these the optimum storage atmosphere can be obtained by allowing the apples themselves to generate the necessary carbon dioxide, its amount being controlled by ventilation. Unfortunately this is not a plan which can be followed with most varieties of apple, but the problems of construction which the gas-storage of various strains involves are now being studied.

An inquiry into the vitamin C content of canned apples, carried on at the low temperature station, showed that the removal of the peel before steaming was responsible for a great loss of vitamin during canning. Kohman, Eddy, and Carlsson had previously shown that apples soaked in 2 per cent. salt solution for 18 hours before canning retained their vitamin; but this process makes the canned apples rather insipid and salt to the taste. The workers at the research station found that if apples were cored but not peeled, immersed for a short time in brine to keep them from turning brown, steamed on a hair sieve for 3 or 4 minutes, canned, and then cooked, in the can, for 25 minutes in boiling water, the finished product contained about as much vitamin C as the unpeeled raw apple. Canned apples are not a thing one hears of people eating much in this country, but it is gratifying to know that they can be so efficiently prepared should the demand arise.

Curing of Bacon

Experiments on bacon-curing have been continued at the research station, and in view of the reorganisation of the pig industry a special study has been made of tank curing. Tank pickle contains 25 to 28 per cent. of salt and from 3 to 4 per cent. of saltpetre, according to the recipe followed, but before it can be employed for curing it must be matured by using it to salt heads or small pieces of meat. When mature it contains, in addition to salt and saltpetre, a trace of nitrite, and hæmoglobin and proteins which have diffused out of the meat. Mature pickle can be used over and over again; when a batch of sides is removed from the tank the pickle is found to be more dilute and to have increased in volume, and the strength has to be maintained by the addition of salt and saltpetre before each new batch of sides is put in. The concentration of nitrite and proteins remains fairly constant.

An investigation was also made into the penetration of salt, both by tank curing and dry-salt curing. The electrical resistance decreases as the concentration of salt increases, and can accordingly be measured. In curing Wiltshire sides the interior of the lean meat is injected with pump-pickle before being salted or immersed in the tank. The salt was found to penetrate far more quickly in the pumped sides than in unpumped controls, both in dry-salt and tank curing, and moreover the salt was much more evenly distributed in the mature bacon in sides which had been pumped. Penetration of salt was much more rapid in a lean than in a fat side. Experiments on gas-storage were also carried out on pork and bacon; a side of tank-cured bacon, stored at 0° C. for 18½ weeks in an atmosphere of carbon dioxide, when exhibited in an unsmoked state at Smithfield was pronounced to be hardly distinguishable from fresh bacon. Other sides, A_1 and A_2, from the same pig were dry-salted and stored unsmoked at $-3°$ C.; another pair, B_1 and B_2, were frozen at $-35°$ C. and stored at $-10°$ C. Sides A_1 and B_1 were stored in air, A_2 and B_2 in carbon dioxide. After 8 months they were all taken out of storage and smoked. Both A_1 and B_1, stored in air, were badly dried out and the fat was rancid. There was no rancidity in A_2 and B_2, and they were indistinguishable in appearance from fresh bacon.

Other activities reported by the Board are concerned with respiration in the potato, storage of soft fruits, bacteriological problems of storage, disease in fruit, post-mortem changes in the haddock, biological engineering and engineering problems connected with apparatus, and investigations on meat and its storage. Gas-storage has proved as valuable for meat as for other perishable foodstuffs, and enables meat to be stored at temperatures which preclude the formation of ice in the tissues—a problem of cold storage which has long exercised the trade.

Though the results of many of the inquiries have a universal application, others—notably the investigations on fruit—have little bearing on the problems of overseas producers who are working under quite different conditions. Each area of production must undertake its own research—it cannot be done elsewhere. "Work of this kind," Sir Joseph Broodbank says, "is slow, costly and unimpressive, but it is necessary."

PUBLIC HEALTH

ADULT SERUM IN THE CONTROL OF MEASLES

BY ELWIN H. T. NASH, M.R.C.S., D.P.H.
MEDICAL OFFICER OF HEALTH, HESTON AND ISLEWORTH; CONSULTING PHYSICIAN, MOGDEN ISOLATION HOSPITAL; AND

A. E. GAMMIE, M.B.
MEDICAL SUPERINTENDENT TO THE HOSPITAL

DURING the biennial epidemic of measles which began in November, 1933, an unusually large crop of cases admitted to the Mogden Isolation Hospital proved to be incubating this disease while suffering from another. Accommodation at the hospital is short, and, as it will be so until the newly formed joint board for South-West Middlesex commences to function, it is important to keep the wards fully open. Steps were taken, therefore, to limit the spread of measles within the hospital by protecting susceptible children.

At first, thanks to Dr. R. A. O'Brien of the Wellcome Physiological Research Laboratories, a few doses of convalescent serum were obtained. Five doses of adult serum were also obtained from Dr. D. N. Nabarro at Great Ormond-street Hospital. Soon, however, we had to look for a source of supply of our own, and the District Commissioner of Boy Scouts was asked to obtain volunteer donors of blood among the rover scouts who had had measles. Three volunteered at once, and about 1200 c.cm. of blood were obtained. This was sent to Dr. O'Brien who kindly carried out the necessary tests and put the serum up in ampoules ready for use. When the stock ran low another appeal was made, and three more volunteers came forward with equal readiness. This time a rather larger quantity was obtained.

It will be noted that the doses of adult serum have as a rule been moderate in comparison with the dosage recommended in the L.C.C. report[1] on the measles outbreak of 1931–1932. No sliding scale of dosage according to age was used by us. The average dose given was about 10 c.cm. Possibly our younger class of donor may be found to give a more potent serum, but we feel that it ought to be possible, when protecting children brought up under ordinary urban conditions, to count upon some degree of immunity gradually developing with age, and thus to avoid giving the larger doses recommended for older children. No attempt was made in any of the cases to produce a modified attack, as especially in the hospitals it was desirable to secure complete protection. All injections save one were given on the third or fourth day of exposure.

TABLE I.—*Convalescent Measles Serum*

Sex.	Age.	Dose in c.cm.	Date given.	Result.
F.	1 6/12	4	22/11/33	Protected, but had measles 6/1/34.

F.	5	15	26/4/34	Modified measles 4/5/34.
M.	12	15	26/4/34	Protected.
M.	3	15	26/4/34	Modified measles.
M.	5	12	22/11/33	Protected.
M.	5	20	2/6/34	,,

* In this the period of protection under our definition was exceeded by three days, but the case is classed as unprotected but modified.

TABLE III

Sex.	Age.	Dose in c.cm.	Date given.	Result.
F.	14/12	10	4/5/34	Protected.
F.	6	10	19/2/34	,,
F.	11	12	19/2/34	,,
F.	9/12	7	19/2/34	,,
M.	3/12	3	24/2/34	,,
M.	4	10	1/3/34	,,

The tables show the results obtained in the individual cases. The cases listed as modified are those in which the patient was never really inconvenienced by the disease, having little or no rise of temperature or catarrh, and a pale rash.

During the outbreak in the children's ward of the Hounslow General Hospital, adult serum was used in six cases. All were completely protected. The ward was not closed (Table III.).

Doses of adult serum were also given to three children in private practice, and a dose of convalescent serum to one. All were protected. These cases were not isolated from the source of infection.

Principally as a result of the action of the rover scouts it was possible for the first time on record to keep the isolation hospital and the children's ward open throughout a severe epidemic of measles. During the previous outbreak of measles one of the scouts had to be refused admission to the hospital for acute appendicitis as the ward was closed on account of measles.

Each batch of rover scouts was presented by the mayor at a public council meeting with an illuminated certificate of appreciation over the official seal, and we wish personally to place on record our own indebtedness to them. Our thanks are also due to Dr. C. D. Meadowcroft for taking the blood from the volunteers.

---

[1] London: P. S. King and Son. No. 2996. 2s. 6d.

SUMMARY

Taking as a standard of complete protection freedom from the disease for one month the results are as follows :—

Convalescent Serum (18 cases).

Complete protection .. .. (1 measles six weeks after injection)	16
Complete failure	1
Modified attack	1

One boy was exposed to infection at home five weeks after injection and completely protected.

Adult Serum (32 cases).

Completely protected .. .. (1 modified case five weeks after)	25
Modified cases	6
Modified case five days after injection—i.e., too late for full protection to be likely	1

Standards of Malnutrition in School-children

COUNTY school medical officers have much opportunity of assessing malnutrition in elementary school-children. Dr. W. G. Booth, reporting to the Lincoln (parts of Holland) council gives a comparative table which shows unmistakably the immense improvement of average physique in his area in the past twenty years. He is in a strong position, for it was in his county that Dr. A. W. Tuxford established his well-known standards in the three years preceding 1914. Exactly similar measurements and calculations have been carried out for 1933 by Dr. N. J. England.

Age.	Height (inches).		Weight (lb.)	
	1910–13.	1933.	1910–13.	1933.
Boys 5½ ..	41·4	43·0	39·5	42·4
Boys 12½ ..	55·4	56·8	74·9	80·1
Girls 5½ ..	41·0	42·9	38·3	40·5
Girls 12½ ..	56·2	57·7	76·5	81·4

The average boy is now 4 per cent. taller and 7 per cent. heavier than 20 years ago ; the girl's increase is little less. Dr. England remarks that, judged by the standard of to-day, the normal child of 1913 would be regarded as a case of malnutrition (at all events undersized). For this alteration in physique Dr. Booth can find many causal factors. First the wages of the agricultural labourer are about twice as high as in 1914, while the cost of living is not 50 per cent. up, and the average family is smaller. Yet the present-day labourer has little enough money, for the prices of foodstuffs in his area are higher than in industrial areas, a fact which (Dr. Booth adds) "lends considerable support to the view that the rental of agricultural labourers' cottages must be kept at the lowest possible level if the nutrition of the family is not to suffer." No credit can be given to the school medical service for the change, since the improvement in physique takes place before the children attend school and is only maintained during school years. He does not however discount the influence of education on the mothers who have been led to a realisation of the importance of proper feeding, while the deeper interest in the welfare of children by all classes of society "has had a far-reaching effect upon wages, housing, sickness and every form of communal advancement." Much of this enlightenment, we cannot help feeling, has had its origin in the knowledge of health that has developed in the schools as a result of the existence of a school medical service.

In Cumberland Dr. Kenneth Fraser says that investigation does not reveal increased incidence of malnutrition. The number of cases reported in 1933 was 137 as opposed to 45 in 1932, but he does not think these figures are of great significance. He writes :

> "In the first place, out of a school population of something like 25,000, the percentage increase is very small indeed ; but, apart from that, when any particular subject is in the air more cases are classified accordingly than under normal conditions. This is a psychological fact from which the school medical officer is not free any more than is the man in the street. The trouble of the whole matter, of course, is that malnutrition is not a definite disease like diphtheria or deafness, but is largely a matter of individual opinion. There are no standards of comparison, and when one says that there is no increased incidence of malnutrition one is saying no more than that the physical appearance of the children, their height and weight, their muscular tone, their colouring, appear more or less normal."

Later in the report however he admits that the evidence is not altogether satisfactory, for there has been an increase in the incidence of rickets in young children and in the number of cases of chronic inflammation and ulceration of the eyes—examples (he adds) "par excellence" of the results of malnutrition. That the children have stood the period of economic distress as well as they have is largely due to provision of extra nourishment and milk and to supervision by welfare centres and other agencies.

Dr. C. Franks (Durham) has an interesting note on the "time lag" between a return to employment and any improvement in the nutritional condition of the family. Dr. O. Sullivan (Northumberland) has found that, while defective feeding in adolescence may leave a legacy of physical impairment which persists throughout life, a striking rectification may occur after puberty ; these years may, he suggests, be regarded as a "period which affords great possibilities of physical regeneration, especially if the tide of growth is taken at its flood."

In Hampshire Dr. H. L. Cronk reports in detail on 110 cases of malnutrition, of which the causes were found to be per cent. : fatigue and inadequate rest 20, recent illness 13, incorrect diet 18, oral sepsis 15, unknown 33. In four cases only could it be attributed to poverty. In East Sussex Dr. W. R. Dunstan has for several years made a special study of the ratio between heights and weights of children. He thinks that by the use of tables (and he is a recognised authority on the method) the actual weight at any height can be compared with the standard weight and thus wide variations from the normal are easily detected and a "preliminary sieve" is obtained. In his view any child with weight as much as 7–9 per cent. below the normal should be weighed quarterly and if the deficiency is over 10 per cent. the case should receive special investigation.

In the Isle of Ely Dr. T. C. Lonie has carried out a statistical survey of height, weight, and nutrition, using the tables of Tuxford, Dunstan, and others, and finds that both in height and weight the children of the area are above the standard. He considers that for the measurement of nutrition, comparative tables of heights, weights, and age are valuable, but that a satisfactory height-weight ratio is not enough. The well-nourished child, he says, has also other characters.

> "His posture and general physique are good, his body well covered but not fat, his muscles firm, his skin elastic,

and of good texture, his hair smooth, glossy and of good amount, his organs sound and circulation good; clear of eye and with a bright expression; alive and alert in body and mind. It will be seen, therefore, that there are many respects other than those of height or weight wherein a child may fail to reach the ideal of fitness, and since each of these particulars is capable of being modified by diet, those children who fail to reach the standard may be considered to suffer in some respects from malnutrition and as such to be in need of treatment."

In Kent Dr. J. Selfe divides the under-weight child into seven classes: (1) Normal thin child; (2) Indigestion; (3) Throat infection; (4) Rheumatism; (5) Tuberculosis; (6) Chronic (non-tuberculous) chest trouble; (7) Diabetes and *B. coli* pyelitis. It is certainly important that all who see under-weight children should remember how many other reasons besides lack of food there may be for deficiency in weight, not forgetting the constitutionally thin child who has his own optimum weight.

In Notts Dr. P. H. Deeny has carried out a thorough investigation of 461 children reported by teachers as possibly suffering from malnutrition due to underfeeding. For height-and-weight ratios he used Tuxford's formulæ, not of course gauging the presence or absence of malnutrition by these alone. He found no evidence of widespread malnutrition due to lack of food; in a school population of 49,000 there were only 29 such cases and in these the condition was aggravated by fatigue and ill-chosen diet. The need for instruction of parents in food values appears to him urgent.

Dr. J. N. V. Potts (Yorks, West Riding) finds the Quetelet standard $\frac{100W}{H}$ is the most trustworthy index of malnutrition but not by itself adequate as a guide; his practice is for two examiners to work over the same children to check standards and he has found that the agreement is remarkably close.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 18TH, 1934

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 1973; diphtheria, 992; enteric fever, 31; acute pneumonia (primary or influenzal), 368; puerperal fever, 45; puerperal pyrexia, 103; cerebro-spinal fever, 10; acute poliomyelitis, 18; acute polio-encephalitis, 6; encephalitis lethargica, 7; dysentery, 11; ophthalmia neonatorum, 75. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Inf [illegible] Hospitals of the London County Council [illegible] is as follows: Small-pox, 0; scarlet fev [illegible] 1399; measles, 415; whooping-cough [illegible] r, 20 mothers (plus 7 babies); encephalitis lethargica, 269; poliomyelitis, 4; "other diseases," 261. At St. Margaret's Hospital there were 16 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 12 (2) from measles, 3 (0) from scarlet fever, 12 (1) from whooping-cough, 30 (4) from diphtheria, 49 (13) from diarrhœa and enteritis under two years, and 12 (3) from influenza. The figures in parentheses are those for London itself.

Newcastle-on-Tyne reported the only death from enteric fever. Whooping-cough was fatal in 5 cases at Liverpool. Liverpool also reported 5 deaths from diphtheria, Birmingham 4. Birmingham with 7 showed the highest deaths from diarrhœa, Liverpool following with 4.

The number of stillbirths notified during the week was 264 (corresponding to a rate of 38 per 1000 total births), including 45 in London.

MEDICINE AND THE LAW

Coroner's Jury and Witness

At a Hammersmith inquest this week, where a death apparently due to a traffic accident was being investigated, the deputy coroner found himself obliged to discharge the jury and to adjourn the proceedings to another day. This was because one of the witnesses had been seen talking to members of the jury outside the court. A solicitor's clerk reported the irregularity to counsel engaged in the case, and counsel protested to the deputy coroner. It was not clear that the witness had been practising advocacy or indeed doing more than pass the time of day in conversation, but the incident was rightly described by the deputy coroner as capable of unfairness. Without attributing any sinister intention to this particular witness, we can all appreciate that jurors ought to give their verdict upon evidence heard in open court and not otherwise. Lately, it is believed, the authorities at the Central Criminal Court have been disquieted by suspicions that persons have attempted to tamper with juries at criminal trials; if the fears are well founded, it is a grave matter. Yet, as legal historians have satisfied themselves, it was not always the rule that juries must hearken only to the evidence of publicly examined witnesses. Our jury system traces its pedigree back to the assembly of neighbours who in Norman times were made to give answers on oath out of their own knowledge to questions (usually relating to revenue) administered to them by officers of the Crown. Somehow, by steps which are not conspicuous, a declaration based on personal knowledge of local events was converted into a verdict based on the formal evidence of witnesses. In 1670 Chief Justice Vaughan laid down in Bushell's case the rule that a jury could not be punished for giving a perverse verdict contrary to the evidence. One of his reasons, he explained, was that the jury may have personal knowledge which will assure them that what they hear in court is untrue. Gradually, during the eighteenth century, the modern principle was established. By 1824 a text-book writer was able to state confidently that a juror could not give a verdict founded upon his own private knowledge, although in 1836 (in R. *v.* Rosser) Baron Parke was obliged to admit that it was impossible to prevent a jury in a criminal case from making use of its general knowledge. The coroner's jury seems to provide a missing link in the development of the modern blank-minded juror from his predecessor who was specially selected because he already knew everything without hearing evidence. At any rate there is a curious survival in the oath of the juror at an inquest as prescribed in the Coroners Rules of 1927 (following the Act of 1887 which in turn had followed much earlier precedents). He swears that he will "diligently inquire" and that he will give a true verdict according to the best of his skill and knowledge as well as according to the evidence. The language seems to be a relic of the ancient practice of the Norman period. Yet, inasmuch as coroners have long ago evolved a stabilised judicial technique of examining witnesses and of summing up their evidence to the jury, it is obvious that a juror at an inquest cannot nowadays be encouraged to prosecute his own inquiries outside the court or to discuss the case with a witness in an informal way.

CORRESPONDENCE

PUBLIC EXHIBITIONS OF CRUELTY

To the Editor of THE LANCET

SIR,—In your leading article of August 18th, entitled the Death Penalty and the Public, an interesting point is raised with regard to the influence of executions on the public at large. We read that

> "the sufferings of murderers and their families are still used for public entertainment [by the press] . . . and the sadistic element which is to be found in everyone, normal or abnormal, is regularly exploited in this way, in the name of the State and for the sake of large circulations."

Prima facie, such exploitation will probably strike us as undesirable, degrading, and calculated to increase those sadistic tendencies in all of us which we may deplore but cannot deny. Have we any real evidence, however, that such appetite does in fact grow by what it feeds on ? Is it not rather that sadism tends to become canalised in channels which may be either superficially obvious or deeply hidden, and that sadists (made, like Jesuits, in the nursery) are a menace or an asset to society according as to how successfully their tension is released ? If we consider the professional sadists (amongst whom I would include surgeons, butchers, and those who hunt the fox more than three days a week), we may, and indeed generally do, observe in them a certain grossness and blunting of the finer feelings, but we can hardly claim that they are any more cruel in their social relationships than, shall we say, the average film star or street hawker, whose professional rôle is (presumably) to please.

The present age has brought to a fine art the practice of being kind only to be cruel, and by the studied removal of those outward and visible signs of brutality and violence, in the witnessing of which the average man can release his sadism, we are simply forcing personal and mass cruelty to find other and often incalculable means of satisfaction. It would perhaps be far-fetched to diagraph the decrease in bear-baiting and cock-fighting against the overwhelming increase in divorce, but there can be little doubt that the present century, for all its apparent dislike of open brutality, has witnessed a world war and, in a highly civilised country, a series of official pogroms and murders almost without parallel since the Middle Ages, because in each case the community was psychologically "ripe" for such things to happen. So far, one comparatively harmless outlet has been left unobstructed, and the reading public (with that unerring instinct with which a child starved of sweets makes up for them with bread) has very properly indulged in an orgy of murder, horror, and "war" literature. There is a kernel of truth in the comment:

> The War we suffered not so long ago
> Now makes an excellent *Grand Guignol* show,
> Which earnest youths enjoying cheap sensations
> Call "Propaganda for the League of Nations."

Until we can produce a change of heart in future generations, not by emasculating films or by hearing murder trials in camera, but by a saner and more sympathetic attitude to the infant and child; and by such long-period psychological experiments as those suggested by Dr. Edward Glover (in his book, "War, Sadism, and Pacifism"), we should probably do better to allow the comparatively harmless indulgence of sadistic appetites in public exhibitions of cruelty than to attempt to suppress them. Meanwhile, I for one shall continue to read Edgar Wallace and to attend the all-in wrestling matches at the "Ring" from a stern sense of duty, in the hopes that by so doing I shall save my unconscious the necessity of clapping on the fomentations dangerously hot, or of strangling my last duchess, or of causing my children's feet to stumble at the head of the cellar stairs. And though it is doubtless too late to put back the clock, I should warmly welcome the reintroduction of public executions that the watchers might be purged through pity and horror.

I am, Sir, yours faithfully,

August 20th. EGENS MAURIS JACULIS.

HYPEREMESIS GRAVIDARUM

To the Editor of THE LANCET

SIR,—In her admirable Ingleby lectures on the toxæmias of pregnancy (in your issues of August 11th and 18th) Dame Louise McIlroy describes hyperemesis gravidarum as a symptom of severe toxæmia, to be distinguished from frequent or prolonged vomiting in early pregnancy, which she ascribes to carbohydrate deficiency associated with an anxiety neurosis. She has, however, brought forward no evidence to shake the belief I first expressed twenty years ago that excessive vomiting beginning in early pregnancy is always due to hysterical exaggeration and perpetuation of the morning sickness which occurs in 50 per cent. of normal women, and that there is no dividing line between such cases and hyperemesis gravidarum, the so-called pernicious vomiting of pregnancy. The symptoms and signs which are supposed to indicate the presence of profound toxæmia are, I believe, simply the result of starvation and dehydration, and the artificial termination of pregnancy only acts by suggestion, as the patient naturally expects to recover when what she regards as the cause of her vomiting is taken away.

Dr. J. S. Fairbairn in supporting my views on the subject in 1920 stated that he had not required to terminate pregnancy for vomiting during the previous ten years, and Dame Louise McIlroy has had the same experience in the last ten years. I feel sure that in both cases this is due to the success of the psychotherapy practised in the early stages, in the absence of which severe cases of hyperemesis would have been very much more common, as no less that 60 fatal cases occurred in England in 1930 compared with 38 in 1910 and 34 in 1920. I fancy that Dame Louise really agrees with me, though she has not the courage of her convictions, as she concludes her discussion of hyperemesis gravidarum by saying that success in treatment depends upon "the assurance given to the patient that she has nothing to fear and that she will get well," and that without psychological treatment dieting would be ineffectual.

I feel sure that the psychotherapy is the only essential part of the treatment. I cannot understand the object of giving a patient, who is already suffering from the effects of starvation, nothing by mouth for 24 or 48 hours, nor can there be any need for gastric lavage which can only act by suggestion in the absence of pyloric obstruction or severe gastritis. I doubt whether there is ever any need for special dieting. Twelve years ago I reported in your columns (THE LANCET, 1922, i., 528) the following case :

A woman of 32 was admitted into hospital at the end of the third month of pregnancy. She had vomited all her food since the third week and during the last ten days had retained no fluids. She was very emaciated, her skin was dry and inelastic, and her tongue was dark brown and very dry. Her pulse was 136. The ammonia index of her urine was 28 compared with the normal of 5;

according to Whitridge Williams an increase to 10 per cent. "affords an urgent indication for the prompt termination of pregnancy." In spite of being given fluid by rectum and none by mouth the vomiting persisted. She told me that when she began to vomit her father had said: "You will have a bad time of it, as your mother vomited all the time she was carrying you." I explained to her that there was no real reason why she should have continued to vomit after the first six weeks, but that what her father had said had suggested the idea that the vomiting would continue, and such a suggestion, coming at such a time, was all that was needed to lead to the condition she was now in. We talked about her illness for ten minutes, at the end of which I had succeeded in convincing her that she would not vomit again. I then watched her eat some toast and tea which she had chosen for her first meal. She felt no inclination to vomit. She had a good supper, but vomited her breakfast next morning. She was then transferred to my ward, and had meat and pudding for dinner which she kept down. Except for a slight tendency to vomit after breakfast a week later she had no further trouble, and left the hospital a month after admission having gained 16 lb. in weight. The ammonia index fell rapidly to normal, and the diacetic acid, which had been present in large quantities, disappeared. The pregnancy ran a normal course and a healthy baby was born at full term.

Only those who have watched such a case as this can realise the amazing way in which all signs and symptoms of severe toxæmia disappear when the patient is persuaded to take and to retain an adequate supply of food and fluid.

I am, Sir, yours faithfully,

New Lodge Clinic, August 26th.   ARTHUR F. HURST.

THE SURGEON AND THE GUNMAN

To the Editor of THE LANCET

SIR,—The facts with reference to the treatment by Dr. Clayton May of Dillinger are as follows. Dr. May was not sent to the Penitentiary for failure to report the dressing of Dillinger's wound. He had a perfect right to do this. But after dressing the wound he took Dillinger and two associates of the gunman to a private apartment and kept them there for a week while the authorities were hunting for them. He was sent to the Penitentiary for aiding a criminal to avoid arrest, and the housekeeper of the apartment was sent to the same place on the same charge.—I am, Sir, yours faithfully,

FRANKLIN R. WRIGHT, M.D.

Minneapolis, U.S.A., August 17th.

MEDICINE AND DENTISTRY

To the Editor of THE LANCET

SIR,—The suggestion made by Mr. Meynell Pearson in your issue of August 11th (p. 334), that the alleged shortage of dentists should be made good by newly qualified doctors gradually learning the elements of dentistry by association with dental surgeons in their private practices, ought not to pass unchallenged. It is true that the Dentists Act, 1921, allows doctors whose names appear on the Medical Register to practise dentistry. Since dentistry must be regarded as a special branch of medicine it would have been illogical to debar them. But its highly technical nature makes it incumbent on the doctor who wishes to practise as a dentist to take out a course of study at a dental school. He need not take the L.D.S. examination; on the other hand, unless his name appears on the Dentists Register he would be under a grave disadvantage, for he would not be entitled to undertake any work for members of approved societies—and this work forms an increasingly important proportion of the practices of the majority of dentists.

The course for the L.D.S. covers four years. A doctor by virtue of his medical qualification is exempt from the study of general subjects, such as anatomy, surgery, and medicine, and from examination in those subjects. He is only required to work at a dental school for two years and to take the examinations in dental subjects. As a teacher and examiner for many years I can assure Mr. Pearson that a doctor who wishes to take up dentistry has to work hard during these two years in order to attain a standard of technical ability sufficient to pass his examinations and to practise dentistry with any hope of success. Is it likely that the casual crumbs of knowledge which could be picked up from an "established" dentist, presumably in busy practice, could turn a doctor into a dentist capable of carrying out his work as such efficiently and with benefit to the public? If so why not revert to the old system of apprenticeship?—I am, Sir, yours faithfully,

Brook-street, London, W., August 24th.   A. T. PITTS.

DOES THE PUNISHMENT FIT THE CRIME?

To the Editor of THE LANCET

SIR,—I should like to support Dr. Phillipps's suggestion that the law regarding mental aberrations should be amended. I am a little sceptical regarding the theory of exhibitionism being due to enlargement of the prostate; it is, I think, more likely to be caused by the regression which occurs in senility. No matter what its cause, it is, as Dr. Phillipps says, intensely cruel to punish these old men—some of whom have lived distinguished lives—with imprisonment. Similarly, I believe that perverts, particularly if they are young, should have the benefit of psychological treatment before they are abandoned as hopeless, and even then prison does not seem the right place for them.

There is another side of the question of mental aberration which is equally neglected although equally important. I know of a case of a mentally unstable girl who accused a man of attempted rape. He was tried and sentenced to some months' hard labour. On a number of occasions afterwards this girl accused men of similar behaviour, but was found on each occasion to be virgo intacta. She is now suffering from schizophrenia.

The ignorance of some who should know better is appalling. I have a cutting of an inquest which occurred a few months ago. A man was found to have gassed himself while wearing woman's clothes. The coroner said "the condition in which the man was found was so abnormal as to be beyond his comprehension"—but it would not have been beyond the comprehension of a psychiatrist, and the necessity of having a consulting psychiatrist for such cases is obvious. If those who administer the law are so ignorant of psychological matters can we hope that those who make them will have any more insight? It seems that the only way to bring about a change in the law is for medical men to reiterate the necessity of changing it.—I am, Sir, yours faithfully,

London, August 28th.   CLIFFORD ALLEN.

To the Editor of THE LANCET

SIR,—Dr. Phillipps has done good service in drawing attention to a very important and far-reaching subject. The condition exists and it should be recognised as a disease and not a crime. Many years ago, when I was sitting on the bench, a case convinced me of its existence. A man, probably in the middle sixties, married with a large family, and belonging to the lesser gentry class, was charged with indecency in a public place. The charge was that, late at night, the accused had entered a urinal, had passed the penis through an opening in the eroded iron work, and stood with it there. Curiously the urinal was situated within a short distance of the police office. Attention was called to the circumstances and the man was charged at the next meeting of the magistrates.

The chief constable said he felt compelled to bring this case before the court; there were other cases known to him but he did not wish to mention them. A caution and a fine was inflicted. Within a short period the man was again charged with exposure. No doubt the sitting magistrates would double the fine and further threaten him. The family, however, realising the unfortunate position in which the head was placing them had a strict guard placed upon him, and he troubled the court no more. Before he was gathered to his fathers, to my surprise his family doctor asked me to see him in consultation. I give the bare facts of the case, without comment, in support of Dr. Phillipps's theory.

I am, Sir, yours faithfully,

August 18th. A MEDICAL MAGISTRATE.

GROUND TEMPERATURE AND EPIDEMIC DISEASE

To the Editor of THE LANCET

SIR,—The research on summer enteritis of children in which I assisted the late Dr. de Rienzi Morgan (Morgan's No. 1 bacillus) in 1906–07, established the fact *that the epidemic did not appear until* the 4-ft. earth thermometer registered 56° F. This fact may have a bearing on the recent outbreak of so-called Wimbledon throat, in view of the June average of 56·5° F. registered at Kew this year, being 1·4° F. above the normal. In a very courteous reply to my inquiry the Director of the Meteorological Office has sent me the mean values of ground temperature for England and Wales during the three summer months in conspicuously warm years, and these I hand on for the information of your readers.

Year.	June.	July.	August.	Average of three summer months.
	°F.	°F.	°F.	°F.
1899	55·8	59·6	62·1	59·2
1911	55·9	58·8	61·7	58·8
1921	55·8	60·1	60·4	58·8
1933	56·0	59·5	61·1	58·9
Normal.	54·7	57·7	58·8	57·1

I am, Sir, yours faithfully,

A. WHITE ROBERTSON.

Welbeck-street, W., August 20th.

A PROTEST

To the Editor of THE LANCET

SIR,—An article appears in the *Evening Standard* of August 14th in which my name is freely mentioned, with an *old photograph incorporated. I should* like to assure members of the medical profession *that not one single word on this or any other subject* has been communicated to any representative of the *Evening Standard* by myself or my two secretaries. I wish to make it quite clear that the article and photograph were published without either my knowledge or consent.

I am, Sir, yours faithfully,

Harley-street, W., August 18th. H. D. GILLIES.

MUSHROOM POISONING

To the Editor of THE LANCET

SIR,—The mushroom season is now with us and already one case of poisoning has occurred. In this connexion the observations of Fabre are worth recording. Briefly he states ("The Life of the Fly"; trans. by De Mattos) that in the district of Serigan where he resided for 30 years he never heard of a case of poisoning from mushrooms; that he attributed this immunity to the custom of the peasants of boiling all fungi in salt and water as a preliminary preparation; that the peasants ate indiscriminately all fungi, even those reputed to be poisonous; that he, together with friends, had proved the correctness of this by themselves eating the same poisonous fungi so treated. I met a man collecting "Jews' ears" in this neighbourhood who told me that they always soaked them in salt water before preparing them for the table.—I am, Sir, yours faithfully,

Easterton, Wilts, August 25th RICHARD LAKE.

IONISATION OF THE UTERUS

To the Editor of THE LANCET

SIR,—In your report (p. 376) of my paper read at the B.M.A. section of electro-therapeutics the substitution of "discharge from the cervix" for "discharge from the *uterus*" has altered the entire meaning of my communication. Treatment of the cervix by zinc or copper electro-deposition is a ready means of cure of discharge which originates from the cervix.

When the discharge comes from the body of the uterus treatment may be very difficult, because much patience and skill are required in order to pass the *electrode up beyond the inflamed cervical canal.* But this can be accomplished and, where no source of discharge is present beyond the uterus itself, cure is certain. I am, Sir, yours faithfully,

Devonshire-place, W., August 23rd. AGNES SAVILL.

ADMINISTRATION OF FLUID IN GALL-STONE SURGERY

To the Editor of THE LANCET

SIR,—Mr. E. R. Flint's article on the problems of gall-stones *in your issue of August 18th* concludes with the following astounding sentences:—

> "I have had a considerable experience of this [the intravenous method], and for those cases which really require fluid I am certain it has very great advantages over any other parenteral method; 50 pints can be given without trouble in 4 or 5 days, and is for the most part retained, since there is no obvious sweating or proportionate increase in urinary excretion."

The following criticisms of these statements are so obvious that one is diffident about making them:

1. The only advantage which the intravenous method has over other methods is the rapidity of the addition of fluid—its main disadvantage is the extremely rapid elimination of fluid which has been added. It is also the only method by which such *enormous quantities of fluid* could be added to the blood stream, but such quantities are never necessary. *If there is true dehydration* five pints are as effective as fifty.
2. There are other paths for the elimination of water from the body besides the kidneys and skin.
3. Perception of "obvious sweating" is not an accurate method of estimating water elimination through the skin.
4. A more accurate method of assessing the amount

of retained fluid is to weigh the patient; if the "most part of 50 pints" were retained the patient would have gained about two stones in weight in five days!

5. If this quantity were retained the patient would show œdema of the tissues or heart failure, or both.

The low mortality rate in Mr. Flint's series of cholecystectomies must depend on his operative skill and not on such a preparation for operation. Moreover, such a procedure is obviously inadvisable in a group of people in whom there is a high incidence of myocardial degeneration.

I am, Sir, yours faithfully,

Derby, August 20th. DOUGLAS HUBBLE.

THE WOES OF A HOSPITAL RESIDENT

To the Editor of THE LANCET

SIR,—In view of the present interest in the harmful effects of noise, it is surprising that those responsible pay so little attention to the design of hospitals, for it is doubtful whether any other person is so much exposed to irritations and interruptions as a hospital resident. For some years, in my bed-sitting room, I have been exposed to a cross-fire of the following:—

> Piano, loud-speaker-gramophone, door-bell, ambulance noises, another gramophone, howls from infants' wards, groans from men's ward, chapel organ on Sundays, nurses' rising bell, noises from kitchen and bathroom two yards away, comings and goings of all and sundry. Add to the above the strain of living with several others in crowded quarters and the futility of trying to sleep before midnight.

I doubt whether the usefulness of my reading is augmented thereby; certainly my contributions to medical thought are not as numerous, nor my value to my patients as great as they might be if only I could have quiet.

Oh, for a gas-oven and a shilling's-worth of sleep!

I am, Sir,

A FRENZIED CORRESPONDENT.

A BREACH OF CONFIDENCE

To the Editor of THE LANCET

SIR,—I should be grateful if you would bring to the notice of your readers the following instance of breach of confidence with regard to medical reports for compensation cases, as I feel that a very big principle is involved.

I had examined a man several times for an insurance company from the surgical point of view, and a colleague examined him from the medical side, both of us reporting fully and frankly to the company concerned. When I was recently asked to examine the man, I found to my surprise that he had in his pocket copies of my own and my colleagues reports, and also of the report of a surgeon who had examined the man for his own solicitor. He was thoroughly disgruntled about various remarks made by myself and my colleague, and extremely resentful that it should have been suggested that there was any connexion between the payment of compensation and his disability. Possession of the report of the surgeon who examined him for his own solicitor had had a particularly bad effect on him, and the moderate physical disability from which he suffers was enlarged to cover his whole mental horizon.

I took the matter up with the insurance company for whom I was reporting on his condition and they informed me that they had exchanged medical reports with the man's solicitor and that the solicitor had without their consent or approval handed them over to the man on his insisting on seeing them. The company wrote to the solicitor protesting at this breach of confidence, and apparently he admitted his error and expressed regret. I feel however that this is a glaring instance of breach of professional confidence and that the medical profession generally should be warned to insist that these reports are confidential, and under no circumstances, without the consent of the examining doctor or surgeon, should they be shown to the person examined.

I am, Sir, yours faithfully,

"CONSULTING SURGEON."

THE "GAS WEDGE" IN THE ÆTIOLOGY OF FISTULA IN ANO

To the Editor of THE LANCET

SIR,—In his letter on this subject in your issue of August 18th it surprises me that Dr. Young Kenny has omitted all mention of an obvious aggravating factor in the causation of what might be termed "rectal hypertension." I refer to that form of self-control imposed upon us by the demands of modern polite society. Indeed, Dr. Kenny's letter has revealed for us in a new way the wisdom of that popular saying:

"Where'er you be,
Let your wind go free."

I am, Sir, yours faithfully,

A. L. JACOBS.

University College Hospital, W.C. 1, August 21st.

INDIAN MEDICAL SERVICE

Lt. J. M. Davidson relinquishes his prob. appt.

The undermentioned grant of leave has been made by the Commander-in-Chief in India: Maj.-Gen. T. G. F. Paterson, D.S.O., Deputy Director of Medical Services at Northern Command headquarters, on leave until October.

DEATHS IN THE SERVICES

The death is announced from London, Ontario, of Col. Claude Kyd Morgan, who was a distinguished member of the R.A.M.C. After graduating in medicine at Aberdeen in 1893 he entered the Corps in the following year, and shortly afterwards, being promoted captain, distinguished himself for plague duty in Poona. His work was highly commended in a resolution of the Government of Bombay. He did excellent service in the European war, was thrice mentioned in despatches, received the C.M.G. in 1916, and was an officer of the Legion of Honour. He was a member of the British Mission to Washington in 1918, and at the close of the war was appointed C.B. He was a Knight of Grace of the Order of St. John of Jerusalem. Col. Morgan was a Scotsman and was born at Inverkeilor, Montrose, in 1871; he married in 1905 Eleanor, daughter of the late Mr. T. H. Smallman of Ontario. She was created O.B.E. in 1919.

OBITUARY

GEORGES DREYER, C.B.E., F.R.S.

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF OXFORD

THE death has been announced from Denmark of Prof. Georges Dreyer which occurred at Söllestedgaard, Laaland, on August 17th. The event was due to a sudden heart failure; he was 61 years of age.

PROF. DREYER

[Photograph by Elliott & Fry

Georges Dreyer was the son of Captain G. H. N. Dreyer, an officer in the Danish Royal Navy; his mother was the daughter of a well-known Danish jurist, Judge W. T. Qvistgaard. He was born at Shanghai and having decided, after preliminary education, to enter the medical profession, he graduated in medicine at the University of Copenhagen and embarked upon a long course of post-graduate study. From this there emerged some fine original work, biological and chemical, on, for example, the action of light and the estimation of toxins in all of which he manifested his devotion to quantitative methods and the close application of mathematics. He was undoubtedly influenced by Madsen.

In 1907, having made real mark, he was appointed professor of pathology at Oxford with a fellowship at Lincoln College in accordance with the procedure adopted both at Oxford and Cambridge of electing university professorships to a college society. The compliment thus paid to a young foreigner was a high one, and Dreyer earned his new position by the thoroughness with which he undertook the duties. During the seven years before the war he worked strenuously for the organisation and advancement of his department, while he made contributions,
resulting from original wc quently in
collaboration with Dr. E. W. , on the
therapeutic effects of ligh many
important problems of inflan n, and
immunity. Most of the p ibuted
to the *Journal of Pathology* and
were seen to redound great f the
Oxford school.

At the outbreak of war Dr to

on the patients in the base hospital at
Extreme care was taken to classify all cases
in accordance with the results of detailed
logical examination, particularly as regar
differentiation between *B. typhosus* and *B.*
typhosus, although it was found that prote
could be effected simultaneously against both
using a mixed vaccine. Details of the research we
published in the first instance in our columns e
in 1915. Records were continued in 1918 when
report was published by Prof. Dreyer, associated agai
with Gibson and Walker, with the assistance
Mr. Duncan Gardner, then bacteriologist to th
Standards Laboratory. This record of useful wo
took the form of a report to the Medical Researc
Committee. The consecutiveness of the two doc
ments was marred by the incidents of the war, th
latter communication being originally written i
1916 when the material already completed, with
other valuable data, was lost by fire. The report was held back in the hope that the details of certain of the investigations might be forthcoming later, but this unfortunately did not take place. Though the observations were worked out in a limited manner the authors were able to establish points of great practical importance in support of the production of immunisation by means of typhoid, paratyphoid A, and paratyphoid B. Dreyer determined the detailed form and time relations of the immunity curves for agglutinins following a single or a repeated dose of this triple vaccine; he showed how the time interval between the first and second inoculation influenced the effects. Immunity lasted far longer when the second dose was given at a time when the first had reached its maximum effect; this suggested the advisability of lengthening the interval between them to about three weeks. The standard suspensions prepared in Dreyer's laboratory for this work were issued for general use, making it possible to compare results in terms of agglutinin units and so to follow
of the unity reaction in different

pointed out that when Dreyer applied the measurement for the vital capacity to the assessment of physical fitness he had found the older methods of estimation inadequate, as they were based on assumed relationships between age, height, and weight which could not be substantiated. Dreyer had set out the principles of his researches into vital capacity in tabular form, and with elaborate mathematical calculations had demonstrated the connexions between vital capacity, the weight of the body, the sitting height, and the chest circumference. A clear deduction from this work was, he considered, that the careful study of vital capacity in its proper relation to the body size could give guidance as to the effects to be expected from the sanatorium treatment of pulmonary tuberculosis. In 1920 he published bservations bearing upon the matter in collaboration with Dr. L. S. T. Burrell, who contributed clinical notes of the cases seen in Brompton Hospital, and took the measurements required for application of formulæ, which had emerged from Dreyer's previous investigations into vital capacity. The great variations in vital capacity which must depend upon occupation and modes of life of the individuals being admitted—the athletic and outdoor subject displaying greater capacity than the sedentary one—Dreyer held that these differences in normal persons were not solely related to fundamental bodily deficiency. The careful analysis made by himself and Burrell of the signs revealed by patients of different ages and sexes yielded the practical points that in pulmonary tuberculosis there is a distinct decrease in vital capacity as compared with the normal individual; that an improvement in the clinical condition of the patient under treatment is accompanied by increased vital capacity, while the advance of the disease resulted in a decrease. Thus the vital capacity, the work suggested, could be used as a quantitative measure of benefit received and as an assistance in classification and diagnosis. Dreyer was elected F.R.S. in 1921, served on the Medical Research Council for a period, and was a fellow of the Royal Danish Academy of Letters and Science.

While such are the researches and their results with which Dreyer's name will be most closely associated, he was an endless experimenter and has left behind him incomplete much work, some of it in connexion with his first great subject of interest, the biochemical effect of light rays. But though closely occupied in the duties of his appointment, always interpreted by him in a large fashion, he found time to become an important figure in university life; he was for many years on the Hebdomadal Council, was a curator of the University Chest, and an energetic worker in the affairs of Lincoln College. As teacher and colleague he commanded the high respect and regard of those who worked with him and much well-
d ony to his private and social virtues
public. We are permitted to publish

mathematician he could not tolerate inaccurate work, and his orderly nature required neatness and cleanliness in his laboratory, and he saw that he got them. His work requires no comment from me, but his last published paper on Bovine Tuberculosis, in collaboration with Dr. R. L. Vollum, illustrates the care and the time which he gave to his experiments before he was satisfied with the findings. Georges Dreyer's kindness and thoughtfulness were unfailing; his lovable disposition and large-hearted recognition of the merits of others will live always in the memories of the many to whom he set his great example."—M. C. R.

Prof. Dreyer married in 1900 Margrete, daughter of Laurits Jörgensen, of Söllestedgaard Manor, Laaland, who survives him. He died in her Danish home.

ROBERT ALEXANDER GIBBONS, M.D., F.R.C.S. Edin., F.R.C.P. Lond.

We regret to announce the death of Dr. Gibbons, well known as an obstetrician and gynæcologist although he held no teaching appointment in the London teaching schools, which occurred on Thursday last, August 23rd, at his house in Cadogan-place, London. His interests ranged beyond the technical side of his specialty, for his studies, especially of the causes of sterility in women, led, late in his career, into advanced pathological studies and the deliberation of eugenic questions.

Robert Alexander Gibbons was educated at University College, and completed his medical education at University College Hospital, St. George's Hospital, and the University of Edinburgh. He graduated M.B., C.M. Edin. in 1874 and later proceeded to the M.D., taking also the diploma of F.R.C.S. Edin. At Edinburgh he was house physician and house surgeon at the Royal Infirmary, and was also president of the Royal Edinburgh Medical Society. He took a course at the Rotunda Hospital, Dublin, and held several residential appointments in England, and coming to London was both house surgeon and house physician at Great Ormond-street Children's Hospital.

Gibbons was therefore unusually well-equipped when more than 40 years ago he established himself in general practice in Cadogan-place, London, in the house where he died. He soon became favourably known to a large number of patients; he made practical contributions to medical literature and became a frequent speaker at the Obstetrical Society. He was appointed physician for the diseases of women and children at the St. George's and St. James's Dispensary and at the Royal Pimlico Dispensary, and also physician to the Grosvenor Hospital for Women and Children. Various aspects of his practical experience he recorded in the articles on sterility, dyspareunia, and dysmenorrhœa, contributed to Latham and English's "System of Treatment," and other papers from his pen deserving of mention are articles on the influence of the gonococcus on the female pelvic organs contributed to the *Practitioner*, and on the causation of the onset of labour contributed to the *British Journal of Obstetrics and Gynæcology*.

Some ten years ago various aspects of eugenics, made familiar to him from his professional work, attracted his attention, and he wrote on contraception temperately and with clinical acumen. But his final interest was in an attempt to find out an explanation for the onset of labour. How closely he had thought of the matter, and how intelligently as well as assiduously he had availed himself of assistance where his equipment failed him, may be seen in an article speculating on the rôle of the fœtus in labour, published in THE LANCET last June. Entirely as a result of personal cost and efforts he raised a small fund to be employed by a research worker on this problem and recently investigations were conducted into the question at the Courtauld Institute of Biochemistry. One who was in a position to follow this work writes to us: "It was remarkable to see the way in which Gibbons would follow up the results and his industry in reading the literature which might assist in the investigations. Despite his age and the fact that he did not enter the field of experimental pathology until late in his career he acquired a remarkable grasp of the principles of modern endocrinology as applied to sex hormones."

Gibbons, who was elected F.R.C.P. Lond. and F.C.O.G. was a Knight of Grace of the Order of St. John of Jerusalem. His courteous and handsome presence will be missed at the deliberations of the Council of Epsom College whose meetings he attended regularly.

CECIL W. HUTT, M.D. Camb., M.R.C.P. Lond.

WE regret to announce the death, on August 20th, of Dr. C. W. Hutt, medical officer of health for Holborn, in his fifty-fifth year.

Cecil William Hutt was born in 1880 and was educated at St. Paul's School, going on to Trinity College, Cambridge, with a sizarship. He took first-class honours in his tripos in 1901, and completed his medical education at St. Bartholomew's Hospital, gaining the Brackenbury medical scholarship in medicine and the Matthews Duncan prize in obstetrics. After qualifying in 1905 he held a house appointment at Bart.'s and a series of resident appointments in Manchester and Liverpool before his bent for the preventive side of medicine led him to take the D.P.H. Oxon., and accept the post of assistant M.O.H. at Warrington. From that time his promotion in the public health service was steady: deputy M.O.H. for Brighton, M.O.H. for Dudley, M.O.H. for Richmond (Surrey), and finally in 1922 the chief medical officership of a London borough, which he was holding at th

greatly widened the possible range of its activities he gladly took the opportunity offered of revising Crowley's "Hygiene of School Life." It was a source of regret to him that his work in Holborn, important and interesting though it was, cut him off from this and other branches of preventive medicine, although through the child welfare centres he was able to initiate one of the first attempts to immunise London school-children against diphtheria. He was perhaps never completely at home as a municipal officer; "M.O.H.'s," he once remarked, "should be civil servants responsible only to the Government." But he held teaching appointments at Charing Cross and the Royal Institute of Public Health, at the latter institution training D.P.H. students in the routine duties of an M.O.H. In this way he came into contact with students from India and other parts of the Commonwealth and found himself happy in society of this kind. His class instruction was by no means confined to his own borough, but extended to institutions of all kinds in the metropolitan area and he took his students as far afield as Southend and Brighton.

Hutt was a ready writer and a frequent contributor to medical journals at home and abroad on public health and social matters. His book on hygiene for health visitors and social workers was one of the best of its kind—lucid in exposition and concise in information—and he collaborated with Sir William Hamer in "A Manual of Hygiene" (1925) which went far beyond its original modest aim of meeting the needs of those seeking to obtain a public health diploma. A more comprehensive work on preventive medicine, edited jointly with Dr. Hyslop Thomson, is in the press. A volume on "International Hygiene" (1927) was the result of congenial holiday visits to continental countries in search of new and fresh methods of dealing with problems which interested him. His instinctive leanings were cosmopolitan and on these tours he would as gladly interview a simple peasant as a distinguished colleague if there was knowledge to be gained. During the past year he had given much time as technical advisory officer to the subcommittee preparing a scheme for dealing with the refuse of London. He was in fact always ready to help with his store of knowledge in the solution of any difficult problem. He gave himself little time for pursuits not in some way connected with his work. He was however always a keen country rambler, and in recent years had taken up sailing with great enjoyment. As a Thameside resident the attraction of the river gripped him, and there he spent much of his summer leisure. He had evidently en working beyond his strength for some months but his death was unexpected outside the circle friends.

Hutt married, in 1909, Jennie, daughter of te Mr. Hesse of Richmond, and leaves a widow ur grown-up children, one of whom is at present at his f r's college at Cambridge, while has rece lified at St. Mary's Hospital.

f
VO

: "A few details as to may form an interesting ry notice in THE LANCET embrey married Cicely, rake, rector of Jevington, dren, five sons and five happy family life, and all ced in their choice of a profession by their father's scientific outlook, two of them being medical men, one being a veterinary surgeon, the profession for which the youngest is at present studying, while another son is studying agriculture at Oxford. Others have spoken of his work, which was in directions very different from mine, but I can say that as a teacher he was inspiring and had a gift of attracting his pupils and of getting the best out of them by not only being ready to help them but by listening to their views and arguing with them when necessary. A Tory at heart he was a reformer in deed. However forcible he was at times in argument and, indeed, in objurgation, no one who knew him could take offence, first, because the kindly spirit was always obvious, and, secondly, because he generally turned out to be right. His discourse was salted with wise sayings, especially from biblical sources. His favourite quotation, 'All things work together for good,' is characteristic of the man and is to be the epitaph on his tomb."

PANEL AND CONTRACT PRACTICE

The Llanelly Dispute

THE dispute between the doctors serving the Llanelly area and the local workmen's medical committee, in which about 18,000 workers and their dependents are concerned, drags on in spite of meetings arranged to compose the differences under the chairmanship of the mayor. The committee expressed dissatisfaction that the service did not provide certain drugs and preparations, and the doctors were asked either to accept lower fees or to provide the drugs. In support it was pointed out that in 1921, when the rates of payment were agreed, there was an understanding that when wages fell in the district the rates were to be subject to revision. The committee also argued that the work required from the doctors was substantially less owing to the introduction of two specialists for eye, and ear, nose and throat, work paid out of additional contributions, and owing to medical and dental treatment provided for schoolchildren by the local authority. When the workmen's committee gave notice to the 19 doctors concerned of a reduction in payment for medical attendance from 10*d.* to 6*d.* per month for single persons, and from 1*s.* 8*d.* to 1*s.* per month for married persons with dependents, they were met by united resistance to the proposal. Last May the Insurance Acts Committee, sitting as the National Defence Trust, in view of the proposed displacement of insurance practitioners by salaried whole-timers, declared its competence to offer financial support to practitioners who sustained monetary loss in resisting the demands of the workmen's committee; and under the signature of Dr. Robert Forbes, deputy medical secretary, a statement has been issued that the resources of the B.M.A. are to be utilised to maintain the honour of the profession and the well-being of the public.

Local practitioners have now set up a public medical service providing full general practitioner treatment and some consultant service. The rates of this service are the same as existed under the old arrangements, single workmen contributing towards the service in the same degree as before—in spite of the fact that they are entitled to medical benefit under the Insurance Act; but the matter is not quite so simple as might appear, because the workmen's committee controls the local hospitals and has great influence with the local authority. The committee's reply is to start a new medical service with doctors on a whole-time salaried basis. Of the two doctors secured one is believed to have been engaged under a misapprehension, for on discovering the actual state of affairs he resigned. The two specialists engaged by the committee have tendered notices terminating their contracts. Dr. Oscar Williams, secretary to the Llanelly doctors, addressing a public meeting, is reported to have said that 70 per cent. of the workmen have adhered to their doctors. The workers who have thus accepted the public medical service in preference to the committee's scheme propose to form a separate body so that they can be represented in medical matters with delegates from various local works.

The dispute is becoming a serious matter, and unfortunately it cannot be ventilated in the House of Commons until after the recess. In the meantime it should be possible to discover how far the grievances are felt to be serious by the working people themselves. The position of any medical men who take up work for the committee can hardly be other than difficult, and the conditions will be such as to offer little attraction to really good candidates. Disputes of this kind have generally been composed in the past owing to the workmen's committee finding itself unable to obtain competent men to do the work. In the early days of the service they were more frequent owing to the pernicious amendment in the original Act allowing approved "institutions" to use financial payments made to them on behalf of insured persons with no official audit. In the present dispute it should surely be possible for the 18,000 workers and their dependents to see that they are unlikely to get adequate attendance from two or possibly three full-time outsiders when their own 19 doctors did not give them as much as they wanted. Is it not a case in which an inquiry by the Ministry of Health might clear the position?

Births, Marriages, and Deaths

BIRTHS

BRIGG.—On August 22nd, at Chipping Norton, Oxfordshire, the wife of D. A. Brigg, M.B., B.S. Lond., of a daughter.

BUTLER.—On August 14th, at a nursing-home, Cambridge, the wife of Richard Weeden Butler, F.R.C.S., of a son.

RICHARDS.—On August 20th, the wife of F. Alan Richards, B.Chir., M.B. Camb., of a son.

WARNER.—On August 21st, the wife of E. C. Warner, M.D. Lond., of a son.

WIGFIELD.—On August 23rd, the wife of Alan Wigfield, M.B., B.S. Lond., of a daughter.

MARRIAGES

PARR—HERON.—On August 23rd, at Holy Trinity Church, Brompton-road, London, Percy Crowe Parr, M.B., T.C.D., to Dorothy, second daughter of Mr. and Mrs. H. H. Heron, North Finchley.

WINGFIELD—KERR.—On August 15th, at the Parish Church, King's Norton, John Martin Wingfield, M.R.C.S., L.R.C.P., to Madge Durie, younger daughter of Mr. and Mrs. J. Durie Kerr, of King's Norton.

DEATHS

GIBBONS.—On August 23rd, Robert Alexander Gibbons, M.D. Edin., Knight of the Order of St. John of Jerusalem.

HARVEY.—On August 22nd, at Fareham, Hants, Joshua Harold Harvey, O.B.E., M.R.C.S., L.R.C.P. Lond., aged 67.

MACNAMARA.—On August 24th, after a short illness, Eric Danvers Macnamara, M.D., F.R.C.P., of Harley-street, W.

TURNER.—On August 21st, Olive Muriel Turner, M.B., M.S. Lond., the wife of Alfred Charles Turner, of the Bank of England, Liverpool.

WICKHAM.—On August 16th, *at Cobbles, Sutton Scotney,* George William Wickham, L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg., L.S.A.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

his equipment failed him, may be seen in an article speculating on the rôle of the fœtus in labour, published in THE LANCET last June. Entirely as a result of personal cost and efforts he raised a small fund to be employed by a research worker on this problem and recently investigations were conducted into the question at the Courtauld Institute of Biochemistry. One who was in a position to follow this work writes to us: "It was remarkable to see the way in which Gibbons would follow up the results and his industry in reading the literature which might assist in the investigations. Despite his age and the fact that he did not enter the field of experimental pathology until late in his career he acquired a remarkable grasp of the principles of modern endocrinology as applied to sex hormones."

Gibbons, who was elected F.R.C.P. Lond. and F.C.O.G. was a Knight of Grace of the Order of St. John of Jerusalem. His courteous and handsome presence will be missed at the deliberations of the Council of Epsom College whose meetings he attended regularly.

CECIL W. HUTT, M.D. Camb., M.R.C.P. Lond.

WE regret to announce the death, on August 20th, of Dr. C. W. Hutt, medical officer of health for Holborn, in his fifty-fifth year.

DR. HUTT

[*Photograph by H. J. Whitlock*

Cecil William Hutt was born in 1880 and was educated at St. Paul's School, going on to Trinity College, Cambridge, with a sizarship. He took first-class honours in his tripos in 1901, and completed his medical education at St. Bartholomew's Hospital, gaining the Brackenbury medical scholarship in medicine and the Matthews Duncan prize in obstetrics. After qualifying in 1905 he held a house appointment at Bart.'s and a series of resident appointments in Manchester and Liverpool before his bent for the preventive side of medicine led him to take the D.P.H. Oxon., and accept the post of assistant M.O.H. at Warrington. From that time his promotion in the public health service was steady: deputy M.O.H. for Brighton, M.O.H. for Dudley, M.O.H. for Richmond (Surrey), and finally in 1922 the chief medical officership of a London borough, which he was holding at the time of his death. This orderly career was interrupted only by the war, when he held a temporary commission in the R.A.M.C. and served in Egypt, being invalided home in 1917 with dysentery, from the effects of which he never wholly recovered. He had wide interests and a knowledge of several languages. At Brighton he was senior school doctor, and his zest in the development of the school medical service remained with him, so that when the Education Act of 1918 greatly widened the possible range of its activities he gladly took the opportunity offered of revising Crowley's "Hygiene of School Life." It was a source of regret to him that his work in Holborn, important and interesting though it was, cut him off from this and other branches of preventive medicine, although through the child welfare centres he was able to initiate one of the first attempts to immunise London school-children against diphtheria. He was perhaps never completely at home as a municipal officer; "M.O.H.'s," he once remarked, "should be civil servants responsible only to the Government." But he held teaching appointments at Charing Cross and the Royal Institute of Public Health, at the latter institution training D.P.H. students in the routine duties of an M.O.H. In this way he came into contact with students from India and other parts of the Commonwealth and found himself happy in society of this kind. His class instruction was by no means confined to his own borough, but extended to institutions of all kinds in the metropolitan area and he took his students as far afield as Southend and Brighton.

Hutt was a ready writer and a frequent contributor to medical journals at home and abroad on public health and social matters. His book on hygiene for health visitors and social workers was one of the best of its kind—lucid in exposition and concise in information—and he collaborated with Sir William Hamer in "A Manual of Hygiene" (1925) which went far beyond its original modest aim of meeting the needs of those seeking to obtain a public health diploma. A more comprehensive work on preventive medicine, edited jointly with Dr. Hyslop Thomson, is in the press. A volume on "International Hygiene" (1927) was the result of congenial holiday visits to continental countries in search of new and fresh methods of dealing with problems which interested him. His instinctive leanings were cosmopolitan and on these tours he would as gladly interview a simple peasant as a distinguished colleague if there was knowledge to be gained. During the past year he had given much time as technical advisory officer to the subcommittee preparing a scheme for dealing with the refuse of London. He was in fact always ready to help with his store of knowledge in the solution of any difficult problem. He gave himself little time for pursuits not in some way connected with his work. He was however always a keen country rambler, and in recent years had taken up sailing with great enjoyment. As a Thameside resident the attraction of the river gripped him, and there he spent much of his summer leisure. He had evidently been working beyond his strength for some months past, but his death was unexpected outside the circle of his friends.

Dr. Hutt married, in 1909, Jennie, daughter of the late Mr. Hesse of Richmond, and leaves a widow and four grown-up children, one of whom is at present studying at his father's college at Cambridge, while another has recently qualified at St. Mary's Hospital.

THE LATE PROF. M. S. PEMBREY

A CORRESPONDENT writes: "A few details as to Pembrey's family history may form an interesting appendix to your good obituary notice in THE LANCET of August 4th. Prof. Pembrey married Cicely, daughter of the Rev. E. E. Crake, rector of Jevington, Sussex, and had ten children, five sons and five daughters. His was a very happy family life, and all five sons have been influenced in their choice of a profession by their father's scientific outlook, two of them being medical men, one being a veterinary surgeon, the profession for which the youngest is at present studying, while another son is studying agriculture at Oxford. Others have spoken of his work, which was in directions very different from mine, but I can say that as a teacher he was inspiring and had a gift of attracting his pupils and of getting the best out of them by not only being ready to help them but by listening to their views and arguing with them when necessary. A Tory at heart he was a reformer in deed. However forcible he was at times in argument and, indeed, in objurgation, no one who knew him could take offence, first, because the kindly spirit was always obvious, and, secondly, because he generally turned out to be right. His discourse was salted with wise sayings, especially from biblical sources. His favourite quotation, 'All things work together for good,' is characteristic of the man and is to be the epitaph on his tomb."

PANEL AND CONTRACT PRACTICE

The Llanelly Dispute

The dispute between the doctors serving the Llanelly area and the local workmen's medical committee, in which about 18,000 workers and their dependents are concerned, drags on in spite of meetings arranged to compose the differences under the chairmanship of the mayor. The committee expressed dissatisfaction that the service did not provide certain drugs and preparations, and the doctors were asked either to accept lower fees or to provide the drugs. In support it was pointed out that in 1921, when the rates of payment were agreed, there was an understanding that when wages fell in the district the rates were to be subject to revision. The committee also argued that the work required from the doctors was substantially less owing to the introduction of two specialists for eye, and ear, nose and throat, work paid out of additional contributions, and owing to medical and dental treatment provided for school-children by the local authority. When the workmen's committee gave notice to the 19 doctors concerned of a reduction in payment for medical attendance from 10*d.* to 6*d.* per month for single persons, and from 1*s.* 8*d.* to 1*s.* per month for married persons with dependents, they were met by united resistance to the proposal. Last May the Insurance Acts Committee, sitting as the National Defence Trust, in view of the proposed displacement of insurance practitioners by salaried whole-timers, declared its competence to offer financial support to practitioners who sustained monetary loss in resisting the demands of the workmen's committee; and under the signature of Dr. Robert Forbes, deputy medical secretary, a statement has been issued that the resources of the B.M.A. are to be utilised to maintain the honour of the profession and the well-being of the public.

Local practitioners have now set up a public medical service providing full general practitioner treatment and some consultant service. The rates of this service are the same as existed under the old arrangements, single workmen contributing towards the service in the same degree as before—in spite of the fact that they are entitled to medical benefit under the Insurance Act; but the matter is not quite so simple as might appear, because the workmen's committee controls the local hospitals and has great influence with the local authority. The committee's reply is to start a new medical service with doctors on a whole-time salaried basis. Of the two doctors secured one is believed to have been engaged under a misapprehension, for on discovering the actual state of affairs he resigned. The two specialists engaged by the committee have tendered notices terminating their contracts. Dr. Oscar Williams, secretary to the Llanelly doctors, addressing a public meeting, is reported to have said that 70 per cent. of the workmen have adhered to their doctors. The workers who have thus accepted the public medical service in preference to the committee's scheme propose to form a separate body so that they can be represented in medical matters with delegates from various local works.

The dispute is becoming a serious matter, and unfortunately it cannot be ventilated in the House of Commons until after the recess. In the meantime it should be possible to discover how far the grievances are felt to be serious by the working people themselves. The position of any medical men who take up work for the committee can hardly be other than difficult, and the conditions will be such as to offer little attraction to really good candidates. Disputes of this kind have generally been composed in the past owing to the workmen's committee finding itself unable to obtain competent men to do the work. In the early days of the service they were more frequent owing to the pernicious amendment in the original Act allowing approved "institutions" to use financial payments made to them on behalf of insured persons with no official audit. In the present dispute it should surely be possible for the 18,000 workers and their dependents to see that they are unlikely to get adequate attendance from two or possibly three full-time outsiders when their own 19 doctors did not give them as much as they wanted. Is it not a case in which an inquiry by the Ministry of Health might clear the position?

Births, Marriages, and Deaths

MEDICAL NEWS

University of London

As announced in our last issue Prof. G. Grey Turner has been appointed to the university chair of surgery tenable at the British Post-Graduate Medical School at Hammersmith. The chairs of medicine, obstetrics, and pathology have already been filled by the appointment of Prof. F. R. Fraser, Dr. James Young, and Prof. E. H. Kettle (see THE LANCET, 1934, i., 1423).

Mr. Grey Turner, who is at present professor of surgery in the University of Durham, and senior surgeon to the Royal Infirmary, Newcastle-upon-Tyne, was educated at Newcastle and graduated in medicine in 1898. He took up post-graduate study in London, Paris, and Vienna, became M.S. Durh. in 1901, and F.R.C.S. Eng. in 1903, and was surgical registrar at the Royal Infirmary from 1900 until 1906, when he joined the honorary staff. In these capacities and as university lecturer in surgery he showed great interest in teaching. During the late war he served on the surgical side of 1st Northern General Hospital in Newcastle and with a general hospital in Mesopotamia, where he was acting consulting surgeon at Amara; later he worked as consulting surgeon for chest surgery in the Northern Command, and went on a War Office mission to the United States. He has also visited America on three other occasions; in 1931 he delivered the John B. Murphy oration in Philadelphia, and in 1932 the Bigelow medal was conferred on him after an address in Boston, U.S.A. Likewise he has visited the principal surgical clinics on the continent. In 1927 he succeeded to the chair of surgery at Durham, and two years later he was invited to take charge of a surgical unit at St. Bartholomew's Hospital for a short period, being made a perpetual student of the medical college. At the Royal College of Surgeons of England he is a member of the council and has been Hunterian professor. He has also delivered the annual oration of the *Medical Society of London*, in 1929. *Prof. Grey* Turner is editor of a new edition of "Modern Operative Surgery," which is now in the press, and is a contributor to Choyce's "System of Surgery." He has contributed papers to the medical press dealing with a large variety of surgical subjects, including many on cancer. He is especially interested in the history of surgery.

Society of Apothecaries of London

Sir George Buchanan, C.B., F.R.C.P., has been appointed Master of the Society for 1934–35. Sir William Willcox, K.C.I.E., F.R.C.P., and Dr. J. S. Fairbairn, F.R.C.P., have been reappointed senior and junior wardens respectively.

At recent examinations the following candidates were successful:—

Surgery.—F. A. Frank, Univ. of Liverp.; F. M. Kerry, Univ. of Durham; and J. T. Moohalaparackel, Queen's Univ., Belf.

Medicine.—S. Adams, Charing Cross Hosp.; T. D. R. Aubrey, Univ. of Oxf. and Bristol; M. T. Curran, Univ. of Leeds; A. H. El. S. El Mahallawy, Royal Colleges, Edin.; R. C. H. Ensor, Univ. of Belf. and Guy's Hosp.; F. A. Frank, Univ. of Liverp.; W. H. Jervis, Univ. of Manch.; C. W. O'Donoghue, London Hosp.; J. F. Owen, Univ. of Camb. and St. Mary's Hosp.; H. Paroulakis, Univ. of Innsbruck and St. Mary's Hosp.; and D. Walton, Univ. of Manch.

Forensic Medicine.—F. G. S. Alderson, Univ. of Leeds; F. A. Frank, Univ. of Liverp.; and W. H. Jervis, Univ. of Manch.

Midwifery.—J. A. Amor, St. Mary's Hosp.; N. A. Bicchieri, St. George's Hosp.; D. P. Hickey, Univ. of Manch.; F. M. Kerry, Univ. of Durham; and K. P. Pauli, Univ. of Bristol.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery:—

F. G. S. Alderson, M. T. Curran, J. T. Moohalaparackel, C. W. O'Donoghue, J. F. Owen, and H. Paroulakis.

An Exhibition of Inventions

The tenth international exhibition of inventions, which has been organised by the Institute of Patentees, will take place in the Central Hall, Westminster, London, from Oct. 3rd to 13th. It will be open from 11–10 daily.

Chartered Society of Massage and Medical Gymnastics

The annual congress of this society will be held at Bedford College for Women, Regent's Park, London, N.W., from Sept. 24th to 28th. The first lecture will be delivered by Prof. John Fraser on vascular disturbances of the extremities. The founder's lecture will be given by Sir Humphry Rolleston who will speak on occupational diseases of those in attendance on the sick. The meetings are open to all medical practitioners and further information may be had from the secretary of the society, Tavistock House (North), Tavistock-square, London, W.C.1.

Prof. Bernhard Zondek has accepted an invitation to become director of the obstetrical and gynæcological unit of the Hadassan-Rothschild Hospital in Jerusalem. Dr. Zondek was formerly professor of obstetrics and gynæcology in the University of Berlin, and has made important contributions to the study of sex hormones.

National Smoke Abatement Society

The annual conference of this society will be held at Glasgow from Sept. 27th to 29th under the presidency of Dr. H. A. Des Voeux. The speakers will include Dr. J. R. Currie, Dr. J. S. Owens, and Dr. J. Johnstone Jervis. Particulars may be had from the general secretary at 36, King-street, Manchester 2.

Photographic Documentation in Science

The second congress of the Association pour la Documentation Photographique et Cinématographique dans les Sciences will be devoted to the work of its physical and chemical sections, including surgery. It will take place at the Musée Pedagogique de l'Etat, 29, Rue d'Ulm, Paris, from Oct. 4th–12th. The secretary of the congress is Dr. Claoué, 39, rue Scheffer, Paris XVI.

Medical Officers of Schools Association

A meeting of this association will be held at the Town Hall, Grove-road, Eastbourne, on Saturday, Sept. 15th, at 10 A.M., when Dr. J. Alison Glover and Dr. Fred Griffith will read a paper on acute streptococcal throat infections. The secretary of the association may be addressed at 11, Chandos-street, London, W.1.

Middlesex Hospital Medical School

On Oct. 1st, at 3 P.M., the hundredth winter session of this school will be opened, when Dr. Henry MacCormac delivers an address entitled Our Profession. The prizes gained during the previous year will afterwards be distributed by Sir Farquhar Buzzard. The address and prize-giving will take place in the Queen's Hall, Langham-place. On the same evening the annual dinner will be held at the Savoy Hotel.

Memorial to Dr. Stenhouse Williams

On Oct. 13th Sir Hilton Young, the Minister of Health, will open a library, which has been established at the National Institute for Research in Dairying, at Shinfield, near Reading, as a memorial to Prof. Stenhouse Williams, the late director.

Blindness in Buckinghamshire

The National Institute for the Blind announces that during the past two years there has not been one blind child under 5 years of age in the whole of Buckinghamshire. Out of a total blind population of 310 in the county, exactly 200 are over 50 years of age, and of these 111 are over 70 years of age.

Enlargement of Porth Hospital

A new ward of this Glamorganshire hospital was recently opened by Sir W. J. Thomas and Lady Thomas. The ward, which has cost £7000, is named after the three children of the openers in recognition of the benefactions of the Thomas family to the institution.

Medical Society of London

The programme for the first half of the 162nd session of this society opens with the annual general meeting at 8 P.M. on Monday, Oct. 8th, after which, at 8.30 P.M., Lord Horder will give a presidential address on medicine and morals. Subjects for the Monday evening discussions are as follows: Oct 22nd, the anæmias and their treatment, to be introduced by Dr. Leslie Witts; Nov. 26th, the value of accessory methods in the diagnosis of intracranial tumours and allied conditions (Mr. Hugh Cairns); and Dec. 10th, the future of diagnostic radiology (Dr. H. Graham Hodgson). On Nov. 12th there will be a clinical meeting. The Lettsomian lectures for 1935 will be delivered by Mr. J. E. H. Roberts, and the annual oration by Sir William Willcox.

A Children's Ward at Ilfracombe

The Ilfracombe Tyrrell cottage hospital has been enlarged by the addition, at a cost of £2500, of a children's ward containing ten cots. There are also three wards for paying patients.

Donations and Bequests

Among other bequests, the late Miss Constance Leete-Absolon, of East Sheen, left £2000 to the Royal Hospital, Richmond, part of which is for the endowment of a bed, and £1000 to St. Mary's Children's Hospital, Paddington Green, for a cot to be called the "Leete-Absolon Cot."—The late Mrs. Constance Blyth Watson, of Lindfield, Sussex, widow of Innes Watson, barrister-at-law, left £6000 to Dr. William F. Simpson "in recognition of his great kindness to my late husband during his long illness and to myself during that strenuous and anxious time."

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

Monday, Sept. 3rd, to Saturday, Sept. 8th.—Infants Hospital, Vincent-square, S.W. Course in Infants' Diseases. All-day.—Medical Society of London, 11, Chandos-street, Cavendish-square, W. Lecture-Demonstration by Dr. A. E. Clark-Kennedy on Pleural Pain, at 2.30 P.M., on Tuesday, Sept. 4th.—National Temperance Hospital, Hampstead-road, N.W. Lantern-demonstration on Some Practical Points in the Diagnosis and Treatment of Urological Cases, by Mr. H. P. Winsbury-White, at 3 P.M., on Saturday, Sept. 8th.—Panel of Teachers. Individual clinics in various branches of medicine and surgery are available daily.—Courses of instruction, clinics, &c., arranged by the Fellowship are open only to members and associates.

Appointments

Figdor, Julius, L.D.S., has been appointed Dental Surgeon to the City of London Maternity Hospital

Macdonald, C. R., M.B., F.R.C.S. Edin., Assistant Registrar and Tutor at the Jessop Hospital for Women, Sheffield.

Simmonds, F. A. H., M.B. Camb., D.P.H., Tuberculosis Medical Officer under the Middlesex County Council.

Stewart, Prof. M. J., M.D. Glasg., F.R.C.P. Lond., Hon. Pathologist to the Leeds Public Dispensary and Hospital.

Royal Liverpool Babies' Hospital, Woolton.—The following appointments of honorary physicians are announced:—
Gaisford, W. F., M.D. Lond., M.R.C.P. Lond.: and
Forshall, Isabella, M.B. Lond., F.R.C.S. Edin.

Royal Sussex County Hospital, Brighton.—The following appointments are announced:—
Castleden, L. I. M., M.D. Lond.;
Price, R. Kemball, M.D. Lond.; and
Windle, R. W., M.B. Camb., Honorary Medical Registrars.
Mackenzie, K. F., M.B. Dub., F.R.C.S. Irel.;
Williams, J. C. F. Lloyd, M.B. Camb., F.R.C.S. Eng.; and
Wood, W. R. Forrester, M.B. Camb., F.R.C.S. Eng., Honorary Surgical Registrars.
Drynan, A. E., M.B. Edin., Honorary Clinical Assistant to the Dermatological Department.

Certifying Surgeons under the Factory and Workshop Acts: Scholefield, B. G., M.D., M.Ch. Oxon., F.R.C.S. Eng. (Great Malvern, Hay, Hereford, Ledbury and Leominster Districts); Poole, J. C. C., B.Chir., M.B. Camb. (Crowborough District of the County of Sussex); and Newman, T. B., L.R.C.P.I., and L.M., L.R.C.S.I. (Mullion District of the County of Cornwall).

Vacancies

For further information refer to the advertisement columns

All Saints' Hospital for Genito-Urinary Disease, St. George's-road, S.E.—Res. H.S. At rate of £100.
Birmingham and Midland Eye Hospital.—Res. Surg. O. At rate of £200.
Birmingham Ear and Throat Hospital.—Third H.S. At rate of £150.
Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. £200.
Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.
Brighton Sanatorium and Infectious Disease Hospital.—Jun. Res. M.O. At rate of £150.
Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
Central London, Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Assts. in Out-Patient Dept.
Cobham, Surrey, Schiff Home of Recovery.—Res. Surg. O. At rate of £200.
Coventry and Warwickshire Hospital.—Res. Cas. O. £125.
Deal, Walmer and District War Memorial Victoria Hospital.—Hon. Physician.
Derby, Derbyshire Royal Infirmary.—Cas. O. and Orthopædic H.S. Also H.S. for General Surgery, &c. Each £150.
Dewsbury and District General Infirmary.—Hon. Orthopædic Visiting Surgeon. Also H.S. £150.
Doncaster Royal Infirmary.—H.S. £175.
Doncaster Royal Infirmary and Dispensary.—Two Hon. Asst. Surgeons.
East Ham Memorial Hospital, Shrewsbury-road, E.—H.S. and Cas. O. At rate of £120.
Egypt, Ministry of Education.—M.O. for Girls' Schools. £E.40.
Exeter, Royal Devon and Exeter Hospital.—H.S., and H.S. to Ear, Nose, and Throat Dept. Each at rate of £150.
Great Yarmouth General Hospital.—H.S. £140.
Harrogate and District General Hospital.—H.P. and Cas. O. Each at rate of £150.
Hove General Hospital.—Res. M.O. At rate of £150.
Hull Royal Infirmary.—Hon. Asst. Physician.
Leamington Spa, Warneford General Hospital.—H.S. for Cas. and Spec. Depts. £150.
Leicester Royal Infirmary.—Two H.S.'s, Cas. O., H.P., and Two Jun. Res. Anæsthetists. Each £125. Also Jun. Cas. O. £100.
Macclesfield General Infirmary.—Second H.S. At rate of £150.
Manchester, Abergele Sanatorium.—Second Res. Asst. M.O. £350.
Manchester, Ancoats Hospital.—Res. M.O. At rate of £150. H.P. At rate of £100. Also Med. Reg. £50.
Manchester and Salford Hospital for Skin Diseases.—H.S. At rate of £100.
Manchester Royal Children's Hospital.—Two Asst. M.O.'s for Out-patient Dept. Each at rate of £150.
Manchester, St. Mary's Hospitals.—H.S.'s Each at rate of £50.
Margate and District General Hospital.—Res. M.O. £150.
Market Drayton, Salop, Cheshire Joint Sanatorium.—Res. Asst. M.O. £350.
Middlesbrough, North Riding Infirmary.—Hon. Surgeon.
Miller General Hospital, Greenwich-road, S.E.—H.P. and H.S. Each at rate of £100.
Mothers' Hospital, Salvation Army, Lower Clapton-road, E.—Jun. Res. M.O. At rate of £80.
Northampton General Hospital.—Four Res. M.O.'s. Each £150. Also Sen. Res. M.O. £250.
North Middlesex County Hospital.—Jun. Res. Asst. M.O. At rate of £250.
Norwich, Norfolk and Norwich Hospital.—H.S. to Spec. Depts. £120.
Preston, Biddulph Grange Orthopædic Hospital.—Jun. H.S. At rate of £150.
Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Res. M.O. At rate of £150. Also H.P. and Cas. O., H.S. and Cas. O. Each at rate of £110.
Princess Elizabeth of York Hospital for Children, Shadwell, E.—H.P. and Cas. O. Each at rate of £125.
Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.
Radium Institute, Riding House-street, W.—H.S. At rate of £150.
Richmond, Surrey, Royal Hospital.—Jun. H.S. At rate of £100.
Royal London Ophthalmic Hospital, City-road, E.C.—Sen. Res. O. At rate of £150.
Royal National Orthopædic Hospital, 234, *Great Portland-street, W.*—H.S. At rate of £150.
Royal Northern Hospital, Holloway, N.—H.S. Also Obstetric H.S. Each at rate of £70.
St. Mary's Hospital, W. (Venereal Disease Dept.).—Part-time Asst. Director. £350.
St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—H.S. £75.
Salford Royal Hospital.—Hon. Asst. S. Also Two H.S.'s., and Cas. H.S. Each at rate of £125.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.
Scarborough Hospital and Dispensary.—H.S. At rate of £175.
Sheffield Children's Hospital.—H.P. and H.S. Each at rate of £100.
Sheffield, Jessop Hospital for Women.—Res. M.O. At rate of £150.
Sheffield Radium Centre.—Asst. M.O. £300.
Shrewsbury, Royal Salop Infirmary.—Res. H.P. At rate of £160.
Stoke-on-Trent, North Staffordshire Royal Infirmary.—Asst. H.P. £125.
Watford and District Peace Memorial Hospital.—H.S. At rate of £150.
West Bromwich and District General Hospital.—H.S., H.P., and Cas. O. Each at rate of £200.
West London Hospital, Hammersmith-road, W.—H.P. Also 2 H.S.'s to Special Depts. Each at rate of £100.
Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Holt, Norfolk.

Medical Referee under the Workmen's Compensation Act, 1925, for the Aberdeen, Peterhead and Stonehaven Sheriff Court Districts. Applications should be addressed, the Private Secretary, Scottish Office, Whitehall, London, S.W.1, before Sept. 12th.

NOTES, COMMENTS, AND ABSTRACTS

A CHINESE-RUN HOSPITAL

SURG.-COMMANDER J. CUSSEN, R.N., sends us (with permission of the Foreign Office and the Admiralty) an account of the Central Hospital in Nanking which was opened last July on the Chungshan-road overlooking the aerodrome. Most of the hospitals in Yang-tse outposts are under American or British supervision, and the operations are done by foreign surgeons. In this hospital the foreigner would be entirely under the care and treatment of Chinese, there being only one foreign doctor out of a staff of 40. Commander Cussen was shown over the hospital by Dr. J. Heng Liu, the medical director. The framework consists of a central tower, containing the only lift in Nanking, with two long wings each three stories high. The out-patient departments are on the ground floor, classification being much the same as in any London hospital. The first floor contains the beds for poorer patients, who pay 60 cents per diem, the wards being particularly large and airy; "the wall seemed to be all windows," Commander Cussen remarks. Walls and floors are of glazed cement, the beds well spaced, bedsteads painted white, and no sign of spitting on the floor. Above are the first-class patients, who pay 90 cents per diem, which includes medical and nursing attention. There are in all 350 beds, of which 280 were occupied at the time of Commander Cussen's visit. February is recognised as one of the healthiest months of the year in China and the number suggests how well the hospital is patronised even during the slack period. The total cost works out at about 2000 dollars per diem, paid by grant from the central government as the hospital is State-owned. There was, says Commander Cussen, a great air of bustle and slickness about the whole place; it was a weekday on which he inspected the hospital, through all of which he moved quite freely, being much impressed by the orderly routine and daily work of a big organisation. At present the hospital has no medical school, although the nurses, both male and female, are trained there as well as midwives. In the near future it is hoped to have classes and teaching staff for medical students. Most of the electrical fittings and some of the instruments were of German origin, some from America and Vienna; Commander Cussen could find no instrument or object which had been purchased in England. Every appliance likely to help physician or surgeon in his work was there.

The public health department, situated behind the hospital, is a building rather like the hospital in miniature. It might fairly be called the child of Dr. Heng Liu, who is himself vice-minister of public health in the central government. Commander Cussen found there one of the most complete and up-to-date laboratories he had seen. Vaccines are made in the department for protection against cholera, typhoid, and small-pox. There is a room allotted to malaria research, with many types of anopheles in bottles, and charts illustrating the cycle of the disease. Schistosomiasis has a room to itself. The rooms used for preparing health charts and lantern slides in schools interested him especially; models illustrating rashes of scarlet fever, measles, and small-pox were being made. He watched a youth with a plaster cast of a face in one hand and a wire heated over a Bunsen burner in the other, using melted wax to depict small-pox in the vesicular stage—an Epstein at a salary of 80 cents a month. The original models were purchased in Vienna and copies are being made at almost nominal cost. Statistics of tropical diseases are being sent to this department from the country districts, and wall-maps with coloured flags show the prevalence of disease in China. Commander Cussen was impressed by the Stork machine, a ready-reckoner with hand and dial representing months, weeks, and days; by a twist of the handle the expectant mother is told when to date the probable date of labour. Wassermann and Kahn tests are carried out in the laboratory which makes its own antigen for the purpose. Students in the laboratory were preparing mercurochrome in quantity. Throughout there was the appearance of smartness that accompanies recently purchased first-class apparatus, but although, like the hospital, it is still waiting to be proved by time, Commander Cussen was satisfied himself that both had a distinguished future before them.

CANADA AND THE EMPIRE

CANADA has been pleased that Ottawa was selected for the great conference called together with the object of welding the commerical and industrial interests of the Empire, and the *British Trade Review* for July, 1934, in a large and fully illustrated issue, does justice to the industry and perseverance of the country. The letterpress has been supplied by representative and often very important writers, and the general position of the commercial relations between this country and Canada is excellently set out. The exhibition of Canadian products recently held in St. Paul's Churchyard, E.C., was a proof of material progress, and on many of the stalls were to be seen domestic appliances, articles of clothing, and foodstuffs with direct interest to doctors and others in charge of health agencies or health-promoting industries. Canada is now Britain's chief supplier of some of these articles, and the Exhibition proved that coöperative methods within the Empire are on the increase in a practical and valuable manner.

TUBERCULOSIS AT BREST

SOME three years ago we quoted [1] from a paper on tuberculosis at Brest, which ended on a note of confidence that there was to be less in future. But there has since appeared in the same journal another paper,[2] by J. Querangel des Essarts, not quite so encouraging. The situation is undoubtedly remarkable. Whereas the general death-rate of the French navy from tuberculosis is 5·3 per 1000, it is 9·6 in the Brest division. Likewise in the garrison of Brest it is 8·5, or double the general rate of the French army; in the dockyard it is 10·5, and in the town 5·28 (7·9 in the worst districts). The town has 70,000 inhabitants, and is somewhat isolated in its position at the extreme end of the Department Finistère, its main industry being the navy and the dockyard. Some people think Bretons specially liable to consumption, but they give no indication of this susceptibility when they are settled in French colonies abroad. The trouble at Brest is that there is great overcrowding and the families are large. Among the families of invalids visited by des Essarts, of those numbering from 5 to 12 persons, half were living in one room. The surroundings ashore are thought more dangerous than in ships, and it is proposed to reduce the liability to tuberculosis by improving conditions of life, by giving help to invalids to get treatment, by segregating them from their families (who will then themselves need assistance), and by B C G inoculation for their children.

ACCIDENTS IN PNEUMOTHORAX TREATMENT

Dr. E. Frommel and Dr. M. Demole have endeavoured to calculate the frequency of accidents during the induction of a pneumothorax or a subsequent refill (Rev. de la Tuberc., 1934, No. 1). In order to secure adequate data they addressed a questionnaire to the leading chest specialists and sanatoriums in Switzerland, and obtained information about more than a quarter of a million injections. Among these there were 63 accidents—0·28 per 1000—of which only 5 were fatal. About a quarter occurred at the first injection, the remaining three-quarters being associated with a refill; but as, on the average, the patient has some 50 refills in the course of four to five years' treatment and only one first injection, the comparative danger

ADDRESSES AND ORIGINAL ARTICLES

CONCOMITANT SQUINT AND ITS TREATMENT *

BY L. H. SAVIN, M.D., M.R.C.P. Lond., F.R.C.S. Eng.

ASSISTANT SURGEON TO THE ROYAL EYE HOSPITAL; JUNIOR OPHTHALMIC SURGEON TO KING'S COLLEGE HOSPITAL; OPHTHALMIC SURGEON TO THE METROPOLITAN AND WHIPPS CROSS HOSPITALS

THE disadvantages of a squint need little emphasis. At school a squinting child is very apt to suffer from his fellows' youthful dislike of the abnormal; his friends call him "boss-eye," and his enemies exercise a somewhat crude sense of humour at his expense.

Hence the psychological implications of a squint are always worth consideration; but the chief object of treating it is neither the psychological nor the cosmetic one, but the prevention of amblyopia in the squinting eye.

The ætiology of concomitant strabismus is still not altogether understood. Hippocrates[1] recognised a distinction between paralytic and concomitant squint. The latter he thought due to epilepsy, or in some cases to heredity. A parent with a cross-eye often had a cross-eyed child. In 1738 we hear of an operative cure for squint by the Chevalier Taylor, a flamboyant but intelligent quack oculist whose adventures were well described by Coats.[2] The details of the operation were surrounded by deliberate mystification; but the evidence appears to point to Taylor having discovered the secret of tenotomy of the internal rectus. It is difficult to decide how far he was scientist and how far charlatan. The secret discovered by this Englishman was forgotten. It is not till the next century, in 1839, that we have the first authenticated tenotomy of the internal rectus on the living subject by Dieffenbach.[3] Anthony White and Stromeyer[4] had both previously suggested the operation.

At this period the muscular theory of squint held the field. It was thought that strabismus was due to shortening of one of the ocular muscles. In fact such shortening is quite frequently found in a case of long-established squint limiting the movements of the eye in one direction. We now know that such changes are secondary, and are not the primary cause of the condition. Most squints are dynamic and will pass off under an anæsthetic.

In 1864 the great Donders[5] pointed out the association of hypermetropia with many cases of squint. Uncorrected hypermetropia requires the exercise of a constant effort of accommodation; and he observed that normally accommodation is associated with convergence. He suggested that this was the cause of squint, the eye of greater refractive error converging more and turning in. This association of accommodation and convergence is well demonstrated in the following cases.

A girl, aged 12, was said to suffer from transient attacks of partial blindness. On examination her vision was found to be about 6/36 in each eye. I noticed that the eyes now and again converged in a spasmodic fashion. With a −1·75 sphere before each eye she saw 6/6 easily. When the refraction was worked out under a cycloplegic she was found to be emmetropic. This spasm of convergence and of accommodation appeared to be of reflex origin; it cleared up after treatment of a conjunctivitis from which she suffered. Some such cases appear to be hysterical. A youth of 18 years had a narrow escape in a car accident and then complained of diminished vision. On examination both eyes were turned in and in a spasm of accommodation. Under a cycloplegic the convergence was at once materially reduced and soon cleared up.

Donders's theory was of enormous practical value, as it led to the careful correction of refractive errors in squint, under which treatment many cases clear up. Obviously, this theory cannot explain such cases of squint as those in which the refractive error is negligible or in which an eye with poor vision starts to squint, as in the squints so commonly found in cases of central corneal nebulæ in one eye. Obviously, also, there must be some other factor involved, or all cases of high hypermetropia would squint. In Donders's writings one finds the germ of an explanation. He wisely remarks: "The desire to see an object singly with both eyes, at the same moment, makes itself, as a general rule, energetically felt." In this country Claud Worth[6] particularly has stressed the important part played by the "fusion sense" in the causation of squint. Binocular vision he classifies in three grades:—

1. Simultaneous macular perception.
2. True fusion with some amplitude.
3. Sense of perspective.

To this grouping one may perhaps be allowed to add a fourth grade or subgroup—"Highly developed sense of perspective." Anybody who works with a stereoscope finds it more difficult to get a sense of perspective with some pairs of pictures than with others. Some patients who can get simple perspective effects on such a stereoscope as the Worth's amblyoscope, for instance, fail entirely to get the perspective effect with more complicated pictures.

If a series of squint cases is examined it will be found that all have defects in binocular vision. Worth considers defect of the fusion sense the primary factor in the production of squint. A case with high astigmatism in one eye only or with a corneal nebula will obviously have defective fusion and so will be more likely to squint.

Defective fusion sense is not the only factor involved. I recently worked out the degree of binocular vision in 12 medical students all of whom had good visual acuity. Only 7 had perfect binocular vision; 3 achieved plane fusion; 2 had only simultaneous macular perception. None of these students squinted. Many people in ordinary life get on quite happily on plane fusion. A car can readily be driven in the country on second grade binocular vision, though stereoscopic vision is of great help in town driving.

The ordinary person has a master eye on which he mainly depends, usually the right eye. The second eye fills in a few details not visible to the master eye. The truth of this is readily apparent if one tries to use the other eye for shooting.

For the development of a squint some other factor is usually necessary besides defective fusion sense. It may be a neuromuscular incoördination—e.g., following measles, pertussis, or other specific fevers. In some cases, the convergence-accommodation coördination is rendered more difficult by hypermetropia, as Donders described. In high myopia there is little accommodation for close work; the eyes fail to converge; diplopia results and the image of the worse eye is suppressed. The fusion sense becomes more defective and the myopic eye tends to diverge, producing a divergent concomitant strabismus.

---

* A post-graduate lecture delivered at King's College Hospital.

Sometimes the factor predisposing to squint is of such a nature as to suggest some abnormality of genes or chromosomes. Among my strabismus cases are two little girls, identical twins. They are almost indistinguishable now that I have operated on their squints. Features and temperaments are alike; both have rough, dry skins; both have epileptic fits; one is slightly more shy and less round-faced than the other. Their squints were like mirror images; one squinted in the right eye, the other in the left. The refractions were similar, but right and left sides were reversed. Ormond [7] reported a series of mongolian idiots in which 21·4 per cent. had squints. I cannot but suspect that the factors which caused their epicanthic folds, ridged tongues, crooked little fingers, adducted great toes, and mental retardation might possibly be concerned with their squints. In the language of modern genetics, some idiokinetic influence has acted on the chromosomes and their genes; not a very different conception from that of Shakespeare in *King Lear* (Act III., sc. 4):—

> "This is the foul fiend Flibbertigibbet: . . . he gives the web and the pin, squints the eye, and makes the hare-lip."

SUPPRESSION OF VISION

Once a squint has set in, the natural result will be diplopia, as indeed is often seen in paralytic strabismus and heterophorias in adults. The child gets over this difficulty by suppressing the vision in the squinting eye, the eye becoming amblyopic—the so-called amblyopia ex anopsia (weak vision from disuse). This term hardly gives a true conception of what occurs. The process is more in the nature of an active inhibition of vision. One is apt to think of suppression of vision solely as a pathological phenomenon in squint. Actually we tend to suppress or suspend the vision of one eye every time we look down a microscope. I had the curiosity to investigate the power of suppression in a number of normal people. They varied from complete inability to suppress to the power to suppress the vision of one eye at will. I have had much experience in helping medical students to use the ophthalmoscope. Most students can acquire the power of suppression in one eye; but there seem always in each group to be one or two men who have the greatest difficulty and very likely have persistently to close the eye which they are not using for the instrument. At the other extreme are people who suppress with extreme readiness—e.g., hysterical monocular blindness. The amblyopia of the hysteric presents considerable resemblance to that found in squint. It does not seem to be of conscious origin; I have often been thanked with what seems complete sincerity by an hysteric whose blindness has been relieved. Hysterical amblyopia, like amblyopia in squint, may be of long duration.

Ten years after the war I saw a man who lost all but perception of light in his right eye during some frontier fighting in India. The story was that he lost his memory for some hours and then found himself some miles behind the front line. His condition was diagnosed as sunstroke, and he found he could not see with the right eye "owing to a blood-vessel bursting behind it." This disability meant that he could not fire a rifle, and he was transferred to a job at the base. The disability persisted into civilian life. Seen in 1928 for refraction he was unable to count fingers with the eye, which presented no objective signs of disease. He was told there was a chance of late recovery after sunstroke, and after a few lessons on the amblyoscope his vision improved to 6/12. This case responded to tests in the same way as an amblyopia from squint, except that there was constriction of the visual field. The cure was due to removal of a strong inhibition to vision in the right eye.

All the evidence goes to show that the amblyopia of squint is due to inhibition of vision, not disuse. I have operated on a child of 12, practically blind from birth from cataract following corneal perforation in ophthalmia neonatorum. The resulting vision, allowing for corneal nebulæ, was good. If simple disuse could cause amblyopia, surely he would have had it.

The cerebral mechanism of suppression is rather interesting. If the inhibition involved one calcarine cortex, inhibition of half the visual field would be expected. Actually the amblyopia involves cone vision in the whole of one eye except for a small piece of temporal field not overlapped by the field of the straight eye. This is an extraordinarily circumscribed area to be selected for inhibition. In hysterics visual inhibition seems closely associated with an emotional factor. The large majority of squinters seem to be of averagely placid temperament. Whatever the mechanism of suppression, it is a process capable in certain cases of rapid removal.

ALTERNATING CONCOMITANT STRABISMUS

Like migraine, alternating concomitant strabismus is a disease of the mentally intelligent. The patients are active and alert, keenly interested in their surroundings, and are up to all sorts of dodges, such as learning by heart the Snellen's test types and the amblyoscope pictures. At will the patient can see with either eye, while he squints and suppresses with the other. The milder cases blink their eyes in a typical way when changing from one eye to the other. Worth distinguishes between the essential alternators with no binocular vision and the facultative alternators who usually prefer to use one eye but can in emergency use either. Alternators often show signs of incoördination between the two sides of the body. A smile will often start on one side of such a child's face followed at a fractional interval by the spread of the smile to the other side. The rare instances where squint may have an emotional basis are to be found in alternating squinters. One little girl voluntarily straightened her eyes up on the operating table and tearfully promised she would always keep them straight in future. She now alternates (according to her mother) when by herself at home, but straightens up when she meets the formidable bogy of the surgeon at hospital. Of course these dynamic squints may later become organic from actual secondary shortening of the internal recti.

FALSE PROJECTION

If the good eye in a case of squint of long standing is covered and the patient asked to point out the direction of objects, he will make a much better job of it than the observer would expect from the degree of squint. It seems that the brain has realised that the eye is not straight and is making allowances. If the eye is put straight this false projection usually ceases, but not always—as shown by the following case.

A lady, aged 24 years, had since childhood a right convergent concomitant squint of 55 degrees (40 degrees with glasses). Although the right eye usually squinted she could with an effort alternate the squinting eye. An operation was performed which left the eye straight with glasses. In a recent letter from Australia she wrote: "As regards straightness I am glad to be able to say my eye seems to be keeping quite alright. I find myself using the left eye a great deal more than the right. It appears to me that, although my eye itself is straight, the angle at which it had been accustomed to looking when it was squinting is hard to change. If I make an effort to use my right eye when it is straight it seems to be looking to the outer side. Ought I to persevere till I can use the right eye as well as the left ? "

In what part of the brain do these complex cerebral readjustments take place ? Direct evidence is scanty. Holmes and Horrax in 1919 [8] reported a case showing, among other signs, loss of stereoscopic vision following a gunshot wound which seemed, by craniometry and other tests, to involve both angular gyri. Riddoch in 1917 [9] reported a case where stereoscopic vision was lost after a bullet wound which " may or may not have injured the left optic radiation fibres, but certainly passed through those of the right hemisphere." In both cases the lesions were crude and severe.

We may, perhaps, by analogy gain some insight into the nature of suppression by considering the conceptions of Pavlov [10] concerning inhibition. He applies the technical term of " analyser " to the entire mechanism of those parts of the central and peripheral nervous system which are related to each particular receptor organ—e.g., retina, optic nerve, tracts, radiations, and cortex. Inhibition is " local sleep," and the seat of inhibition is within the inhibited analyser and not within the inhibiting one. Little is known of the anatomical localisation of such " local sleep " as the suppression of vision in a squinting eye. Ordinary sleep is a process of widespread inhibition of cortical and subcortical centres. Righetti[11] working on tumours and von Economo [12] on encephalitis have shown that in states of pathological sleep lesions are found in a high percentage of cases in relation to the third ventricle. This association must be of significance.

TREATMENT OF SQUINT

In the treatment of this condition we should have in mind from the start the results for which we are aiming. In a cured case we should find :—

1. The eyes straight.
2. Good visual acuity in each eye when refractive errors are corrected.
3. Full binocular vision.

When a case is seen for the first time the physician should :—

(a) Take a careful history, including a family history of any squint. A knowledge of the social conditions of the family is of importance. Attendance twice a week for orthoptic treatment should not be ordered if it means a struggling parent losing two half-days' work to bring the child.

(b) The visual acuity is accurately measured if possible. Children too young to read letters can use one of the test-type boards with animal pictures of graded sizes. During this procedure the surgeon gains the child's confidence and does his best to break down the rooted idea that a doctor is a bogyman who prises one's mouth open and jams a spoon down one's throat. If vision is poor the squinting eye is tested for central fixation.

(c) By this time the child will usually consent to look down one of the varieties of amblyoscope. A graded series of pictures will soon settle the degree of binocular vision present, if any.

(d) Accurate measurement is made of the degree of squint. The Maddox tangent scale and the Priestley Smith measuring tape are both good for purposes of measurement. Allowance should be made for the angle " gamma," or the angle between the optic axis—or line on which the refracting surfaces of the eye should be centred—and the fixation axis. The latter is a line drawn from the object viewed to the hypothetical centre of rotation of the eye. This conception has recently been disproved by van der Hoeve.[13] In practice the angle " kappa " between the central pupillary line and visual axis is more conveniently measured by clinical methods.

(e) The refraction of the eyes should next be measured under full atropine cycloplegia. Glasses are ordered of such a strength as to give the maximum visual acuity when the atropine has worn off. In all except the most stupid children it is a mistake to over-correct the hypermetropia in the hope of reducing accommodation and convergence for near objects. The patients soon find they can see better without the glasses, and look round them or take them off. Worth, in a series of cases, actually found the deviation was greater when they were over-corrected.

(f) After the glasses have been worn for a month the patients should be re-examined, the squint, if present, accurately remeasured, and the visual acuity in each eye re-determined. In about 33 per cent. of cases the eyes will be straight. If the squint recurs when the glasses are removed, or if the visual acuity is lowered in the squinting eye as compared with the sound eye, further measures are advisable.

(g) If the squint is under 10 degrees in amplitude and the vision in the worse eye is 6/12 or better, fusion training may be tried. It is no good before operation if the squint is of the alternating type. The idea is to train the fusion sense on one or more of the specially adapted stereoscopes known as amblyoscopes. Various firms of opticians have of recent years produced many types of giant amblyoscope specially adapted for use in large-scale orthoptic clinics. They are more imposing-looking machines and will stand heavier wear than their progenitor, the Worth amblyoscope, but the latter will produce equally good results. The patient is exercised once or twice a week, or more often if possible, on graded series of pictures so arranged as to require an increasing degree of binocular vision. Satisfactory perspective pictures must all be capable of being reversed. It is no use making the patient say which of two objects is the nearer if it is perfectly obvious from the shading of the picture. Children often have good memories and will remember from the previous visit which object is in front unless they can all be reversed at will. The Griffith set of amblyoscope pictures fulfils all these difficult conditions.

If one picture in the amblyoscope is imperfectly seen it can be brought to the child's attention by increasing the illumination on that side—e.g., by an electric torch. The child should be encouraged to persevere with what seems like a hard school task, if necessary by bribery, as by drawing pictures for him.

It is interesting to watch how the binocular vision improves. A child may stop at the same grade for several visits, then there is a sudden jump of one or two grades. To my mind this is a strong argument in favour of the idea that the low-grade binocular vision is due to active inhibition of the vision of the squinting eye. Amblyopia is not really from disuse. Hysterical amblyopias also improve on the amblyoscope by sudden leaps from one grade to a higher.

If full-grade binocular vision can be obtained, the squinting eye will come straight at once. It must never be assumed that a patient has really regained stereoscopic vision unless a whole series of pictures is correctly interpreted in succession. One or two pictures may be correctly guessed by any child. Many published results are vitiated by lack of care in avoiding this error. I have often listened to enthusiasts unwittingly suggesting to their patients the replies they ought to give.

When the patient has acquired binocular vision this must be nurtured like a delicate plant. I have seen many cases—believed to be cured or improved—relapse after an untreated interval or an attack of some minor malady. Instruments such as the Maddox "cheiroscope" and the Whittington stereoscope use the principle of coördinating hand and eye and are often of value.

Orthoptic treatment, therefore, is difficult and uncertain. It is no good unless the patient can attend at short intervals over a long period; it is little use in squints of large amplitude or in the presence of amblyopia of any degree. Many cases expected to be favourable do not respond, or relapse. There is, however, some scope for the treatment, which is especially useful when used intensively after a squint has been almost straightened by operation.

OCCLUSION OF THE GOOD EYE

(*h*) If, after the trial month, the squinting eye shows a squint or some amblyopia this is worth trying. It was originally suggested by the naturalist, Buffon, about 1743.[14] In small children, the good eye may be kept shut by a pad and adhesive plaster, as recommended by Worth. In older children, the best way is to get the mother to sew a black patch over the glass before the non-squinting eye. The patch should cover the chink near the nose and should be extended along the limb of the glasses on that side, otherwise the child tends to look round it. There are many manufactured occluders on the market, perhaps the best being Doyne's. In my experience the mother is rather apt to assume that a bought occluder must necessarily be efficient. On the contrary, she is constantly watching to see if the child is looking round the home-made one, and it therefore gives better results.

Occlusion, to be effective, must be continuous. It should be continued until the vision is improved to its maximum possible degree. This may take several months. Over the age of eight years the chances of improvement from occlusion are reduced, but are not so remote as the text-books suggest. I have seen a boy of 16 improve from amblyopia to 6/12 after occlusion.

A similar method, particularly useful in infants, is the instillation of atropine drops into the good eye. In babies the squinting eye quickly acquires amblyopia if left alone, but if the other eye is atropinised the squinting eye is forced into use for close vision.

Glasses can be worn with benefit by infants of nine months and over, but atropine can be used in the good eye whenever a squint is noticed. Delay may cause amblyopia and a squint, irremediable except by operation.

SURGICAL MEASURES

(*i*) If all the methods previously mentioned have been given adequate trial and have failed, as they often do fail, then operation should be performed, provided the child is in good health and free from septic foci. Under modern conditions and with modern needles and instruments, operations for squint can be undertaken at any age over three years with the fair certainty of obtaining at any rate a good cosmetic result. The reluctance shown by some surgeons to operate before puberty is a relic of the reaction which set in against the indiscriminate tenotomies of the end of last century. These tenotomies were uncontrolled surgical procedures and, as Worth recalls, were often followed by secondary divergence of the eye in the opposite direction. In modern squint operations, muscles are advanced or retired over measured distances and fixed by suture to the sclera. It is more and more realised that the sclera, though under a millimetre thick, is so tough that it affords firm hold for sutures if the needles used are sharp and inserted tangentially.

In a concomitant convergent strabismus of small degree it is good practice to advance the external rectus muscle on that side. For squints of larger amplitude retirement of the insertion of the internal rectus is effective. The insertion of the muscle should not be put back behind the equator of the eye, or the muscle will act at serious mechanical disadvantage and there may be danger of a late divergence. The exact distance to which the new insertion is displaced is regulated by experience; there is no rule-of-thumb method of calculation. Details of technique vary extensively.

A successful operation from the cosmetic point of view should not mean the end of treatment. If the eyes are straight, measures such as occlusion of the good eye for amblyopia, and fusion sense training, are much more likely to succeed. The criteria of a cure must not be forgotten: straight eyes, good sight in each, full binocular vision. Once the first factor is achieved the others are more likely to follow. Not long ago I tested the binocular vision of three cases of squint operated on two years before. Owing to circumstances, no training of the fusion sense had been tried before or after operation. They had all acquired full binocular vision by the unaided exercise of their own eyes. I thought wistfully of how well they would have looked in my somewhat meagre statistics of successes under orthoptic treatment.

DISTURBANCES OF THE BODY TEMPERATURE *

BY C. E. LAKIN, M.D., F.R.C.P. Lond., F.R.C.S. Eng.

PHYSICIAN TO THE MIDDLESEX HOSPITAL AND THE LONDON FEVER HOSPITAL

WE have already seen that the various processes which are concerned in the genesis and dissipation of heat are under nervous control, but there is great diversity of opinion as to whether special centres for the regulation of the body heat exist in the brain.

Heat-regulating Centres in the Brain

Sir William Hale-White, to whom I am deeply indebted in the preparation of these lectures, by experimental observations upon animals and by clinical investigation was led to the conclusion that one or more special centres for controlling the mechanism of heat regulation existed. He showed that injury to the brain of an animal in the neighbourhood of the corpus striatum was followed by disturbances of the body temperature most often in the direction of an increase. Further indication that the heat-regulating centre was situated in the neighbourhood of the basal ganglia was suggested by experiments in which the brain was destroyed in front of and behind this region respectively. Destruction behind this part of the brain is followed by an entire upset in the heat-regulating mechanism; whereas in front of the basal ganglia the cerebrum of a dog can be removed without any marked change in temperature regulation. In such a case normal temperature regulation is preserved but is limited in range. The animal responds appropriately to external heat and cold, though its temperature falls if it be left for a long time in a cold room.

---

* The second Lettsomian lecture for 1934, delivered before the Medical Society of London on Feb. 28th. Lecture I. appeared in our last issue and Lecture III. will be published in due course.

Some years ago H. G. Barbour carried out a series of interesting experiments in which heat and cold were applied locally to the corpus striatum. When a tube containing hot water was introduced into the corpus striatum the blood-vessels of the skin dilated, there was increased secretion of sweat, and the rectal temperature fell. When cold was applied muscular metabolism was increased and contraction of the vessels of the skin ensued with the result that the body temperature rose. In eliciting these reactions water had to be employed several degrees above and below that of the body temperature. If the corpus striatum was really a delicate thermostat as has been suggested one would have expected that it would have been extremely sensitive to minute differences of temperature.

Since this time further attempts have been made to localise more accurately the site of the heat-controlling centre, and recent investigations suggest that it is situated in the hypothalamic region and most probably in the tuber cinereum. Careful removal of the corpus striatum has produced no loss of temperature regulation (Samson Wright: "Applied Physiology," 1931, p. 87). Puncture of the tuber cinereum has given rise to a sudden increase in the respiratory rate and often extreme pyrexia—occasionally 109° F.—has been recorded. In many instances glycosuria has occurred, polyuria setting in very regularly within one to three days from the time the puncture was performed. From the fact that Barbour had to employ water several degrees above or below that of the body, it has been argued that the site concerned with heat regulation must be situated some distance away from the corpus striatum where the tubes were applied and in the light of what has just been said this site might well be the tuber cinereum. I doubt in the present state of our knowledge if more can be said. Cramer, whose views on the causation of pyrexia we shall notice more fully presently, regards heat regulation as a function of the sympathetic nervous system controlled by the thyroid-adrenal apparatus, and points out that the so-called heat centre in the tuber cinereum is explicable as a group of nerve-cells representing the central connexions of the sympathetic system.

PYREXIA ASSOCIATED WITH CEREBRAL HÆMORRHAGE OR TUMOURS

It has long been known that hæmorrhage into the pons, or cerebral softening in this position, is usually accompanied by pyrexia. It was Hale-White who furthermore drew attention to the fact that damage to the motor cortex of the brain is likely to be attended by a rise of temperature. He pointed out that in cases of hæmorrhage from the middle meningeal artery, blood clot may press upon the cortex and cause pyrexia which in some instances may reach 109° F. He says:

> "There is hardly any part of the brain a lesion of which has not at some time or another caused a rise of temperature. Seeing, however, that disease of the cord, of the pons, of one crus, of the basal ganglia and of the motor area of the cortex will all cause pyrexia, it is highly probable that in man the course of at least some of the nervous impulses which control the temperature is the same as, or much the same as that of motor impulses. It is true that disease of other parts of the brain will cause pyrexia—thus we have known hyperpyrexia to be due to a cerebellar tumour but . . . parts far removed from the lesion may be exposed to pressure or suffer from interference with their blood-supply. In the case of the cerebellar tumour just mentioned in which the temperature reached 107·4° F. the corpora quadrigemina and surrounding parts were much compressed by the tumour."

The pyrexia consequent upon aseptic damage to the brain both in man and in experiments on animals is usually short in duration and difficult to control, prolonged immersion in cold water being necessary to effect a reduction. A study of the temperature chart in a case of apoplexy is of interest. In an ordinary case of cerebral hæmorrhage where rupture of one of the branches of the middle cerebral artery which pass through the anterior perforated space occurs there is an initial fall of temperature lasting a few hours and attributable to shock, the temperature then rises 2–3° above the normal, the highest point being generally reached in 24 hours. In a case that is going to terminate favourably the temperature then slowly falls, the normal line being reached within a few days. This is usually followed for two or three days by a subnormal reading and then the normal standard is again reached. Not every hæmorrhage in this situation is attended by pyrexia; in some instances the damage is too slight, in others the hæmorrhage is so profuse and the shock so profound that no pyrexial response supervenes. If the temperature be taken in the axilla of the paralysed side in an ordinary case of cerebral hæmorrhage it is likely to be higher than in the axilla of the unaffected side and may remain so for several days, the difference gradually becoming less. At first the difference may be as much as 1° F. Hale-White attempted to discover the cause of this by recording the surface temperature, estimating at the same time the amount of sweat secreted on each arm. He says:

> "It is clear that the arm with the higher surface-temperature or secreting the greater amount of sweat will be losing heat the faster of the two arms. By this method it was found that the loss of heat was greater from the arm of the paralysed side, that is to say, the side on which the axillary temperature was higher. But the axillary temperature is an internal temperature, and the loss of heat is therefore greater on the side on which the internal temperature is higher. This being so more heat must be produced in paralysed than in the healthy muscles. These observations if confirmed suggest that as the muscles are the chief thermogenetic tissues, a lesion which paralyses their motor function exalts their thermogenetic activity" (Allbutt and Rolleston: "A System of Medicine," 1905, vol. i., p. 849).

The statement that more heat must be produced in paralysed than in healthy muscles appears to be at variance with the conception that metabolic activity is the source of heat production. An explanation more consonant with the principle of metabolic activity would, I think, be more convincing, and I think it is to be found.

In a paralysed limb the arterioles at first are dilated on account of loss of vasomotor tone and the early rise of temperature on the paralysed side is to be attributed to the greater amount of blood flowing through the dilated arterioles. Tone in smooth muscle is not so completely dependent on reflex nervous impulses as is the case in voluntary muscle. A certain power of adaptation which is independent of the nervous system appears to be present and asserts itself after a few days (compare the case of a paralysed bladder). In consequence of this less blood circulates through the paralysed limb and, owing to the paralysis of the skeletal muscles, the venous return is impaired. Blood tends to stagnate and, in consequence, the temperature falls till eventually the paralysed limb becomes colder than the unaffected one.

In cases in which the pons or medulla are damaged either a rise or fall of body temperature may ensue. It is usually said that a pontine hæmorrhage causes hyperpyrexia. This, however, is not always so. The greater part of the body is not only paralysed but is cut off from the control of the heat-regulating mechanism. The patient is comparable therefore to a poikilothermic or cold-blooded animal, the temperature following passively the temperature of the environment. Where the person is well covered and surrounded by hot-water bottles the temperature of the paralysed parts of the body will rise. If the paralysed parts are cooled the general temperature will fall. In hospital the former conditions usually prevail and a high temperature therefore is more commonly to be observed. No sensory impulses can pass from the paralysed parts to the brain, nor can efferent impulses reach the affected muscles or the blood-vessels.

Tumours arising in the neighbourhood of the third ventricle by causing downward pressure upon the tuber cinereum and the pituitary body may give rise to irregular pyrexia accompanied by somnolence, polyuria, hyperglycæmia, and glycosuria. In such cases the sufferer may furthermore grow obese and show sexual regression. Neoplastic metastases in this situation may give rise to progressive cranial nerve palsies, drowsiness, cervical rigidity, and pyrexia producing a clinical picture not easy to distinguish from tuberculous meningitis. In a case of paraplegia resulting from a complete transverse lesion of the spinal cord, the man when he feels cold shivers only with the muscles supplied by nerves above the lesion; on the other hand, when he is hot he sweats only down to the line between the sensitive and insensitive portions of his skin. Such observations are of use in investigating the position and severity of a spinal lesion.

Part Played by the Ductless Glands

No one interested in the subject of regulation of the body temperature can afford to neglect the views put forward so succinctly by W. Cramer in the book entitled "Fever, Heat Regulation, Climate, and the Thyroid-Adrenal Apparatus," published in 1928. I do not think I can do better than to state in his own words the conclusions he reaches.

"With the exception of respiration, all the factors concerned in the heat regulation of warm-blooded animals are under the direct control of the sympathetic nervous system, and therefore subject to control by the functional activity of the thyroid and adrenal glands. Increased functional activity of these glands has the effect of stimulating the sympathetic. There is therefore both a nervous and a humoral apparatus for heat regulation. Stimulation of the sympathetic increases metabolism and thereby increases heat production. While it diminishes heat loss through constriction of the cutaneous blood-vessels, it increases heat loss through the stimulation of the sweat glands. This latter effect may be inhibited by the constriction of the cutaneous blood-vessels. In furry animals which cannot regulate heat loss by sweating this function is taken over by the arrectores pilorum: in these animals sympathetic stimulation increases heat loss through stimulation of the arrectores pilorum. This mechanism is, however, less efficient than that of the sweat glands.

"It follows, therefore, that stimulation of the sympathetic by increasing heat production and by preventing a compensating increase in the heat loss or actually diminishing it produces a type of fever: 'sympathetic fever.' Such a fever can be induced by increased functional activity of the thyroid and adrenal glands, even without the presence of bacteria. Evidence is adduced that in many of the fevers due to bacterial infections there is an increased functional activity of these glands. In fever there is a change in body temperature, or as it may be called, the 'internal thermal environment' due to the stimulation of the thyroid and adrenal glands.

"Conversely, the functional activity of these glands can be brought into play by changing the 'external thermal environment.' Exposure to cold, which calls for increased heat production and diminished heat loss, stimulates these glands to increased activity. Exposure to heat diminishes their activity. The thyroid and adrenal glands represent therefore a humoral apparatus for the heat regulation of the body. This accounts for the physiological and psychological effects of climate. A bracing climate is one which stimulates the sympathetic and the thyroid and adrenal glands, a 'relaxing' climate one which fails to stimulate them. The work of Leonard Hill and Argyll Campbell has shown that one of the effects of a bracing climatic environment, such as open air treatment for instance, is a rise in metabolism. But a rise in metabolism in itself does not account for the beneficial effects of such an environment. The explanation is to be found in the increased functional activity of the thyroid-adrenal apparatus of which the rise in metabolism is one manifestation."

He continues: "The conception of heat regulation as a function of the sympathetic which emerges from these conclusions, enables us to dispense with the idea of a heat centre or of several centres, which are supposed to function like a thermostat and which in fever are supposed to be 'set' at a higher temperature. It is curious that such a crudely vitalistic conception, which really explains nothing, should have dominated physiological and pathological thought for such a long time. Since heat regulation is a function of the sympathetic the so-called heat centre in the tuber cinereum is explicable as a group of nerve-cells representing the central connexions of the sympathetic."

We shall be in a better position to comment on the views put forward above after we have considered in further detail the question of fever.

The Meaning of Fever

In the preceding lecture fever was defined as a complex response of the body to infection in which pyrexia or raised temperature was but one of the manifestations. It is essentially a response in metabolism associated with a toxic disturbance of heat regulation. In fever the nervous control of temperature is altered but it does not appear to be thrown out of action entirely; it is merely disordered. The febrile patient still responds to heat and cold, but he is affected more easily than in health as though the nervous control were more labile. The diurnal variations in temperature still occur, though they may be altered in their range or even reversed, as in the so-called inverse temperature sometimes seen in cases of pulmonary tuberculosis. It is a case of altered regulation. Carl von Liebermeister, who was the first pathologist to investigate fever calorimetrically, enunciated the doctrine that in fever the temperature is adjusted to a new norma. Some distinguished pathologists still adhere to this view. They believe that in fever the body adjusts its temperature to a higher level than normal—as though tuned to a higher key—just as the regulator of a thermostat may be moved up a few degrees in order to keep an incubator at a higher temperature. That is to say, the balance between heat production and heat loss is adjusted at a higher level. For example, during muscular exercise heat production may be increased from 200 to 300 per cent., whereas in fever it is only increased from 20 to 30 per cent. Yet in the former the temperature remains normal, while in the latter it is raised (Boyd). Again, in exophthalmic goitre the heat production may be 80 per cent. above normal, yet the temperature of the body is rarely raised for the skin is flushed and moist.

The earlier investigators held opposing views as to the origin of fever. Liebermeister taught that the increased temperature was due to an increased production of heat. Ludwig Traube, on the other hand, held that it was due to deficient loss of heat. Hale-White in his Croonian lectures in 1897 brought forward evidence to show that pyrexia is not to be ascribed in all cases to one common underlying process, it being due in some instances to the one, and in some to the other. He says :—

> "It appears to me to be possible that the discussion has in a sense been beside the mark, for we know that most, if not all, fevers are due to the circulation of poisons in the blood, and there is no reason why we should believe that they all produce pyrexia in the same way. All collateral evidence is against such a view; many poisons accelerate the beat of the heart, but some act upon the vagus, others upon the accelerator nerves; many poisons produce diaphoresis, but jaborandi acts upon the peripheral terminations of the sudoriparous nerves while opium acts centrally. And I hope I shall, in these lectures, be able to bring forward evidence to show that sometimes pyrexia is due to an increased production of heat and sometimes to a diminution of the loss. If this can be done it will put an end to the discussion as to whether in fever the production of heat is increased or the loss diminished; but we shall have to discuss the question for each separate febrile disease" (THE LANCET, 1897, i., 1660).

We now know that even in the same fever one or other of these processes may predominate at different stages of the disease.

CHEMISTRY OF THE FEBRILE STATE

It is very difficult in our present state of knowledge to explain the manner in which invasion of the body by pathogenic organisms leads to the complex response we speak of as fever. It is suggested on the one hand that the toxins produced by the invaders directly affect the heat centre; on the other hand, it may well be that certain substances liberated from the damaged cells of the host are responsible. It has long been recognised that excessive katabolism of proteins is one of the most striking features of the febrile state. When considering the subject of hyperthermia we referred to the fact that the mere existence of pyrexia led to a further increase of metabolism and saw that a vicious circle might thus be set up. The chemical reactions of the body, like those occurring in a test-tube, are speeded up by a rise of temperature. It has been calculated that a patient with a temperature of 105° F. would manifest an increase of 50 per cent. in his metabolism and in his pulmonary ventilation because of the pyrexia alone. The enormous destruction of protein that occurs is shown not only by the increased output of urea, creatinine, and purine bodies in the urine, but also by the wasting and loss of weight that occurs in any prolonged fever. The output of phosphorus and sulphur is also increased for the same reason. The urea may be increased two- or three-fold in the urine. In typhoid fever this increased output of nitrogenous bodies may represent a loss of four or five pounds of muscle in a week.

Loss of weight, however, is not solely to be attributed to destruction of the proteins of the body. Doubtless loss of appetite and diminished intake of food play their part. In this connexion it is interesting to note that free hydrochloric acid is usually absent from the gastric juice if a fractional test-meal is carried out. The glycogen in the liver and muscles rapidly become exhausted. Fats are also destroyed though in lesser degree than proteins, and in the presence of a comparative poverty of carbohydrate some degree of acidosis is often met with. Acetone is frequently to be found in the urine. The rapid respiration characteristic of fever serves to reduce acidosis by eliminating more carbon dioxide through the lungs. The presence of acetone bodies in the urine of febrile patients does not exclude the existence of an alkalosis. Alkalosis is most likely to be met with in pyrexia associated with pulmonary lesions in which the oxygenation of the blood is effected with difficulty and in which hyperpnœa results.

Koehler has recently demonstrated (1923) that an alkalosis may be present in influenza. A slight alteration in the pH of the blood towards the alkaline side is found and is accompanied by a fall in the plasma bicarbonate. The occasional occurrence of tetany in connexion with the acute fevers lends support to Koehler's views. In a paper by Leach, Vickers, and Brown on the reaction of the blood in experimental pneumonia (1924), findings are given which suggest that, while an alkalosis due to increased pulmonary ventilation may occur in the early stages of the disease an acidosis subsequently develops. The development of the acidosis appears to be associated with an increased concentration of the acetone bodies in the blood, and the change in the pH of the blood towards the acid side and the higher grades of bicarbonate reduction, which are found in the terminal stages of the condition, appear to result from a ketosis (O. L. V. de Wesselow).

At the onset of fever and during the stage of rigor there is often increased diuresis due to the increased blood pressure, and copious diuresis often occurs as the temperature falls at the end of a febrile attack. During the height of a fever urine is diminished in amount, becoming concentrated and highly coloured. Urobilin may be present in considerable quantity, apparently resulting from increased destruction of hæmoglobin and in consequence some degree of anæmia is the rule. The urinary chlorides are diminished in all fevers excepting malaria, and the reason for their retention is not understood. It is quite different from the chloride retention of nephritis, for in nephritis the blood chlorides are high, whereas in fever they are low. They must therefore be retained in the tissues. Water retention also occurs; possibly this is to be correlated with the retention of chlorides in the body and the diminished excretion of urine. The diminution of the urinary chlorides is exemplified particularly in the case of pneumonia.

It is usually stated that in this instance they are retained in the inflammatory exudate in the lungs, yet in some cases where a crisis occurs without simultaneous resolution of the lung they make their appearance again in large quantities at and immediately following the crisis. Since the body requires a certain amount of sodium chloride for its metabolic processes and seeing that these are greatly increased during fever, it may be that they are being retained, especially if their intake in the food is deficient. Sollman, who investigated this question more than 30 years ago, concluded that the disappearance of the chlorides from the urine during fever is due entirely to the deficiency of the intake of salt in the food. He recommended that ½ oz. of salt a day should be added to the milk given to a fever patient.

OTHER RESPONSES

In some fevers the skin is dry and burning to the touch, the sweat glands being apparently paralysed by toxins. Pneumonia and scarlet fever are obvious instances. The sweating met with in acute rheumatism and acute pulmonary tuberculosis proves a notable exception to the general rule. The rate of the heart is increased and at the onset of a febrile illness when the arterioles of the skin are contracted the blood pressure is usually raised ; later, when the blood-vessels dilate and the heart is beating less powerfully, the blood pressure falls and the pulse becomes dicrotic, a phenomenon which is particularly well seen in cases of typhoid fever. We have seen that the respirations are increased in rate and there is an increase of CO_2 in the expired air on account of the great increase in metabolism which is occurring. The disturbance of the nervous system is shown by restlessness, depression, and, in more severe cases, by delirium, tremor, and subsultus tendinum.

It may be said that we are still in the dark as regards many of the phenomena occurring in the febrile state, that is, how far they are to be attributed to the state of pyrexia or how far they are the direct result of toxæmia. For instance, albuminuria is in some instances probably the direct result of the pyrexia, but it is so much more frequent in diphtheria and scarlet fever than in other febrile conditions that in these instances it is almost certainly due to specific toxins. In the same way, leucocytosis, though so often associated with pyrexia, can scarcely be attributed to the febrile state, for it is absent in the enteric group of fevers, malaria, influenza, measles, German measles, and tuberculosis. Constipation is of frequent occurrence in the febrile state, and if Cramer's views are accepted this could be explained by the inhibition of intestinal movements from sympathetic stimulation. The same observer also attempts to account for the terminal bronchopneumonia met with so frequently in the infectious fevers. The pulmonary œdema and congestion which arise as the result of prolonged sympathetic stimulation provide a ready soil in the lung for the localised growth of invading organisms.

Other Theories of Fever

So far we have assumed fever to be the result either of the direct action of toxins produced by invading organisms on the nerve-cells in the tuber cinereum, or else on the tissue cells of the body, from which some hypothetical substance is set free which in turn upsets heat regulation. There are, however, other theories of fever which must be more or less briefly noticed. One of these is usually referred to as the water-shift theory of fever. It postulates that as a result of infection there is a shift of water from the blood to the tissues so that the blood becomes concentrated.

As a result of the reduction in blood volume blood is no longer avilable for the skin vessels and the resulting vasoconstriction by diminishing heat loss brings about pyrexia. Much stress is placed on the increased concentration of the blood. It is known that conditions which lead to concentration of the blood such as hypertonic saline concentrated sugar solutions, and certain purgatives may bring about fever and probably do so by increasing the difficulty of perspiring, but in fever the concentration where it exists has not been shown to be the primary cause and may well be a secondary result. What exactly happens to the sodium chloride which leaves the blood has yet to be elucidated, and it has yet to be shown that it takes water with it. Until we know this the water-shift hypothesis appears very uncertain (R. J. S. McDowall).

Another theory of fever is that of lack of free water. There is reason to believe that the greater part of the water in the blood and tissues is bound by the colloids and possibly to some extent by the crystalloids and that blood and protoplasm may be looked upon as hydrates. It is only the free water that can be readily excreted in urine and sweat and which migrates readily from vessels to tissue spaces and back again as need arises. Such an hypothesis serves to explain fever as a lack of free water impairing the temperature regulation capacity of the body (Balcar, Sansum, and Woodyatt, 1919).

A more fascinating theory is that put forward by Cramer and it is necessary to review this in greater detail. According to this observer, as we have already seen, the adrenal medulla, the thyroid, and the sympathetic nervous system constitute the heat-regulating system of the body. His theory rests materially upon the demonstration of extreme secretory activity in the adrenal medulla in fever following the experimental injection of β-tetrahydronaphthylamine or exposure of an animal to cold. In the case of an animal which has been subjected to either of these procedures the adrenal is removed and thin slices are subjected to the action of osmic acid vapour. By this method the specific secretory granules of adrenaline in the medullary cells are rendered visible and their behaviour under various conditions can be studied.

Adrenaline is an easily oxidised substance and reduces readily osmic acid to the black lower oxides or possibly even to the metal itself. If a section of a normal gland which has been treated in this way is examined the cortical cells of the adrenal are seen to be filled with black globules of lipoids and the medullary cells with much finer black granules of adrenaline. It is possible to distinguish between these two groups of substances by immersing the section in crude turpentine, since the turpentine acts as a solvent upon the lipoid material without affecting the adrenaline granules.

In experimentally produced pyrexia Cramer has demonstrated the almost explosive discharge of adrenaline, the granules which have left the cells of the adrenal medulla appearing in the capillaries which separate the alveoli of the gland. When in induced pyrexia animals are killed at a later stage the cells are found to be completely denuded. Signs of similar activity can be demonstrated in the thyroid. The gland becomes intensely congested, numerous capillaries open up between adjacent alveloi and between the lining cells and the wall of the alveolus, the amount of colloid decreases and loses its affinity for hæmoglobin. The lining cells become columnar and the mitochondria become more distinct. On exposure to an external temperature of 37° C. the gland passes into a resting condition similar to that which is observed after thyroid feeding ; the alveoli become distended with deeply staining colloid and the mitochondria become indistinct.

Further evidence in favour of Cramer's theory of fever may be mentioned.

Similar changes to those occurring in experimental fever have been found in certain varieties of fever in man. In certain rare cases of pyrexia of unknown origin the only lesion found on post-mortem examination has been hæmorrhage into the suprarenal gland, and I hope to make further reference to this condition at a later stage. Heat regulation is impaired but not destroyed when the thyro-adrenal apparatus is eliminated by disease as in myxœdema and Addison's disease. It is found that injection of β-tetrahydronaphthylamine into a thyroidectomised animal induces a pyrexia of lesser degree than occurs in a normal control. Experimental hyperthyroidism and experimental hyperadrenalism produce two different types of fever; the one elicits a hectic type, the second a rapid hyperpyrexia.

I will bring this subject to a close by quoting a paragraph from Hadfield and Garrod's "Recent Advances in Pathology" (1932).

> "The significance of these results is questioned by Stewart and Rogoff (1922) on the ground that hyperpyrexia can be induced by means of morphine in cats when adrenal secretion has been totally inhibited by removing one adrenal and cauterising the medulla and severing the nerves of the other; this in spite of the fact that with intact adrenals this hyperpyrexia is accompanied by an increased adrenalin output and a diminution in chromaffin content in the medulla."

Is Fever Beneficial or Not?

The question whether fever is beneficial or not can hardly be answered satisfactorily in the present state of knowledge. We have only to recall the seriousness of those infections in old and enfeebled subjects when unattended by any appreciable rise of temperature to assert that its absence is to be feared. It would appear then that the body is able to deal more effectively with the invading organism when the temperature is raised, and to this extent pyrexia is to be regarded as a defensive mechanism. A very high temperature, 107° or 108° F., is certainly harmful and, if continued, will result in death from injury to the nerve-cells. But there is no ground for believing that a moderate degree of fever is detrimental, and it is not necessary to attack it with antipyretic drugs. The bounding pulse of fever is evidence of the increased energy of the circulation and it is largely by the blood stream that protective substances are carried to every part of the body. In the case of infected animals it has been shown that agglutinins and bacteriolysins are produced more quickly and in larger quantities if the animals are kept at a moderate elevation of temperature than in control animals kept at ordinary temperatures, but, as R. T. Hewlett points out, very high temperatures inhibit these immune reactions. It is well known that high temperatures inhibit the growth of bacteria, but it is only in severe fevers that body temperature could have any definite influence in this direction, and such an argument is unconvincing. Temperatures high enough to produce such effects would induce cloudy swelling of the parenchymatous cells of the body.

PRINCESS BEATRICE HOSPITAL.—This institution (formerly the Kensington, Fulham, and Chelsea General Hospital) is in serious financial difficulties. The Marquess of Carisbrooke, the president, has addressed a circular letter to subscribers and donors in which he says that its financial position is precarious, and that the board has decided that it will have to be closed down altogether unless in the near future a considerable sum is obtained. The hospital, which serves a district with 400,000 inhabitants, last year dealt with 1646 in-patients and 4547 street accidents and casualties. There is a debt of £8000 on maintenance account and £68.000 on building and equipment account.

FURTHER OBSERVATIONS ON FILARIAL PERIODICITY

By G. CARMICHAEL LOW, M.D. Edin., F.R.C.P. Lond.
SENIOR PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES, LONDON: AND

P. H. MANSON-BAHR, D.S.O., M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO THE HOSPITAL

With a Laboratory Report by

A. H. WALTERS
SENIOR TECHNICIAN, PATHOLOGICAL LABORATORY, SEAMEN'S HOSPITAL, ROYAL ALBERT DOCK

SINCE the publication of our last paper, entitled Some Recent Observations on Filarial Periodicity,[1] we have had the opportunity of studying another case of *Filaria bancrofti* infection with a heavy infection of filarial embryos in the blood.

The patient was an Indian lascar, aged 26, from Calcutta, who sought admission to the Royal Albert Dock Hospital on account of rheumatic pains in his legs and abdomen (March 10th, 1933). On examination no outstanding clinical signs of filariasis could be found with the exception of enlarged femoral and inguinal lymphatic glands. On X ray examination small shadows were present at the left pelvic brim and also at the level of the twelfth rib—appearances which might be interpreted as calcified filariæ; meanwhile a uroselectan investigation of the renal tract showed nothing abnormal, the small shadows being present in the same situation as in the plain radiogram. As regards laboratory examinations, the night blood contained numerous embryos of *Filaria bancrofti*. The Wassermann reaction was positive + + and the Kahn test + + + +. The blood counts were up to the normal and an eosinophilia of 5 per cent. was present. In the fæces trichuris eggs (17 per c.cm. by the floatation test) were present.

As the patient came from the same district as that of the case we reported in our previous paper,[1] it was decided to continue the study of the embryonic periodicity of the *F. bancrofti* with a further series of accurate counts over consecutive four-day periods. The same technique as described in the previous case was again used, but in order to make these observations correspond with the earlier work on the subject, Low's standard [2] 20 c.mm. of blood was used as the amount for each count.* Thick wet film embryo counts were again found to tally within 0·5 per cent. of error factor against dry film counts.

LABORATORY REPORTS AND FILARIAL COUNTS

We are much indebted to Mr. Walters for the very careful and accurate observations carried out on the case. This involved sitting up for many nights, taking the blood at two-hourly intervals and counting thousands of embryo filariæ.

The first observation was one of four days of two-hourly counts taken consecutively from 2 P.M. on March 20th, 1933, until 12 noon on March 23rd, and it illustrates the regularity of normal nocturnal periodicity (Fig. 1). It will be noted that the peaks of the waves were reached at 2 A.M. on the first two nights, but came forward to 12 o'clock midnight for the third and fourth nights. This small discrepancy may be due entirely to experimental error or, more likely, to the fact that the patient fell asleep earlier on the third and fourth nights than on the first and second, thus giving an impetus to an earlier influx of embryos.

---

* This is double the amount used in our previous paper (March 4th, 1933).

The second observation was also one of four days of two-hourly counts taken consecutively from 2 P.M. on March 27th, 1933, until 12 noon on March 30th, and illustrated an attempt to influence the periodicity of the embryo filariæ by means of reversing the life habits of the patient.

A meal was given to the patient at 11.30 A.M. on March 27th; slept from 2 P.M. to 5 P.M.; awake but drowsy at 6 P.M.; slept from 8.45 P.M. to 12 midnight. Patient roused at 2 A.M. and given a meal; taken for a short walk from 2.30 A.M. to 3 A.M.; back to bed at 4 A.M.; awake until 7 A.M.; slept from 7 A.M. to 9 A.M.; given a meal at 11.30 A.M.

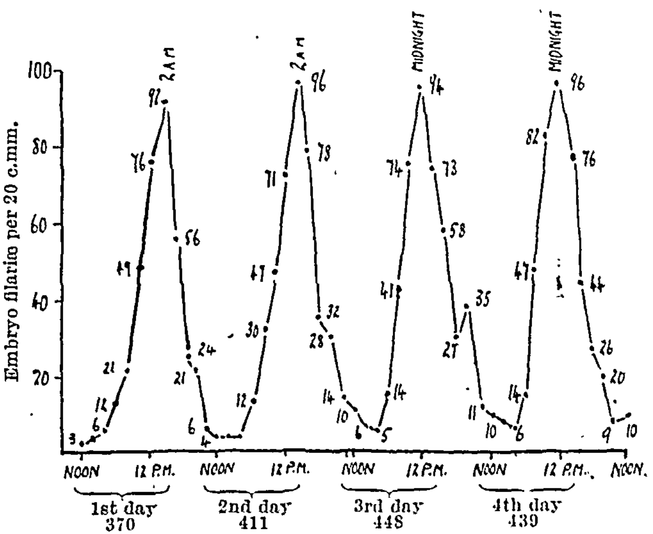
This was the routine strictly adhered to over the four-day period of the experiment, and it will be seen that the patient was resting or asleep from 12 noon until 12 midnight during each successive 24 hours. The graph of results showed no irregularity during the first day; a slight flattening out of the curve between midnight and 6 A.M. on the second day indicating a less rapid fall in the number of embryos; a marked irregularity on the third day, during which the patient was taken out for a car ride between the hours of 2 A.M. and 4 A.M. and kept awake longer until 6 A.M.; and a marked fall in the total number of embryos at midnight on the fourth day, counterbalanced by a marked increase of the total numbers at midday.

Reviewing this experiment it was decided that in order to achieve any satisfactory survey of the variation in embryonic periodicity in the patient's blood stream during the period of reversed life, it would be necessary to continue the observations over a period longer than four days. It was therefore decided to reverse the patient's life once more, but not to commence the observations until the fifth day as the first four days had already been done. In this way an eight day's chart was obtained. The reason for always selecting four-day periods was that the patient's fingers became very sore after being subjected to so much continued pricking.

Accordingly the patient was transferred to a room which was kept darkened during the day and artificially lighted all night. His meals were served at hours of the night corresponding with the usual day times, and between 12 midnight and 3 A.M. he was taken out for exercise and then given light duties of trivial tasks until 4.30 A.M. From then on he amused himself until 8 A.M. when he retired.

Counts were begun at 2 P.M. on the fifth day and were continued at four-hourly intervals for four consecutive days. Although every precaution was taken to ensure quiet rest for the patient, his sleep during the day was not so continuously sound as that during the night. He slept best during the period immediately after he retired—namely, from 8 A.M. to 12 noon, but after having been refreshed by this deep sleep he would mostly doze and sleep only lightly from noon until 6 P.M. when he breakfasted.

FIG. 1



Average number 417

Total embryo filaria counts

It will be seen (Fig. 2) that the first counts done during the fifth day show a marked increase in the number of embryos present at midday, there being 23 present as against an average of 5 in the normal curve seen in Fig. 1. Also, that the bottom point of the curve, denoting the smallest number of embryos counted, is reached at 6 P.M. as against 2 P.M. on the normal curve. This indicated a moving-on of the cycle towards reversal. On the sixth day there was a marked decapitation of the peak of the curve showing the midnight counts increased to 59 embryos per 20 c.mm. of blood and the midday count increased to 67 embryos per 20 c.mm., whilst the bottom point of the curve is reached between 6 P.M. and 8 P.M. From the sixth day onward to the eighth there was no change in the patient's habits, and he continued to sleep well from 8 A.M. to 12 noon and then lightly doze and sleep until 6 P.M. Correspondingly there is little or no change to be observed in the curve. The peaks of the curves for the seventh and eighth days remained decapitated and the midday and midnight figures run in comparatively close parallel.

The total number of filaria embryos which appear during each 24 hours is the next interesting and suggestive observation. In the normal curve (Fig. 1) the total embryo counts are as follows: first day, 370; second day, 411; third day, 448; fourth day, 439. These figures give an average number of 417 embryos per 24 hours over a period of four normal days and nights. During the first four days of the reversed life experiment, the total embryo counts were: first day, 466; second day, 416; third day, 452; fourth day, 401; giving an average number of 434 embryos per 24 hours over a period of the first four days and nights of reversed life.

Continuing the foregoing observation, the total number of embryonic counts from the fifth to the eighth day of reversed life are: fifth day, 472; sixth day, 503; seventh day, 463; eighth day, 415; giving an average number of 463 embryos per 24 hours over a period of fifth to eighth days of reversed life.

The average number of embryos counted during every 24 hours throughout the eight days is 448 per 20 c.mm. of blood, and the average shown in the normal curve (Fig. 1) is 417. The difference between these two average figures is negligible from the experimental point of view, but the curves are vastly different. In the normal curve the peaks are regular and appear between 12 midnight and 2 A.M., whilst the minimum counts occur at 2 P.M. From the sixth to the eighth day of reversed life the curves fail to peak, the midnight to midday counts are nearly identical, and the minimum counts occur at 6 P.M. to 8 P.M. Therefore it seems most likely that the same numbers of filariæ embryos are always poured into the blood stream every 24 hours, no matter what variation of sleeping and waking of the patient is brought about, and this experimental evidence points strongly to daily migration and reappearance of the same undamaged embryos *rather than to regular death and exact numerical parturition of embryos by the adult female* worm or worms. It seems most unlikely that female *F. bancrofti* should give an even yield of embryo when subjected to adverse circumstances.

Two weeks after the termination of the reversed life experiment the embryos were found to have returned to their normal nocturnal periodicity as shown in Fig. 1, and then the following animal inoculation experiment was kindly carried out for us by Dr. H. M. Hanschell. At 1 A.M. 20 c.mm. of blood was taken from the patient in the usual manner and the embryos were found to number 92; 5 c.cm. of blood was removed from the median basilic vein of the patient and immediately transferred to the heart of an ether anæsthetised guinea-pig. The animal fully recovered inside of three minutes, and 20 c.mm. of blood was then taken from the marginal vein of the ear and examined for embryos; none was detected. Five minutes after the transfusion the animal was killed by means of a sudden sharp blow on the back of the neck and a post-mortem examination was held at once. The heart was first punctured and 20 c.mm. of uncoagulated blood removed for standard thick film preparation. Smears were then prepared from the heart, lungs, liver, spleen, kidneys, and brain, and the respective tissues sent to the laboratory for sectioning. No embryos were detected in the marginal-vein or heart-blood films, and none in serial sections made right through the organs. Thus 23,000 live filarial embryos were transferred into the heart of the guinea-pig and five minutes later no trace of them could be found in the heart-blood or organs of the animal!

Further experiments to observe microscopically the action of guinea-pigs' blood on the embryos were planned, but unfortunately the patient, having become again fit for work, was obliged to leave hospital and rejoin his ship. Thus we were unable to ascertain whether the embryos were destroyed immediately when transferred to the guinea-pig or not; but it is certain that if they were not destroyed they had not migrated to any of the principal organs, which were thoroughly examined.

For the further elucidation of this, which we considered a crucial matter in the periodicity problem, further experiments on a more extended scale are necessary. What is it that determines the sudden death and disintegration of the embryo in incompatible blood in the guinea-pig? Bahr's experiments in Fiji on the embryo filariæ on a slide show that they are capable of remaining active and unchanged in their morphology in compatible human blood as long as three weeks, and the same phenomenon has been found to hold true for *Loa loa* embryos; but the moment they are transferred to incompatible blood they perish; it is to our minds inconceivable that in the normally infected filarial subject a similar rapid destruction takes place, when at the same time it can be proved that the filarial embryo are capable of living in the blood of the same patient outside the body and under artificial conditions for several weeks.

The following points have been brought out by these observations:—

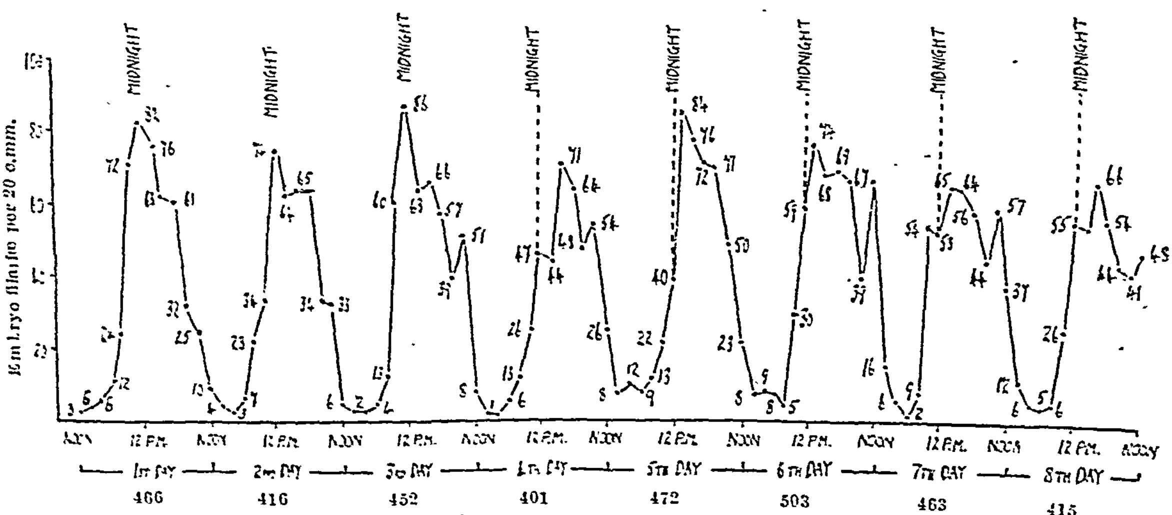
(1) That the curves illustrating this paper indicate to our minds still more emphatically than in our last paper that the phenomenon of periodicity is in some manner dependent upon the habits of the human host.

(2) That the curious phenomenon, so far termed "reversed periodicity," is probably not the correct interpretation. "Irregular periodicity" would be more correct, and the same irregularity can be seen on an analysis of Mackenzie's original case in blood taken every three hours under a $\frac{5}{8}$ in. cover glass.[3]

(3) The type of "irregular curve" shown on the sixth, seventh, and eighth day in Fig. 2 is similar to that obtained in the non-periodic Fijian filaria,[4] and we consider it very necessary that similar observations should be carried out in the Pacific Islands with accurately measured quantities of blood—namely, 20 c.mm. It is hoped that an early opportunity will present itself of continuing this work on the non-periodic *F. bancrofti*.

(4) Another significant fact, as shown in the figures, which also emerges from the observations of Mackenzie, Yorke, and Blacklock, and Smith and Rivas, is that the minimal number of embryo filariæ

FIG. 2



Average number 448

Total embryo filaria counts

in the circulation, whether in reversed or in normal life, occurs at about 6 P.M., and what is the exact significance of this can, at present, only be conjectured.

THE MECHANISM OF FILARIAL PERIODICITY

As regards the mechanism of filarial periodicity, Clayton Lane has recently written upon this subject extensively.[5] As he says:—

> "Periodicity in *Filaria bancrofti* is evidently produced in one of two ways. Either there exists in the circulation a fixed or almost fixed filarial population which shelters in some internal part of the body during the day and reaches the cutaneous capillaries at night only, or parturition is so timed that microfilariæ enter the blood stream at night only. The latter alternative implies, first, simultaneous cyclical parturition, using the term with the same loose regard to exactness as occurs in the reference to simultaneous cyclical sporulation in the tertian or quartan malaria parasites; and, secondly, daily death of the cyclical brood."

Manson considered these two theories over 50 years ago and came to the conclusion that the first was the correct one. To try to prove this he experimented on dogs infected with *Dirofilaria immitis.*[6] In such an infection there is a certain periodicity though not so perfect as in *F. bancrofti.* Embryos are never entirely absent from the peripheral blood, though their numbers are always greater during the evening and night than during the day. The time of greatest scarcity is in the early morning. Having discovered this Manson took an infected dog and examined a drop of its blood at 6 A.M., this showing 82 embryos. He then administered a dose of prussic acid, did an autopsy, and counted the numbers of embryos in drops of blood from the different internal organs. The slides from the lungs (three in number) showed enormous numbers of embryos—viz., 4582, 1591, 2738.

In the heart of the dog four female and three male adult worms (*D. immitis*) were present. Of the four females three were found to be crowded with embryos at all stages of development, whilst in one the uterine tubes were found to be quite empty, save for a few dead embryos near the vaginal opening and the debris of a former pregnancy.

Taken in conjunction with the register of embryos free in the blood at different times of the day, he concluded that the embryos of *D. immitis* do not die or disappear after a short existence of less than 24 hours, but that they rest periodically in the minutest branches of the pulmonary artery; and that when they disappear from the general circulation they are to be found in the lungs. Further proof of this was forthcoming when in 1897 Manson in London had the opportunity to conduct an autopsy on a classical case of *F. bancrofti* infection which showed an exact nocturnal periodicity. The patient died about 8.30 one morning after taking a large dose of prussic acid. At the post-mortem the larger blood-vessels of the thorax and the blood-vessels of the lungs, just as in the dog, contained enormous numbers of filarial embryos.

Low[7] described a somewhat similar case of a slight infection in a Barbadian negro, death in this case taking place at 10 A.M. At the autopsy embryos were found in the lungs only. Clayton Lane, however, does not accept these cases as proving that the embryos were necessarily there during the life of the patient, and believes they accumulate in these situations from the lymph trunks at or after death only. It is not easy to see how this could have taken place in Manson's cases of the dog and human subject as death was sudden, owing to the large dose of the prussic acid taken, and therefore all the embryos must have been immediately immobilised. Even if the embryos had escaped in these poisoning cases or remain alive in cases dying of ordinary causes, how could embryos enclosed in a sheath find their way from the periphery, from the legs and arms, into the large vessels of the thorax and lungs after the circulation has stopped and the blood and lymph are no longer flowing.[3] Clayton Lane believes it is physically unthinkable that filarial embryos can hold their position in the overwhelming current of the large blood-vessels, and likens this to a man keeping his position swimming against the current half-way down the Niagara Falls. The fact nevertheless remains that apparently they are able to do so as the following experiment shows. The peripheral blood of a Barbados blackbird (*Holoquiscalus fortirostris*) when examined at 10.45 A.M. showed only one filarial embryo in an ordinary thick film. It was then killed, its thorax opened, and blood was taken from the right heart, which was still beating. Over 200 filarial embryos, in a similar thick film, were counted, and in blood from the lungs over 50. This experiment, together with other and later observations made upon *Dipetalonema perstans,*[8] in Uganda, seem to us to point to a seat of special selection in these organs, especially in the lungs. Why embryos should be able to hold their own against the currents of blood in the heart and large vessels is not clear, but it is a fact that they do. The same is true for the adult *Dirofilaria immitis* of the dog which live in the right ventricle of the heart, and which must have taken up their position there, as far as we know, on entering the definitive host after quitting their intermediary, the mosquito.

Indeed, here we are driven back to one of Manson's original suggestions based upon his observations on the filariæ of the Chinese black-necked grackle (*Gracupica rigricollis*),[8] that the embryos are provided with an oval spicule and surrounding papillæ by means of which they are able to adhere to the blood-vessel walls, and it is probable that the human embryo filariæ do the same thing. It is a common observation that embryo *F. bancrofti* are able to adhere to a coverslip and to clumps of red blood corpuscles by this means, and no other use has been suggested for this particular organ, save as a means of anchoring the embryo to the capillary wall.

Further, there is no violent current in the capillaries of the lungs, and once carried there by the pulmonary arteries the embryos should have no difficulty in maintaining their position. Possibly they are attracted there chemotactically to get the benefit of the freshly oxygenated blood. What factor supplies the stimulus to urge them to come out again at night is another matter, just as what is the corresponding stimulus which makes the diurnal embryos of *Loa loa* retire from the peripheral blood at night to some place inside the body at present unknown. We also know that ascaris and ancylostome larvæ are held up in the lung capillaries on their journey to the intestine.

Another point, to our minds, against a daily destruction of the embryos, is the long time that these will live outside the body in sealed blood at room temperature. The conditions are not strictly analogous, of course, but one must take all factors into consideration.

There are many other points that one could criticise in the deductions Clayton Lane has drawn from the study of Prof. F. W. O'Connor's sections. The fact that adult filariæ are found all with their uteri empty in blocked and therefore pathological lymphatics, does not necessarily mean that this *is* what takes place when the parasites are inhabiting normal lymphatics. As has often been pointed out, heavy blood infections with embryos may not be associated with any observable pathological lesions at all. There are other strange happenings in *F. bancrofti* infections which are not easy to explain. The counts described in the paper show that the total number of embryo filariæ present each 24 hours appears to be constant, regardless of external conditions, and if one does systematic counts with measured blood every night over weeks and even months, one finds that the nightly number of embryos may vary very little. This, we hold, indicates a more or less constant stream of embryos emerging from the uteri of the adult worm daily, with a corresponding destruction constantly going on, otherwise how account for the constant figure.

There are many other points awaiting solution in *F. bancrofti* infection; more extensive study of the non-periodic human filariæ and further accurate studies on the *Dirofilaria immitis* of the dog are required. When these have been accomplished then we may learn something more about the strange phenomenon of periodicity. For the moment we, just as Manson did some 50 years ago, believe that filarial periodicity is best explained by parturition going on more or less continuously, the young being, as Manson put it, nearly constantly carried along the lymphatics and thoracic duct to the blood, while the excess that would in time take place is checked and kept more or less constant by a mortality amongst the older and effete embryos.

TREATMENT OF
EXOPHTHALMIC GOITRE WITH DEEP X RAY THERAPY

BY E. P. POULTON, D.M. Oxon.
PHYSICIAN TO GUY'S HOSPITAL; AND

W. L. WATT, M.D. Manitoba
SURGEON-IN-CHARGE, DEEP THERAPY DEPARTMENT OF THE HOSPITAL

IN all, 61 cases are included in the present series. The minimum period since commencement of treatment is three years and the maximum period of subsequent observation nine years. So far as is known, no series of cases treated by deep therapy has hitherto been published, and although successful cases treated by ordinary X rays have been reported from time to time, notably in this country by Dr. Florence Stoney,[1] yet the general impression has been that such treatment, to say the least, is uncertain. A note on a further 40 cases is appended, in which more recent treatment has been given.

Twenty of the combined cases were directly under the care and observation of one of us (E. P. P.) who classifies and reports upon them as shown in Table I.

L. = little and G. = great improvement.

Remarks.—Case 1: Rheumatoid arthritis. 2: Auricular fibrillation for 2½ years. 7. Mild diabetes. 11. Mitral stenosis. 16. Treatment not completed.

The results of treatment are tabulated in two ways. Patients were asked to state whether they considered they had improved greatly or a little or not at all since treatment had been begun. From this point of view the results are gratifying, as 18 out of 20 stated that their improvement was "great." The final column of the Table gives results in accordance with Dr. F. R. Fraser's classification.[3]

Class 1.—Patients who can do full work.

Class 2.—Patients who can do their work with difficulty or are obliged to do lighter work.

Class 3.—Patients who are obliged to lead an invalid life.

The present state of the patient has been taken as the only criterion. No difference has been made, even though a present disability might not be thought to be due to the original thyroid disease. It has the disadvantage of making the outlook a little more unfavourable, as is illustrated in the following two cases.

Case 2 (Class 3). A year later her only symptom was occasional tachycardia; all other signs had disappeared. But the concurrent rheumatoid arthritis was worse and she was crippled. Case 11 (Class 2) was admitted for further treatment in April, 1933. She was found to have developed *mitral stenosis*, which caused some disability. There were no signs of hyperthyroidism. The B.M.R. was + 2 per cent.

The first patient (Case 13) was a boy who had previously been treated with ordinary X rays and whose age, 16 years, is generally considered a contra-indication to operation. He was treated first in April, 1924, when a dose of 25 per cent. was given to the thyroid gland. He was treated six times in all between April, 1924, and March, 1928. His basal metabolism before treatment was + 43 per cent. At Christmas, 1932, he wrote stating he was working at Pickford's lifting sugar, milk, and other heavy articles without trouble. In July, 1933, he was lifting packages of 1 cwt. and over; his only symptom was at times a tightness of the throat with extra heavy effort. As a result of these repeated small treatments on top of his previous ordinary X rays he developed a capillary telangiectasis of the skin over the thyroid. In the light of further experience the treatment given was much too light and too often, although the end-result was satisfactory.

Deep X ray treatment suffers perhaps one disadvantage as compared with operation. It is only in the mildest cases that a single treatment is required, consisting of a series of four exposures spread out over a week or ten days. The second treatment follows in two or three months; but the patient may feel so well by now that she refuses to give up further time to treatment in hospital. The surgeon, on the other hand, usually aims at a cure after a single operation.

Case 16, a nurse, was one of this kind; her symptoms were more severe than is indicated by a B.M.R. of + 21 per cent. Her pulse-rate was 120, and she was so weak that towards the end of the day she could not walk upstairs without holding on to the banisters. She only had one treatment of three exposures in October, 1926. She was seen two and a half years later because she wanted to pass her Central Midwives Board examination and she was not allowed to enter without a medical certificate. She said that she did not now feel any weakness. She became hot on exertion, but there was no palpitation. The beat of the heart was forcible and the pulse-rate 120; there was some exophthalmos. She was given the certificate but was told there was some activity of the thyroid still present which it would be advisable to treat. She wrote later saying she had been allowed to continue her training. In March, 1933, she wrote that her eyes were prominent, she was shaky after exertion or excitement, and the pulse-rate was quick after exertion. The neck was not swollen. Apart from these symptoms she had been very well indeed for the past two years. Since November, 1932, she had been night sister; she did not think she could do heavy nursing which entailed lifting. She falls into Class 2, but with further treatment might have been graded higher.

Case 9 illustrates the very gradual improvement that may take place in a patient insufficiently treated, and the improvement in this case was not attributed by the patient to the treatment at all, although Dr. A. C. Lewis, of Rochford, wrote three years afterwards that she had been in very good health since her treatment at Guy's for a goitre which was much smaller, and that she did not have attacks of tachycardia. The patient wrote in 1931 as follows: "You state you are trying to assess results from the treatment; I think it only right to tell you that I do not honestly think I derived any benefit from it, and for that reason I did not return for the third treatment. I did not notice any change in my condition until late in 1927 (last exposure June 4th, 1926); I apparently got stronger after that and gradually regained my normal health. I have not filled up the form you enclosed, under the circumstances. Whilst in the hospital every kindness and courtesy was shown me, for which I was very grateful; but feeling as I do about the treatment I think it fairer to write and say so." She has been placed in Class 1!

Case 18, another nurse, may be taken to illustrate the criteria for Class 2. She came first under treatment in January, 1926, and she had six small treatments up to May, 1927; at the present time she would be treated more vigorously. At the end of 1927 her B.M.R. was + 9·5 per cent. and no further treatment was advised. She writes that in March, 1933, she has palpitation at times with breathlessness and slight shakiness; she walks upstairs slowly. In 1932 she did heavy surgical nursing for five months; it is during these times that she becomes conscious of her heart if she gets overtired. She adds that she is very well indeed on the whole. She has been placed in Class 2.

TREATMENT (BY W. L. W.)

There was little to go on except previous experience with ordinary X rays. Tentatively a total depth dose of about 25 per cent. of the skin erythema dose was tried. It was found that two, three, or even more treatments were necessary. The depth dose was then increased to about 50 per cent. and, as this was found to be well tolerated by the thyroid, the total amount was gradually increased to what was formerly called the sarcoma dose—a depth dose of 80 per cent. S.E.D.—and for the past years this has been more or less the standard. With this dosage in the milder type of the disease one treatment only and in the severer type two treatments are usually sufficient. This massive treatment is practically a bloodless operation and the quickness of results apparently equals that of surgery, so that one of the chief claims of the latter is more or less neutralised.

It is interesting to note that five cases in the series had previously been treated with ordinary X rays without any marked benefit. This only confirms what the writer has already observed in the leukæmias and in Hodgkin's disease: that cases which had ceased or failed to respond to ordinary X rays will still improve if treated by deep therapy. In time it may be possible to determine the optimum wavelength for any particular disease. That toxic goitre is apt to recur is evidenced by the fact that post-operative recurrences are stated to be from 5 to 20 per cent. according to the experience of different observers. In this series six cases were of this class, and treatment by deep therapy was found to be very effective.

Adenomas, if associated with severe symptoms, would probably be safest treated by deep therapy first, and if it caused disfigurement subsequent removal could be carried out. One case in the present series was operated on one year after the deep therapy and is quite well to-day. There was an interesting case of recurrent adenoma. The patient had previously been operated on three times and refused to have any further operation; she came with a history of toxic symptoms for the previous nine months. She had three large adenomas the size of hen's eggs and several smaller ones. As the result of treatment the toxic symptoms disappeared, the large adenomas have slowly diminished to about one-half their original size, and the smaller ones are barely palpable. No new ones have appeared in the four years she has been under observation, and although the patient could obviously be benefited from the æsthetic point of view by surgical removal, she refuses.

END-RESULTS

Consideration of the cases shows but little difference in the final result whether the patients were treated (as originally) with comparatively small doses repeated as necessary or with the present massive dosage. It is in the time taken to achieve the result that the great variation is found. In all those who depend upon their own effort for a livelihood, or who are the mainstay of their home and family, early recovery is of the greatest importance. For this reason the massive dosage is the best. The earlier the treatment the more satisfactory is the result likely to be. The longer the delay the greater the strain on the heart and the slower the recovery. In the severer cases at least a year should be allowed. Surgical treatment was considered in two cases. One patient (Case 13), owing to the slowness of recovery, was examined by a surgeon, who was unable to operate owing to the condition of the skin; this showed a telangiectasis of fine capillaries involving the thyroid area, which was the result of further treatment after previous ordinary X rays. The other patient was advised operation by the surgeon but refused. Both these have subsequently made marked improvement and are well to-day. Rest is an important element in quick recovery, but in many cases, from the very nature of the surroundings, it is very difficult to obtain. One month should be the minimum in all cases.

SUMMARY

The results given in this paper compare very favourably with other published results. It is to be noted that not one patient has died of the disease up to the present.[*] If further experience bears out these results, the treatment of exophthalmic goitre by deep therapy should become a very formidable rival to any other method.

Ambulatory cases.—Where early recovery is important a full "sarcoma dose" should be given. If time is not a factor, medical treatment may be followed later by radiation if there is failure to improve. A treatment consists of a series of four radiations—right, left, front, and back—spread over five to seven days, with the patient in bed. Total depth dose = 80 per cent. S.E.D.

Severe cases.—If associated with adenoma, preliminary radiation and later removal when a source of annoyance are advised. With general thyroid enlargement radiation is given and should be repeated in two to three months if necessary. With no marked improvement in one year, then either surgery or further radiation is indicated. A treatment consists of a similar series spread over eight to ten days. Total depth dose = 90 per cent. S.E.D. to allow for dispersion.

Grave cases.—Combined medical treatment with radiation is given.

Recurrences.—Radiation is usually successful in post-operative recurrences. If recurrence takes place after previous radiation then either a further treatment or surgery is necessary. In very grave cases a series of five radiations is advised, four as above and one extra to the whole thyroid region from the front, spread over five to six weeks. Total depth dose = 100 per cent. S.E.D.

TABLE II.—*Published Results*

Remarks.—(*a*) Includes 4 not traced and 36 post-operative. (*b*) Not all deaths due to Graves's disease. (*c*) Duration not given of fatal cases. (*d*) Duration 2½ to 8 years. (*e*) Class 3 includes 3 doubtful cases.

ADDENDUM

Forty additional cases have been treated between July, 1931, and July, 1933. It is too early to assess permanent results, but they show:—

In 22 cases marked improvement = 55 per cent.
„ 14 „ definite „ = 35 „ „
„ 4 „ no change = 10 „ „

This list includes one patient with a history of severe symptoms for 30 months who had lost 5 st. in weight and had severe cardiac symptoms and was for months continuously under digitalis. She improved rapidly but her doctor reported her death some 13 months later. He stated that the toxic symptoms had completely disappeared, but that she died of angina associated with jaundice.

---

[*] A patient with a history of chronic phthisis, marked cardiac complications, and severe toxic symptoms was treated in August, 1933. She was reported to have died about two months later and it was stated that the treatment had had no effect in arresting the progress of the disease.

VAPORISED IODINE WITH BIER'S MODIFIED HYPERÆMIA

IN TREATMENT OF PYOGENIC CUTANEOUS AFFECTIONS

By ALBERT STRICKLER, M.D.

MEDICAL DIRECTOR, SKIN AND CANCER HOSPITAL, PHILADELPHIA, U.S.A.

Bier's modified artificial hyperæmia and the germicidal powers of iodine, conjointly used, are proposed as a local treatment for the follicular pyodermias and for the more obstinate non-follicular pyogenic infections. The rationale of these procedures may be briefly stated as follows.

Bier's Modified Artificial Hyperæmia.[1]—Normally the task of the blood is to circulate through the tissues of the body and to maintain therein the various physiologic functions. In Bier's conception, the phenomena of inflammation represent the effort of the circulatory blood to resist the harmful invasion of the body by disease. The redness and swelling of inflammation result from the increased activity of the circulatory blood and the exudation of serum—measures adopted to neutralise the harmful effects of the causative agent as well as to increase the nutrition of the involved structures in the hour of danger. Necrosis in its various forms means that the human structure has been incapable of coping with the particular disease; while disappearance of the inflammatory phenomena means the completion of the victorious fight of the stimulated blood current. The aim of Bier's artificial hyperæmia is to increase and fortify the normal beneficent inflammatory hyperæmia of the body in its time of need.

Bactericidal Properties of Iodine.—Iodine in the form of a tincture has enjoyed and is enjoying a unique favourable position as a cutaneous antiseptic. Simmons,[2] using modern bactericidal investigative methods, studied the effects of alcoholic solutions of iodine (both half and full strength tincture) upon certain bacteria, both in vitro and in actual skin disinfection experiments. The pathogenic bacteria used were: *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus scarlatinæ*, *Escherichia coli*, *Clostridium welchii* (spores), and *Bacillus anthracis* (spores). Simmons summarised the results of his laboratory studies as follows:—

1. The bactericidal efficiency, in vitro, of 3·5 per cent. alcoholic iodine solution was greater than the various mercurochrome solutions tested. Full strength iodine tincture was more efficient than the half strength.
2. Iodine gauze placed on the inoculated surfaces of nutrient or blood agar culture of the test organisms resulted in larger areas of growth inhibition as compared with the mercurochrome gauze.
3. In disinfection experiments on normal rabbit skin inoculated with cultures of the test organisms, iodine in 3·5 per cent. strength killed the organisms in and on the skin in 22 out of 42 tests, and in the other 20 the number of viable germs was greatly reduced.
4. Previous tincture of iodine application protected white mice against *B. anthracis* spores inoculated subcutaneously.

The latest contribution by Simmons[3] on the bactericidal superiority of iodine consisted of observations of its effect on skin abrasions, superficial incisions, and deep incisions, contaminated with undiluted broth cultures of either the *Staphylococcus aureus* or the *Streptococcus pyogenes* for various periods of time. Application of tincture of iodine to 151 wounds contaminated with staphylococci resulted in the following percentage of sterile cultures: abrasions, 83·4 per cent.; superficial incisions, 83·1 per cent.; and deep incisions, 31·2 per cent. The use of the tincture of iodine on 59 wounds contaminated with streptococci yielded the following results: abrasions, 75 per cent. sterilised; superficial incisions, 80 per cent.; and deep incisions, 82 per cent.

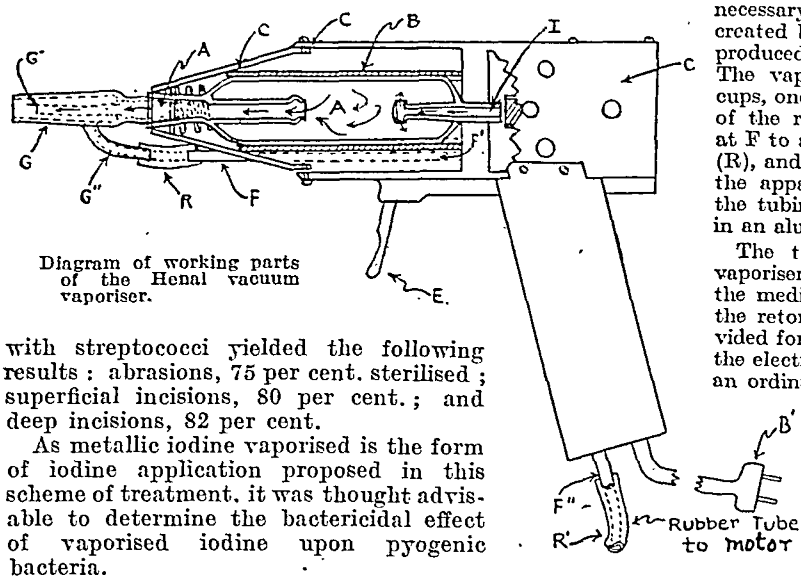

Diagram of working parts of the Henal vacuum vaporiser.

As metallic iodine vaporised is the form of iodine application proposed in this scheme of treatment, it was thought advisable to determine the bactericidal effect of vaporised iodine upon pyogenic bacteria.

The organisms used were cultures of the *Staphylococcus aureus* and of the *Streptococcus hæmolyticus*. The plan followed in these experiments was similar to that employed for the determination of the fungicidal properties of iodine. Filtered plain broth cultures of these cocci 24 hours old and of various strengths were enclosed in collodion sacs and suspended in the Strickler-Borneman apparatus,[4] and the vaporised iodine was delivered by the Henal vacuum vaporiser.[5] Six shots and a vacuum of 15 inches was the routine procedure, and each culture was kept in the iodine atmosphere for one hour prior to incubation. The cultures were observed for ten days, then subcultured by placing 1 c.cm. of the contents into a flask containing 100 c.cm. of Harmone broth. (This is an infusion beef medium made by a process in which digestion takes place in the ice-box.) Inhibition tests were done on each culture. Presence of iodine on the inside surface of the sacs as well as in the enclosed fluid cultures was determined routinally by the starch test. A control culture was used with each group of experiments.

A résumé of the bactericidal results is given in the accompanying Table.

Note.—It is most important to place considerable powdered metallic iodine in the retort of the Henal Vacuum Vaporiser so as to obtain quite a heavy iodine vapour.

THE HENAL VACUUM VAPORISER

Description.—The essential parts of the apparatus are a Pyrex retort (see Diagram, A) enclosed in an electrical unit (B) designed to produce the exact temperature necessary to generate the vapour. Vacuum is created by an electrical motor apparatus and the produced vacuum is transmitted to the skin. The vapour is carried through special vacuum cups, one of which is shown inserted in the throat of the retort (A). The apparatus is connected at F to a vacuum line by means of a rubber tube (R), and the vacuum thus created passes through the apparatus through channels F' and F" and the tubing R'. The entire apparatus is enclosed in an aluminium casing.

The technique of using the Henal vacuum vaporiser is as follows. A measured amount of the medicinal powdered substance is poured into the retort through a glass funnel especially provided for that purpose. The electric cord, part of the electric heating system, is connected either to an ordinary light circuit or to a circuit included in the motor vacuum apparatus, and about ten minutes are allowed for the attainment of a maximum efficiency heat. The vacuum motor pump is then started. The mouth of the vacuum cup (G) is placed against the skin, and the air inlet (I) is closed by pressing the trigger (E). Vacuum is thus produced by the instrument and with it the desired hyperæmic condition of that area of the skin is covered by the mouth of the cup. On releasing the trigger (E) the air inlet (I) is opened and the atmospheric pressure drives the vapour from the retort channel (A) through the directing tube (G) and against the treated area. This procedure can be repeated on the same area as often as desired. Cups varying in design have been found best suited for treatment of various surfaces, as satisfactory creation of the vacuum depends on the snugness with which the cups are applied to the surface of the skin. It is most important to avoid air pockets between the margin of the cup and the surface of the skin. A set of five cups has been devised and found ample for treatment of any cutaneous surface.

In attaching the suction cup (G), the grinding is first slipped into the throat of the retort (A). Care should be exercised not to use too much force, for if the cup becomes jammed considerable difficulty will be experienced when it is desirable to change the cups. Each of these cups has a slim tube (G") which connects with a piece of rubber tubing (R). The other end of the rubber tubing (R) is connected to a slim tube (F) that is part of the vacuum system. It is necessary to exercise a little care when connecting G" to R. When the apparatus becomes too hot it is urgent to disconnect the current for a few minutes, and then restore the circuit. The presence of an excessive amount of crystalline substance on the skin indicates that there is too great heat, but lack of vapour shows insufficient heat. The apparatus may be refilled at any time, but when it is recharged while hot it is best to rotate the instrument for a few minutes to ensure even distribution of the powder in the retort.

Care of the Apparatus.—After giving a number of treatments the operator will notice that the rubber tubing connecting the pump with the instrument has lost its softness and elasticity. This is due to a coating on the inside of the rubber tubing, the result of condensation of excess vapour drawn toward the pump. If this process is permitted to continue, it will eventually close the tube and prevent the production of a vacuum within the applied suction cup. It is necessary from time to time to renew the rubber tubing. In order to lengthen the life of this tubing and keep the air channels clear, it is necessary to rinse or clean the instrument once daily, provided a large number of treatments have been given.

The rinsing or cleaning is done by connecting a small section of rubber tubing (about 12 inches (30·48 cm.)) to the front part of the instrument at R. The open end of this tube is submerged in a cup of alcohol. The trigger (E) is pulled back, as when a vacuum is being created.

This will draw the alcohol through the instrument and down through the vacuum tube. To conserve the amount of alcohol used it is suggested simply to dip the tube into the alcohol for a few seconds and then withdraw it. This is repeated a few times. A small amount of alcohol going through at intervals tends to dissolve the deposit within the rubber tubing more efficiently. After the alcohol, lukewarm water is used in the same manner for the last rinsing. The 12-inch rubber tubing is then removed. It is used only for cleansing the instrument.

The same condensation that takes place within the lumen of the rubber tubing also forms in the interior of the suction cups, but it is even heavier, owing to the fact that the applicators are of lower temperature than the vapour. It is absolutely essential to cleanse the cups after every treatment, and after every application when exudate of pus or serum is present and finds its way into the cup. When serum, pus, blood, or epithelial debris clings to the applicating cup it must first be removed with cotton swabs saturated in water. The cup is then soaked in an alcohol bath, rinsed with warm water and allowed to dry. It is then again ready for use.

SCHEME OF TREATMENT

Carbunculosis.—In the treatment of carbunculosis the tissues about the border of the lesion, both the hyperæmic and the normal, are to be treated with the vacuum alone. The degree of vacuum should vary from 10 to 25 inches; the time of application, one-half to one minute to each area; the number of reapplications, two to four; and daily treatments at the start. The infected area is to receive vacuum applications of 15 to 20 inches plus the vaporised iodine. Two to three reapplications with time duration of 30 seconds each usually suffices. With the subsidence of the inflammatory symptoms the vacuum treatments about the lesions are discontinued, and more intensive application of the vaporised iodine and vacuum made to the central necrotic area. With the removal of the necrotic "core" this treatment is stopped, and either metaphen solution 1:2500 or a 3 per cent. aqueous solution of gentian-violet is applied.

The following history typifies the events in the treatment of a case of carbunculosis by this method.

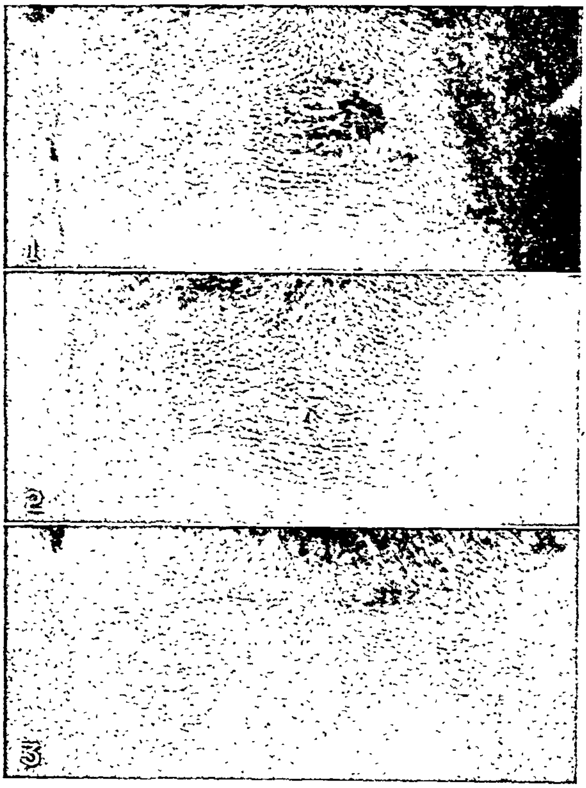
History.—W. A. B., aged 58 years. Admitted to the Skin and Cancer Hospital of Philadelphia with carbunculosis of the neck. Duration: four weeks prior to admission. When condition first began patient noticed a small furuncle on the back of the neck, accompanied by pain, chills, and fever. The lesion was incised, but did not improve. The inflammatory area began to involve the entire neck and constitutional symptoms became more pronounced. During these four weeks various established antiseptic applications were applied locally.

Condition on Admission.—A large, swollen, elevated, inflammatory mass was present on the back of the neck, measuring 5 in. × 4 in. The centre was necrotic, pus oozed from multiple openings, and the surrounding tissues were tender, indurated, and dusky red. The posterior cervical glands were enlarged. The pain in the back of the neck was quite severe and the patient complained of chills and fever. Temperature was 100° F.; pulse-rate, 120; respirations, 22. Nothing abnormal was found in the urine. A blood count showed moderate leucocytosis (11,000). There was no hyperglycæmia (blood-sugar 88 mg. per 100 c.cm.). Culture of pus showed *Staphylococcus aureus*. Medical examination was negative. Blood pressure, 126/65.

Treatment.—Vacuum treatment begun on day of admission (Nov. 28th, 1933). Daily treatment given, and by Dec. 1st, after three treatments, all discomfort disappeared. Drainage of the multiple openings continued until Dec. 12th, and by the 24th the wound was completely healed.

Very large furuncles are treated by the same technique as that suggested for carbuncles.

Furunculosis.—A furuncle seen early usually yields to one treatment to the lesion of two applications of vaporised iodine with a vacuum of 15 inches. Advanced furuncles usually require three to five consecutive daily treatments of 15 to 25 inches, of vacuum with vaporised iodine, and two to four reapplications to each lesion. The cup used for treatment should be sufficiently large to include the lesion as well as a portion of the adjacent skin. It is advisable, prior to treatment, to remove the epiderm overlying the infected follicle, as this facilitates more certain penetration of the vaporised iodine.



CASE I.—The patient, a diabetic, had a blood-sugar of 210 mg. per 100 c.cm., and the carbuncle had been present for three weeks before the author's method of treatment was begun (1). Twenty treatments were given. (2) Shows the beginning of healing. (3) Shows healing complete.

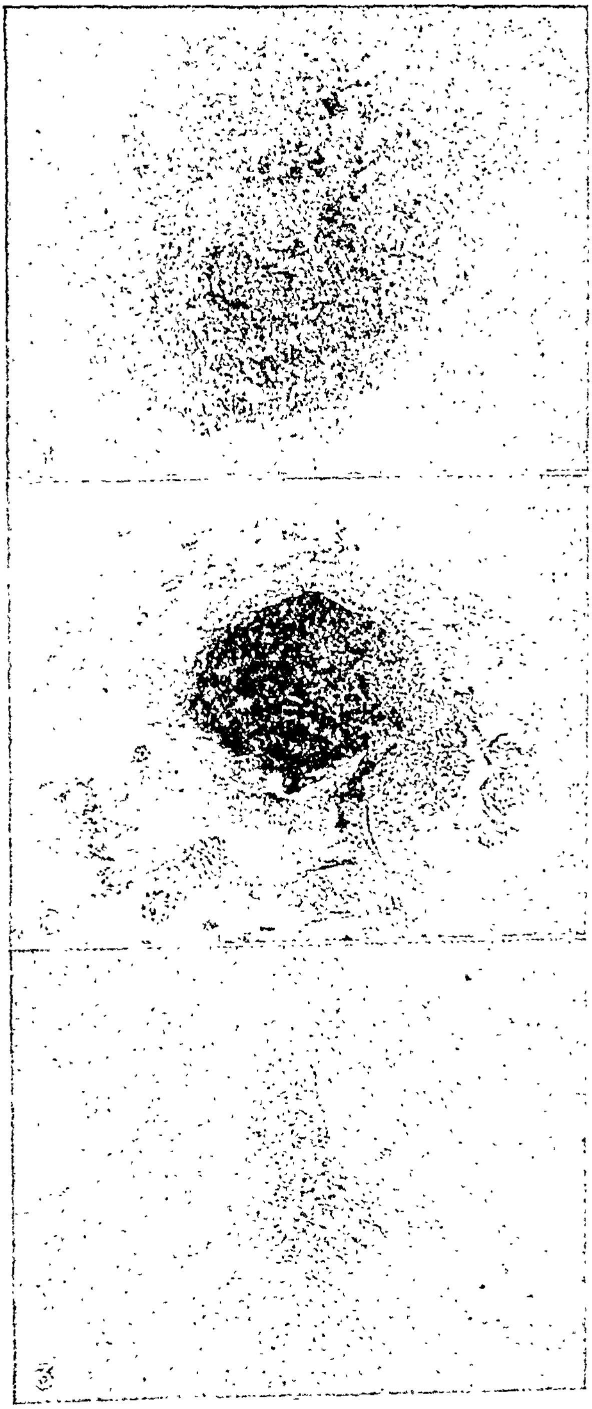
Abscesses.—This treatment has no direct favourable effect upon the course of an abscess. Its value lies in the necessity of only a small incision, for the vacuum will empty the pus contents and the vaporised iodine will antiseptise the cavity. No packing is required.

Non-follicular Pyodermias.—Such cutaneous affections as ecthyma, infectious eczematoid dermatitis, and dermatitis repens have been successfully treated by vaporised iodine and vacuum, provided constitutional factors are corrected if present. The affected part as well as the non-involved skin for a distance of several inches is to be included in the area of treatment. The vacuum recommended is from 10 to 15 inches to each area with three applications of the vacuum and of the vaporised iodine to each part of the affected skin. The time recommended for each application is from 10 to 20 seconds.

DISCUSSION

In advocating this method for carbunculosis it is important to weigh the advantages this procedure offers over other treatments—i.e., surgery and the X rays.

Surgery often calls for a general anæsthetic with its possibilities for dangerous complications, especially in subjects with severe vascular disease, advanced renal disease, or diabetes. There is also a small but definite surgical risk, necessity for skilful nursing, possibility of a long convalescence, and an unsightly scar. The value of X rays in carbunculosis depends upon the production of a mild hyperæmia. This treatment calls for the services of an expert and use of expensive apparatus, and perhaps, in the end, for surgical interference.



CASE II.—The patient, who had generalised lichen planus, developed a carbuncle over the lower dorsal vertebræ, and this reached 3 inches in diameter. (1) Shows the condition on Jan. 18th, 1933. He received 16 treatments up to Feb. 5th when healing began. (2) Shows *marked circumscription* of the lesion and the beginning of separation of necrotic material. (3) Shows healing completed.

The modified Bier's hyperæmia and vaporised iodine treatment is advocated both because of its logical experimental basis and the good results obtained. It has these advantages: simplicity of application with no special training required; absence of any risk; rapidity of relief from pain; speedy control of the septic phenomena when present; quick healing with but insignificant scarring. The aim of this treatment is to assist Nature in its effort to fight infection by increasing vascularity and favouring the interchange of blood in the congested area. Using iodine as the germicide, we are employing a remedy which clinically and in the laboratory has proven to be a dependable agent.

RÉSUMÉ OF CLINICAL RESULTS

Carbunculosis.—Fifteen patients with carbunculosis have been successfully treated by this method. The duration of the active treatment—i.e., up to beginning of healing—varied from 7 to 18 days. Constitutional evidences of septic absorption were not encountered. In some cases the pain subsided rapidly, and in others it was quite severe for a few days. Severity of the pain can be mitigated by warm metaphen (1 : 2500) application. The accompanying photographs illustrate the results of two patients with carbunculosis treated by this method.

Furunculosis.—Fifty patients with furunculosis have been successfully treated by this method. The inflammatory phenomena and the pain usually subside very rapidly. At times, however, the treatment appears to intensify the discomfort for a short while. Healing as a rule begins after three to five treatments. Dry dressings are used.

Non-follicular Pyodermias.—Six patients with obstinate infectious eczematoid dermatitis, two with ecthyma, and one with dermatitis repens were cured by this treatment.

At present we are treating a number of patients with rebellious sycosis vulgaris by the iodine and vacuum method. As a whole our results are not very encouraging. We are now planning to use X ray depilation of the affected area, and follow this by the vacuum vaporised iodine treatment. It seems logical that this method should succeed.

PALMER MEMORIAL HOSPITAL, JARROW. — The closing of Palmer's shipyard and works has produced a critical situation for this hospital, the only one in the town. Its principal source of income has been the contributions from Messrs. Palmer's employees which for the last 11 years have averaged £1250 per year. This source of income has now ceased, and the hospital is in danger of being closed at the end of September. Should £500 be forthcoming the hospital could pay its way to the end of the year, which would allow time for the preparation of a scheme which, it is hoped, would enable it to go on. *Three-fourths* of the insured working in Jarrow are unemployed.

"CURIOUS BODIES" FOUND IN THE LUNGS OF COAL-WORKERS

By Enid Williams, M.D. Wales
ASSISTANT LECTURER IN THE TUBERCULOSIS DEPARTMENT, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

Three years ago Tylecote and Dunn[1] gave an account of a case in which bodies resembling the "curious bodies" of asbestosis were found in the lungs of a coal-miner who had never worked in asbestos. He had worked in the coal-mines of Alabama and Lancashire. The "bodies" described by them simulated asbestosis bodies in shape and size and also in their abundance of free iron. The authors presumed them to be minute fragments of some inhaled iron-containing material which had undergone a chemical change under the influence of the body fluids. W. E. Cooke[2] in 1932 reported a case of "curious bodies" similar to those found in asbestosis occurring in a Lancashire coal-miner. He suggested that the formation of the "bodies" depended on the presence of silica and altered hæmoglobin. Last year Gloyne[3] stated that he had found these "bodies" in coal-miners' lungs "and in anthracosis." He considered them to be minute particles of carbonaceous material which occasionally had a deposit of yellow pigment around them, and thought them to be of no significance.

This paper is based on the examination of lungs from 26 selected cases. I am indebted to Prof. J. B. Duguid and his staff of the Welsh National School of Medicine for the material. The lungs were obtained from autopsies on individuals who died at the Cardiff Royal Infirmary during a period of six months. The investigation was meant to be confined to coal-workers' lungs in the first place, but it was later considered necessary to include lungs from another type of person to act as controls. Sixteen of the coal-workers were miners and seven trimmers. Three "controls" were taken; two were women and one a salesman. The causes of death were various. In seven cases death was due to injuries. There was only one death attributed to silicosis with tuberculosis. In two others, both coal-trimmers, however, there was in certain parts of the lungs a marked degree of fibrosis which may have been a contributory factor to the cause of death.

1. The *technique* employed was similar to that described by Cooke.[4] Representative portions of lung were taken and cut into very small pieces. These were put into tap water which had been made alkaline with sodium carbonate. To each 10 c.cm. was added 1 c.cm. of liquor trypsinæ co. After digestion for three or four days at 37° C. the material was centrifuged. The deposit was washed with water and examined microscopically.

2. In some cases the following method was employed and found to be easy and very successful. Paraffin sections of the lungs were mounted on slides in the usual way. After treatment with xylol, alcohol, and water, each section was ringed with paraffin to anchor it. Several slides were immersed in an alkaline solution of trypsin and left in the incubator overnight. They were then washed with water carefully and the ring of paraffin removed with a needle. After drying thoroughly in an oven the sections were mounted in Canada balsam. On microscopical examination a network pattern of dust was seen in which "curious bodies" were easily found.

3. Blocks of lung were also fixed in formalin for routine histological examination.

MORPHOLOGY

Out of 26 lungs examined, "curious bodies" were found in eight, or 30 per cent. They were exceedingly constant in structure, consisting of a black, slender, rod-like core at the poles of which was a golden yellow deposit. The appearance was reminiscent of a collection of iron filings at the poles of a bar magnet. Sometimes there was also a pale yellow annulated encrustation around the core. Unlike the asbestosis bodies, they did not vary much in shape, nor did they appear to originate in granular amorphous material. They always had a spicule as their basic structure. A Prussian blue reaction for iron was given in every case by the golden yellow deposit at the poles of the body. The deposit failed to take any of the aniline dyes, but in some cases it stained black with hæmatoxylin. It stained a very deep yellow with iodine. When treated with 25 per cent. sulphuric acid, the core was left with a colourless faintly outlined ghost of the deposit. The "bodies" resisted prolonged trypsinisation. Neither the core nor the deposit was doubly refractile, although doubly refractile particles were frequently seen in the same lung debris.

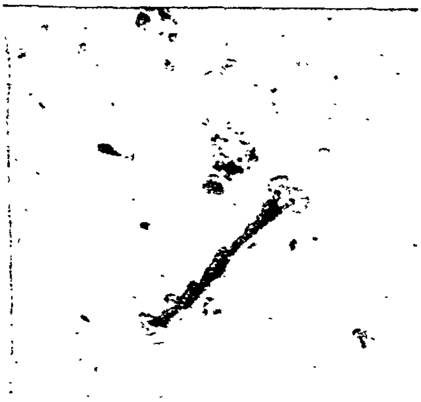

FIG. 1.—"Curious body" from a coal-miner's lung. (× 500.)

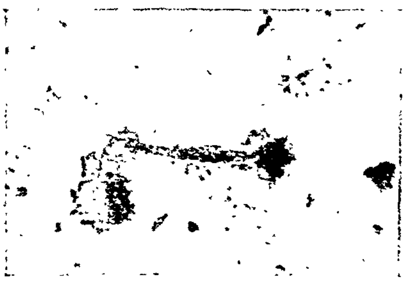

FIG. 2.—"Curious body" from a coal-trimmer's lung. (× 700.)

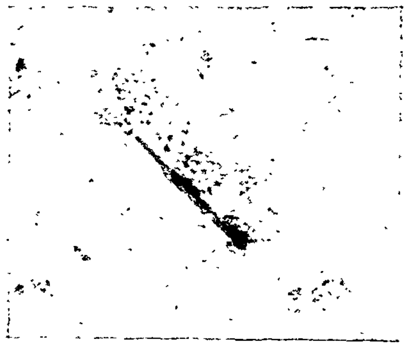

FIG. 3.—"Curious body" from the lung of a young woman. (× 400.)

Coal-miners' lungs.—Portions of lung from 16 miners were examined. It was difficult to obtain detailed "industrial histories" of these men. They had worked, with one exception, in the Eastern Glamorganshire coal-field. Fifteen were hewers and one a colliery mason whose work had been underground. They had all been exposed, therefore, to both coal dust and rock dust. In the strata of this coal-field sandstones and ironstones are found. The sandstones contain high proportions of silica. The average age of the men was 53. The youngest was 45 and the eldest 63. It is therefore probable that the length of service underground in all cases exceeded 30 years.

"Curious bodies" were found in five cases. They were present in very great numbers in one case, and were easily demonstrated in the lung sections. This patient had died of silicosis and tuberculosis, and had typical whorled fibrosis of his lungs. All the other lungs of this positive group showed various degrees of diffuse fibrosis, which was accompanied in one case by early nodulation. Doubly refractile particles were seen in the sections of three lungs. The histological findings in the 11 negative lungs were very similar to those of the positive group. Diffuse fibrosis, varying greatly in degree, was present in 10 lungs. In one case early nodulation was seen. There were doubly refractile particles in six sections.

Coal-trimmers' lungs.—Seven trimmers' lungs were examined. These men had trimmed coal at the Cardiff docks. Their average age was also 53, so that one can presume that their length of service was the same as the miners'. As far as could be ascertained, six of these men had been coal-trimmers for the whole of their industrial lives. One, however, had been a miner for five years before becoming a trimmer, at which occupation he had worked for 30 years. With the exception of this man, the trimmers had been exposed, presumably, to coal dust alone. Coal which is loaded and trimmed for export is usually "washed" free of extraneous dusts before it is delivered to the dockside.

"Curious bodies" were found in two cases. In one case they were even more numerous than in the miner who died of silicosis. They were abundant in the histological sections, lying among the coal dust deposits and in areas of fibrosis. In the other the "bodies" were few but were quite typical. Both these lungs showed almost no fibrosis. Two of the negative trimmers' lungs showed much diffuse fibrosis. Both men had died after a long period of dyspnœa and had been bedridden for many months before death. There was no evidence of active tuberculosis in either case. In one of these cases portions of lung were submitted to chemical analysis. In two blocks of lung, selected as specially hard and black, 11·9 per cent. and 4·8 per cent. of silica was found in the ash. There was practically no fibrosis in the sections from the other three negative cases. Although large deposits of coal dust in peribronchial and perivascular lymphatics were a feature of all the trimmers' sections, doubly refractile particles were not seen in any instance.

"*Control*" *lungs.*—Two of the three control lungs gave negative results. In the third, the lungs of a young woman, one "curious body" resembling, though possibly not identical with, those found in the coal-workers' lungs was seen after examining several slides. The lung debris contained many spicules which appeared to be mineral dust. There was no trace of fibrosis in the lung sections, but there were small deposits of coal dust, such as one would expect to find in the lungs of a woman who had lived in a narrow colliery valley where the atmosphere is laden with dust from the coal screens.

DISCUSSION

In this paper the term "silico-anthracosis bodies" has been avoided because it appears to me that no connexion with silico-anthracosis as a disease has been established. From the data reviewed here it appears that the presence or absence of "curious bodies" is of no help in establishing a diagnosis of the disease. It is true that a large number of "curious bodies" were present in the lungs of the only miner who died of silicosis. They were, however, still more numerous in the case of the coal-trimmer whose lungs showed practically no fibrosis. There was a marked degree of fibrosis and a large amount of dust in the lungs of two other trimmers, yet no "curious bodies" were found in these cases even after repeated examinations. It is difficult to assign significance to these "bodies" until more is known of their structure.

In this series of coal-workers were trimmers who had been exposed exclusively to coal dust and miners who had worked in coal and rock mixtures. "Curious bodies" were found in both groups. There was nothing to suggest from the mere finding of the bodies that one of these dusts was responsible for their formation. They were found in lungs which showed much fibrosis and in lungs where there was none; in miners' lung sections where doubly refractile particles were present and in trimmers' lungs where no bi-refringent particles were seen. It has been suggested that these "curious bodies" are formed by the adsorption of disintegrated blood substances by spicules of silica or particles of carbon. Another view is that they are due to the chemical interaction of an iron-containing mineral with the tissue fluids.

So far it has been impossible to obtain the "curious bodies" in sufficient numbers to investigate them minutely. It would be useful to identify the spicule by a petrological method such as measuring its refractive index. The deposit at the poles of the body may be a manifestation of some type of "crystal growth" such as is often seen in some siliceous minerals.[5] Quite often the deposit is arranged in a radiating fashion which suggests a phenomenon of this kind. Whatever may be the constitution of the "curious body" it appears that a gross pathological condition of the lungs is not necessarily present in cases where they are found.

SUMMARY

Portions of lung from 26 cases were digested with trypsin and the deposit examined microscopically. "Curious bodies" were found in eight cases. They were found in lungs from five of 16 miners, two of 7 trimmers, and one of 3 controls. From evidence collected in this investigation, it appears that gross pathological lesions of the lungs need not be present where "curious bodies" are found, hence it is difficult to ascribe any significance to their presence.

I am greatly indebted to Prof. S. Lyle Cummins for his help and encouragement during this investigation, to Prof. Duguid for the autopsy material and for allowing the microphotographs to be made in his department. A grant from the Medical Research Council greatly facilitated the research.

CLINICAL AND LABORATORY NOTES

THE NATURE OF HENRY'S REACTION IN MALARIA

By R. Howitt Wiseman, M.B. Glasg.

HOUSE PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, LONDON

In 1928 A. F. X. Henry described a new serological test for the diagnosis of malaria, depending on the property of malarial serum to flocculate a solution of melanin pigment. This he called melano-flocculation. The nature of this reaction has still to be determined. Although various suggestions have been put forward no satisfactory explanation has been given.

Henry (1934) favours the view that the reaction occurs as the result of interaction between melanin pigment acting as "antigen" and a corresponding antimelanin-agglutinin developed in human sera after malarial infection. Chorine and Gillier (1933), however, have suggested that the reaction is due to an increase in the serum globulins accompanied by a disequilibrium in the other soluble constituents of the serum. They have shown that negative sera can be transformed to positive sera by the addition of four volumes of 1/2000 formalised distilled water, that positive sera become negative when heated at 55° C. for half an hour, and that the melanin pigment used for the test proved to be non-antigenic by animal immunisation.

Greig, van Rooyen, and Hendry (1934) favour the latter view, since by a number of experiments they found the reacting principle in positive serum to be thermolabile at the relatively low temperature of 55° C., and that melanin pigment failed to produce an agglutinin response after repeated inoculation in rabbits. Consequently they consider that the phenomenon cannot be regarded as a true flocculation following interaction between antigen and antibody and suggest the term melano-precipitation is more correct than melano-flocculation. They also refuted the idea that the reaction might be due to some other substance or substances which happen to be present in colloidal solutions obtained from hair in the preparation of the solution used, by demonstrating that dioxyphenylalanine, the natural precursor of melanin, also gives a positive reaction.

Chorine and Gillier (1933) have further suggested that the reaction is due in part or in whole to an increase in the blood of such substances as lecithin, cholesterol, and uric acid, but it has been shown by Fairley and Bromfield that in malaria there is, if any change, a hypocholesterolæmia and a slight increase in the blood-urea. Thus the reaction cannot be considered as due to an increase of cholesterol, and it still remains to be proved that the increase of blood-urea is in any way related to the cause of the reaction. Greig, van Rooyen, and Hendry have come to the conclusion that phospholipoids are intimately bound up with the melano-precipitation reaction, and have published graphs to show how any rise in the titre is accompanied simultaneously with a fall in the lipoid phosphorus and vice versa, at the same time proving that the reaction is not due to an increase in lecithins.

Recently I have been investigating the value of the melano-precipitation test in cases of malaria, following strictly the improved technique introduced by Greig, van Rooyen, and Hendry. While the investigation was in progress it was noticed in estimating blood-urea that when 0·2 c.cm. of serum were added to 2·0 c.cm. of distilled water precipitation frequently occurred. A mental note was made of the degree of turbidity produced, and this was later found to correspond with the reaction obtained in the melano-precipitation tests. Consequently it was decided to run a parallel series of controls containing serum and distilled water only, the melanin solution being excluded, and it has been found that under these conditions exactly similar precipitates are found, except that the precipitate in the controls is white while that in the original tubes is brownish in colour owing to the presence of the melanin solution. In fact, on occasions the reaction in the water control has been positive in higher titre than in the melanin tubes; further, in one or two instances where cases have had parasites in the blood, the melanin tubes have been negative while the water controls have been quite strongly positive. Finally, so far in the investigation, every case which has given a positive result in the melanin tubes has done so in the controls with distilled water. These facts are exemplified by the accompanying Table of cases selected from the series.

Case No.	Parasites.	M.P.R.	Titre.	W.C.	Titre.	Remarks.
1	B.T.	+	1/16	+	1/32	—
2	B.T.	+	1/32	+	1/64	W.R. + +
3	B.T.	—	—	+	1/8	—
4	B.T.	+	1/16	+	1/128	—
5	B.T.	—	—	—	—	—
6	B.T.	—	—	+	1/8	—
7	S.T.	+	1/16	+	1/8	—
8	S.T.	—	—	+	1/128	Saline control also negative.
9	S.T.	+	1/4	+	1/128	—
10	Nil	—	—	—	—	Blackwater fever. Rigor 105°.
11	Nil	—	—	+	1/16	Chronic malaria. After treatment with atebrin M.P.R. —ve. W.C. 1/128.
12	Nil	—	—	+	1/8	Chronic malaria. Last rigor nine days before admission.
13	Nil	—	—	+	1/32	M.T. malaria when in S. Africa and in Ceylon. Returned to England 4½ years ago.

M.P.R. = Melano-precipitation reaction; W.C. = water control; B.T. = benign tertian; S.T. = subtertian; M.T. = malignant tertian.

On further reviewing what has been written on Henry's test it was discovered that previous workers, employing the original technique, had already noted that the reaction sometimes occurred with distilled water alone. This flocculation with serum and distilled water Henry calls "surflocculance." Trensz (1932^a) considered the difference between this and the flocculation in the melanin tubes to be a matter of degree only, Henry's reagent assisting the flocculation. He injected 11 guinea-pigs with trypanosomes (*T. berberum*) and the reaction became positive soon after the appearance of trypanosomes, and as the reaction became stronger "surflocculance" occurred in six of the control tubes. Chorine (1933), on the other hand, does not agree with Trensz that they are the same phenomenon. From observations in the present preliminary investigation I have formed the opinion that these phenomena are one and the same, the melanin merely adding a brown colour to the flocculation; and it appears that the reagent tends if anything to hinder the reaction, but whether it does so as a result of its pH factor, chloride, or other salt content has not been determined. In this connexion it is interesting to note that in Case 8 where parasites were present in the blood the melanin tubes were negative, the water controls were positive 1/128, and when the serum was put up with normal saline only a negative result was obtained. This suggests that the salt content of the solution in itself tends to inhibit the reaction. Thus, while we are at a loss to account for the true nature of the reaction, it would appear from the observations here made that the precipitate is in all probability a globulin. Furthermore, the pigment produced in malaria has been identified as hæmozoin (Wats and White, 1932) and so it is difficult to understand why melanin should have anything to do with the reaction. In view of these findings it is considered that the melanin employed in the test since its inception plays no real part in the reaction and since it is difficult to prepare could be abandoned. Finally, the terms melanoflocculation and melano-precipitation would appear to be misnomers.

The investigation has been carried out in the Hospital for Tropical Diseases, London. I am grateful to Dr. G. Carmichael Low, Dr. Philip Manson-Bahr, and Dr. N. Hamilton Fairley for permission to use their cases, to Mr. R. J. Bromfield for valuable aid in the laboratory, and I am deeply indebted to Lieut.-Colonel E. D. W. Greig, Dr. C. E. van Rooyen, and Mr. E. B. Hendry, of Edinburgh University and Edinburgh Royal Infirmary, for so kindly furnishing all the melanin solution used in the tests, and to Dr. van Rooyen for demonstrating the test to me.

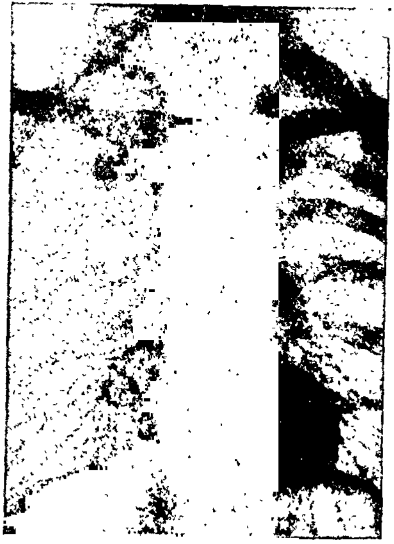
CARCINOMA OF THE ŒSOPHAGUS WITH FISTULA INTO THE AIR-PASSAGES

BY W. G. SCOTT-BROWN, M.D. Camb., F.R.C.S. Eng.
ASSISTANT SURGEON TO THE EAR, NOSE, AND THROAT DEPARTMENT, ROYAL FREE HOSPITAL, AND CENTRAL LONDON EAR, NOSE, AND THROAT HOSPITAL

A MAN, aged 59, was first seen on Oct. 16th, 1933, complaining of difficulty in swallowing. Eight months previously he had felt "the throat getting fuller" and for the past three months it had become difficult to swallow; he developed a cough and there was regurgitation of food with coughing, in attacks which were often severe during and immediately after a meal. He described himself as otherwise "as fit as ever," and, being a professional tramp, had walked 20 miles a day for some previous days.

On examination of the nose, throat, and larynx nothing abnormal was discovered except some frothy mucus in both pyriform fossæ. Cervical and axillary glands were not palpable. At the X ray examination by Mr. Ulysses Williams the thin barium emulsion produced a spasm of coughing, and during deglutition it was difficult to follow the barium on the screen. Immediately afterwards it was seen that the barium was passing through a fistula just below the cricoid and that the bronchial tree was clearly outlined (see Figure).

Œsophagoscopy revealed a large ulcer extending across the anterior wall of the œsophagus with the upper edge situated 1½ in. below the cricoid cartilage. The surrounding œsophageal wall was infiltrated and a small piece of tissue was taken from the edge of the ulcer for section. Bronchoscopy revealed a swelling on the posterior tracheal wall about 2-2½ in. below the cords. The posterior wall could not be seen completely beyond the swelling, but a dimple was visible with a drop of blood-stained fluid by it. A section of the edge of the ulcer confirmed a diagnosis of carcinoma of the œsophagus.



Radiogram taken after the patient had swallowed barium emulsion. It has passed through the fistula and into the bronchial tree on both sides.

A gastrostomy was performed by Mr. L. E. C. Norbury on Nov. 8th, and the patient declared himself, and appeared, fit when he was transferred to a L.C.C. hospital on Nov. 22nd. The cough was very much improved. He lived for four months after the diagnosis was first made, and was free from any cough or regurgitation, and indeed of any symptoms referable to his respiratory or alimentary tract. During these four months he became increasingly cachectic and gradually went downhill and died on Feb. 19th, 1934. A postmortem examination could not be obtained.

There were found to be three other similar cases in the hospital records for the past ten years, and a summary of the case notes is given below. There are one or two interesting points. It will be observed that they were all diagnosed by X ray examinations, though on careful questioning a history could be obtained from them which indicates the presence of a fistula in addition to the œsophageal obstruction. In two cases it appeared that some of the food swallowed was regurgitated with coughing. In another there was a history of being frightened to swallow. The fourth merely complained of a cough which produced a great deal of sputum and that this had had a definite and marked commencement unassociated with any illness.

CASE 2.—Male, aged 59. Admitted Oct. 18th, 1926. Three months ago: lump in throat, difficulty in swallowing. Two months ago: pain on swallowing. Five weeks ago: vomits and coughs after meals; wasting rapidly. Cough for one year, much worse last three months. On radiography barium emulsion runs down to the level of the bifurcation, where there is a distinct check. Then some emulsion passes on into the lower part of the œsophagus and stomach, but a large quantity is seen passing into each bronchus. There is a stricture of the œsophagus at the level of the bifurcation of the trachea due to a neoplasm. Also broncho-œsophagoscopy shows a fistula. No treatment was carried out, and the patient died in St. Luke's Hospital on Nov. 27th, 1926.

CASE 3.—Female, aged 46. Admitted July 10th, 1927. Eleven months ago: hoarseness and difficulty in swallowing. Six months ago: worse. For past two to three months: wasted rapidly and "any food taken" was coughed back again. Radiography (Oct. 5th): post-cricoid growth, fistula between trachea and œsophagus; bronchi outlined by barium emulsion. Oct. 11th: gastrostomy. Oct. 13th: died.

CASE 4.—Male, aged 65. Admitted August 5th, 1930. Six weeks ago: first symptoms of difficulty in swallowing solids. Two weeks ago: cough and sputum—no pain on swallowing, but frightened to swallow owing to choking. Radiography (lipiodol): extensive obstruction half-way down œsophagus with ? fistula communication into left bronchus. Broncho-pneumonia left lower lobe. Gastrostomy was performed on August 8th, and the patient died on the 10th. At autopsy the œsophagus showed an ulcerated growth at the level of the bifurcation of the trachea communicating with left bronchus. There was broncho-pneumonia of the left lung.

In any case of carcinoma of the œsophagus in which "cough," "sputum," and "bronchitis" are prominent symptoms, and particularly when these symptoms are aggravated by taking food, a fistula should be suspected. The apparent good health of the patient will be misleading, so long as it is generally thought (and the statement still appears in many text-books) that such a perforation is associated with a rapid onset of broncho-pneumonia and death.

It is seen from these cases that the fistula had probably existed for from two weeks to three months before the patient reported to hospital. In Case 2 the patient lived for five weeks after the diagnosis was definitely made, having probably perforated five weeks previously. There was no treatment. In the first case here reported the patient lived for four months after the diagnosis was made, a gastrostomy having been performed, but there seems little doubt that the fistula was present for seven months in all before the patient's death.

BACILLARY DYSENTERY DUE TO FLEXNER, TYPE "Z"

PRESENTING SOME UNUSUAL FEATURES

By S. D. McClean, M.R.C.S. Eng.
MEDICAL OFFICER, ANGLO-PERSIAN OIL CO., LTD.; AND
Frank Marsh, M.D. Lond., D.T.M. & H. Eng.
PATHOLOGIST TO THE COMPANY

The patient was admitted to hospital at Masjid-i-Sulaiman under one of us (S. D. M.) with diarrhœa and pyrexia of 12 days' duration. The attack began with mild shivering and tenesmus; later there was abdominal discomfort and vomiting, and then diarrhœa. The temperature rose to 101° F. The diarrhœa gradually increased in intensity until she was passing some 12 or more stools a day. At no time did she notice blood or mucus in her motions. She continued to have loose motions until admission, with occasional bouts of mild abdominal pain and discomfort, which were associated with mild pyrexia and marked anorexia. About two days before admission she developed mild gingivitis with two aphthous ulcers on the upper gums between the incisor teeth. Her menstrual periods were regular.

On admission pulse-rate 88, temperature 99·4° F., general condition good, no loss of weight, tongue furred, marked generalised hyperæmia of gums, two ulcers on upper gums. Some injection of throat, tonsils not enlarged. No abnormal signs in chest. No enlargement or abnormal signs in heart; pulse rapid, well-marked sinus arrhythmia. Abdomen: generalised discomfort, no marked tenderness at any one place but diffuse slight tenderness. Sigmoid flexure palpable and slightly thickened. Stools only two der day.

Treatment.—At first she was given Bovril, strained soup, weak Horlick's and weak milk and soda, with sodium sulphate grs. 10 four-hourly. On the following day the sodium sulphate was increased to grs. 20 four-hourly; her temperature rose to 98·8° in the afternoon but she had no pain or discomfort. Next day she felt much better; and on the next her diet was increased to fish, eggs, and milk puddings, and the sodium sulphate was reduced. Next day there was considerable improvement and a soft normal-looking stool. She was given a diet scheme and discharged from hospital to have the vaccine in out-patients.

Pathological Investigations.—The patient's blood was examined for malarial parasites with negative results. A differential count showed: polymorphonuclears 50 per cent., lymphocytes 35 per cent., eosinophils 2 per cent., large mononuclears 3 per cent., no abnormal red cells. The urine was negative. The first stool examined was green, watery, and contained a little mucus and *Entamœba coli.* There were no pus, blood, or epithelial cells, no *Entamœba histolytica* or cysts, no ova. Cultured on McConkey's medium, about 12 pearly-white, irregularly margined colonies were seen, 1 mm. across at their broadest point and centrally clear—not granular. Three were picked off and produced acid but no gas, in the butt only, of three tubes of Russell's triple sugar medium. Taken further, acid, no gas, was produced in glucose, and mannite broth; there was slight indol production in peptone broth; motility was absent; gelatin not liquefied, and there was no change in litmus milk. A 24-hour broth culture put up with Burroughs and Wellcome's anti-B. Flexner serum, No. B.6921.M., titre 1/1600 and incubated four hours, half immersed, in a water bath at 56° C. in Dreyer tubes, was agglutinated at 1/100 but not in the higher dilutions. Later 24-hour broth cultures were put up with Medical Research Council standard agglutinating sera, as under:—

Dilution ..	1/25.	1/50.	1/125.	1/250.	Control.
Type V ..	0	0	0	0	0
,, W ..	0	0	0	0	0
,, X ..	T	T	T	0	0
,, Y ..	T	T	S	0	0
,, Z ..	T	T	T	S	0

Explanation of symbol: T = total; S = standard; tr = trace.

The incubation was for four hours at 56° C. in Dreyer tubes; the titre of the sera was 1/250 and they were dated Oct. 3rd, 1933.

The patient's serum was put up with Medical Research Council standard agglutinable cultures, with the same technique as for the standard sera, the results being:—

Dilution ..	1/25.	1/50.	1/125.	1/250.	Control.
Type V ..	S	tr	0	0	0
,, W ..	0	0	0	0	0
,, X ..	T	T	0	0	0
,, Y ..	T	T	tr	0	0
,, Z ..	T	T	S	0	0
Mrs. W ..	T	T	T	0	0

It was considered unnecessary to proceed with absorption agglutination experiments; it seemed quite definite that the type "Z" antigen was the predominant one in the bacillus.

Successive stools for about ten days were cultured on McConkey; the number of non-lactose-fermenters on the plates progressively declined during the first three days and then disappeared altogether, the remaining seven stools all being negative.

An autogenous vaccine was made and the patient was treated with a full course in order to prevent a relapse. A remarkable feature of this illness was the consistently diarrhœic stool; at no time was the classic picture of blood, pus, mucus, and epithelial cells presented by the stools. Another point was the ease with which dysentery bacilli were isolated from the motions, in comparison with the difficulty of growing the responsible micro-organisms from a typical mass of "pink jelly" of which the great majority of stools from cases of bacillary dysentery are composed. It is possible that the masses of mucus, in these classic examples, actually have an anti-bacterial effect, as demonstrated recently by Prof. Howard Florey, and the result is that the pathogenic organisms are so affected that they are unable to proliferate on a McConkey plate.

We have to thank Dr. E. Jamieson, chief medical officer, Anglo-Persian Oil Co., Ltd., for permission to publish this paper.

REVIEWS AND NOTICES OF BOOKS

Industrial Maladies

By Sir THOMAS LEGGE, C.B.E., M.D. Oxon., D.P.H. Camb., late H.M. Senior Medical Inspector of Factories and Medical Adviser to the Trades Union Congress. London: Humphrey Milford, Oxford University Press. 1934. Pp. 234. 12*s*. 6*d*.

IT was in 1898 that Legge was appointed first medical inspector of factories. In the early part of his career at the Home Office he was chiefly engaged in studying and dealing with the prevention of occupational lead poisoning—and with this disease his name will always be associated. He subsequently worked on anthrax, tetanus, industrial cancer of the skin, toxic jaundice, and poisoning by arsenic, phosphorus, mercury, and the bichromates. It is difficult to find an industrial disease on which he could not speak with authority and experience. He resigned his Home Office appointment in 1926, but was afforded an opportunity of continuing to some extent his life's work when he was made medical adviser to the Trades Union Congress in 1929. Lady Legge explains in the dedication to the book that the author, knowing that his death might befall before the book was ready for press, left directions that Dr. S. A. Henry of the Home Office should be asked to edit it, and this has been arranged.

The first two chapters deal with notification of industrial disease and industrial poisoning and compensation for industrial diseases. The history of the subject is revealed, and the four axioms for which Legge is now well known are laid down:

> (1) Unless and until the employer has done everything—and everything means a good deal—the workman can do next to nothing to protect himself, although he is naturally willing enough to do his share.
>
> (2) If you can bring an influence to bear external to the workman (i.e., one over which he can exercise no control) you will be successful; and if you cannot or do not, you will never be wholly successful.
>
> (3) Practically all industrial lead poisoning is due to the inhalation of dust and fumes; and if you stop their inhalation you will stop the poisoning.
>
> (4) All workmen should be told something of the danger of the material with which they come into contact, and not be left to find it out for themselves—sometimes at the cost of their lives.

Subsequent chapters deal with anthrax, tetanus, and poisoning by lead, phosphorus, mercury, and arsenic. Details are given of industrial processes and methods used in minimising the risks of poisoning. Figures are constantly quoted in tabular form, showing the effects of legislation in reducing the case-incidence from year to year. The subject matter is quite up to date, extensive references being given to new work, such as that of the Harvard workers on lead poisoning, of the Queensland workers on chronic nephritis amongst young people, and of geologists on sericite in quartz. Poisoning by benzene, nitro compounds, carbon bisulphide, carbon tetrachloride, dinitrophenol, and methyl alcohol follow. Separate chapters are devoted to poisoning by fumes and gases, industrial dermatitis, industrial cancer of the skin, and industrial pneumonoconiosis. Tables and figures of the incidence of the various types of poisoning are provided throughout the book, and emphasis is everywhere placed upon the type of protective measure found effective in the industrial process concerned.

In one respect the book could be improved, and that is the choice of illustrations. The pictures of industrial cancer are excellent and to the point, but industrial argyria is profusely illustrated though it has quite disappeared in industry. The picture of the dust cloud from stripping the cylinder of a cotton carding engine suggests that a spinning mule, a grinding shop, and radiograms of the chest in pneumonoconiosis could usefully be added. Illustrations of the methods used in preventing disease in industry would be more instructive to the student than tables and charts showing the incidence of industrial disease at various times, and we should like to see pictures of exhaust ventilation applied in a lead works, of a rock-drill provided with a water-jet, and of a vacuum apparatus in use to clean a carding machine in an asbestos works.

This is a book which should be in the hands of every medical man engaged in the health inspection of factory workers, but it is also a book for the general practitioner, by whom most cases are first seen, and who should have sufficient knowledge of industrial conditions to understand how his patients may become ill as a result of the occupation they follow. To-day 37 occupational diseases are scheduled as compensatable by various Acts of Parliament.

The work is a monument to a man who was not only a pioneer in the prevention of disease in industry, but who was probably the greatest authority on this subject of our times.

Die Postoperativen Pneumopathien

By Prof. C. HENSCHEN. Basel: Benno Schwabe and Co. 1934. Pp. 177. Fr.8 (Swiss).

THIS monograph is in the main a survey of the world's literature on post-operative pulmonary complications. Statistics from the well-known surgical clinic in Basle, and short accounts of the author's views, experiments, and practice are interspersed, but no concise statement of essentials emerges. A vast number of writings have been abstracted, condensed, arranged, and to a certain extent discussed, with painstaking care and thoroughness; the gist of them all is there for the inquirer to consult and judge. It is an excellent example of the agglomerative review. But in this subject, as in many others, most readers would be grateful for that rarer species, the synthetic review, a coherent presentation of what, in the reviewer's judgment, and in the light of his experience, is most valuable in the writings of his predecessors. This monograph will be very useful to the specialist making an intensive study of the subject, but the surgeon or the anæsthetist seeking help in the reduction of post-operative morbidity will have difficulty in seeing the wood for the trees.

Nature and Nurture

By LANCELOT HOGBEN, M.A., D.Sc., Professor of Biology in the University of London. London: Williams and Norgate Ltd. Pp. 143. 6*s.* 6*d.*

THIS book consists of the William Withering memorial lectures delivered at Birmingham last year under the title of "The Methods of Clinical Genetics." It contains little that the author has not previously discussed in his book "Genetic Principles in Medicine and Social Science"; but the essential arguments are here presented in simpler language and are less burdened with higher mathematics. Since his appointment to the chair of social biology in the University of London, Prof. Hogben has in two main ways contributed to the study of how genetic principles might be applied towards the prevention of disease. In the first place, he has drawn attention to the fact that, if adequate statistics could be collected of the familial incidence of certain commoner diseases and defects and of the occurrence of consanguineous marriages among the ancestors of sufferers from them, it might be found that many more than are at present recognised are the product of recessive genes. His influence in stimulating research in this subject is now making itself felt in appropriate quarters.

In the second place, Prof. Hogben's attitude to clinical genetics is avowedly influenced by his dislike of eugenists. In an earlier book he went so far as to advocate the substitution of the term "genetic therapy" for the word "eugenics" on the ground that "the term 'eugenics' has become identified with ancestor worship, anti-semitism, colour prejudice, anti-feminism, snobbery and obstruction to educational progress." Discussing in this book the ambiguities of the word "intelligence" he says, "Dean Inge may describe a social policy as intelligent. In that case, the writer would probably describe it as unintelligent." Now eugenists stress the importance of the rôle of heredity in the causation of human excellencies and infirmities. In many instances they doubtless over-stress it, minimising in the process the importance of the environment. One of the tasks which Prof. Hogben has set himself in this book is to emphasise the possible rôle of the environment. He points out that certain abnormalities in the fruit fly of unquestionably genetic origin, which affect the shape of the abdomen and the number of facets in the eye, largely depend for their appearance on environmental conditions such as moisture and temperature. Unlike the fruit fly, however, human beings begin their lives in an intimate environment, the vicissitudes of which may easily affect them—namely, the uterus. As an example of the possible effects of an abnormal uterine environment, he selects mongolian idiocy—not an entirely happy choice. The genetical statistician, Prof. R. A. Fisher, is especially singled out for attack: working in the rarefied atmosphere of higher mathematics, he is held capable of ignoring completely such trivialities as imperfections of diagnosis and unsuspected defects of environment. The general conclusion is that hereditary human abnormalities are very interesting to investigate, but that our efforts to eliminate them by genetic methods are premature in that we may at any moment learn how to cure them by bringing about changes in the environment. Prof. Hogben quotes Ostwald: "Among scientific articles there are to be found not a few wherein the logic and mathematics are faultless but which are, for all that, worthless because the assumptions and hypotheses upon which the faultless logic and mathematics rest do not conform to actuality."

The combined effect of these two attitudes of the author is somewhat disconcerting. If this book happened to be read by a busy house physician or hospital registrar who had been asked (for no remuneration) to undertake a comprehensive and difficult inquiry into the incidence of consanguineous marriages in the ancestors of all patients suffering from (say) acute nephritis, he might be pardoned for asking what purpose was to be served if the chief promoter of the inquiry regarded it, from the preventive standpoint largely, from the therapeutic standpoint wholly, academic. The answer that the results would be genetically interesting would hardly seem to justify his labours.

A Synopsis of Hygiene

Fourth edition. By W. W. JAMESON, M.A., M.D., F.R.C.P., D.P.H., of the Middle Temple, Barrister-at-Law, Professor of Public Health, London University, and Director of Public Health Division, London School of Hygiene and Tropical Medicine; and G. S. PARKINSON, M.R.C.S., D.P.H., Lieut.-Colonel R.A.M.C. (ret.), Assistant Director of Public Health Division, London School of Hygiene and Tropical Medicine. London: J. and A. Churchill. 1934. Pp. 619. 21*s.*

THIS standard text-book on public health appears in a somewhat changed form. While retaining its attractive features—excellence of style, abundance of references to recent writings, adequacy of treatment—the order in which the various subjects are treated has been totally changed. Thus ventilation, heating, lighting, atmospheric pollution, water-supplies, sewage, housing, sanitary law—matters which form the special province of the sanitary inspector—although fully dealt with are relegated to the end of the book. Public health administration and vital statistics are presented to the student in the first chapter, the latter being particularly well handled. There is much to be said for the rearrangement; the bias in public health has moved away from environmental hygiene and writers of text-books should take cognisance of the fact. The prevention of disease cannot be discussed without reference to statistics.

The book is thoroughly reliable, and gives to each aspect of the various subjects just the right amount of emphasis. We can recommend it without reservation.

A Short History of Some Common Diseases

Edited by W. R. BETT, M.R.C.S., L.R.C.P. London: Humphrey Milford, Oxford University Press. 1934. Pp. 211. 10*s.* 6*d.*

THIS small book contains a series of essays by well-known writers, who have attempted, some with greater success than others, to summarise in a few pages the history of common and prominent diseases. The articles are not written in accordance with any definite pattern, the authors sometimes confining themselves chiefly to a record, with dates, of particular work done by prominent men, while other writers pay particular attention to ancient history, and others to modifications and developments of treatment. As certain of the chapters have very full references to the authorities upon which the writers are relying, the book will serve as a guide to deeper reading. Some of the essays appear scrappy, and all sixteen are not of equal merit, but it is clear that to tell the story in a few pages of (say) tuberculosis, venereal diseases, endocrine disorders, and heart disease is a difficult task and for the most part the authors may be congratulated on their efforts.

The Atom

By JOHN TUTIN, D.Sc. (Durham). London: Longmans, Green and Co. 1934. 6*s*.

IN this book of little more than 100 pages the author challenges acceptance of the Rutherford-Bohr atomic model. We do not think that the challenge is as serious as it is sincere, for the simple reason that there is very little quantitative backing for the claims that are made for this new atom. Briefly, the author seeks to turn the Rutherford-Bohr atom inside out. Instead of the mass being concentrated about its centre as a nucleus, rather is it collected on the periphery, and he then goes on to explain how many phenomena would, in his opinion, receive a much more rational explanation from his model than from the one which has such general scientific acceptance to-day. It may be that, in stating his claims, the author is confusing the rôle of the atom with that of the molecule. One of the essential duties of an atomic model is to provide a rational mechanism for the emission of radiation, and year by year the spectroscopists become more and more impressed with the potentialities of the Rutherford-Bohr atom in this respect. It would be idle to put forward as a competitor an atom which can do none of these things, whatever other phenomena the new model may explain.

British Journal of Children's Diseases

THE July-September issue (Vol. XXXI.) contain the following papers. The Story of Tracheotomy by Dr. E. W. Goodall: brings up to date the histor of this operation. Dr. Goodall has collected 2 examples of successful tracheotomy during the perio of 2000 years up to the time of Bretonneau, the firs having been performed by Asclepiades, who wa born in the second century B.C. Apart from thre cases recorded by Caron in 1766, Andrée in 1782 and Chevalier in 1814, all the successful operation were on adults. The paper will be continued in subsequent issue.—In An Analysis of Over Fou Thousand Cases of Educational Deafness Studie During the Past Twenty-five Years, Mr. Macleo Yearsley records the results of his experience a consulting aural surgeon to the London County Council. The cases are grouped under the heading of congenital and acquired deafness, the forme (with which the present instalment of Mr. Yearsley' study is concerned) being subdivided into hereditary and sporadic cases, and congenital aphasia.—Dr P. D. Davydoff, of the North Caucasus State Institut for the Protection of Maternity and Childhood contributes a paper on Helminthiasis in Children in which he records his experience of the condition in Soviet Russia, where it appears to be unusually prevalent and serious.—In a paper on Nocturna Enuresis, Dr. C. J. C. Earl discusses the incidence causation, psychological explanations, and treatment of bed-wetting from his experience at the London Child Guidance Clinic.—Some Pædiatric Eponyms: (VI.) Eustace Smith's Sign is the title of a paper by Dr. W. R. Bett, who gives an intimate sketch of this well-known pædiatrician, illustrated by his portrait and autograph. The abstracts are devoted to cardiovascular diseases.

NEW INVENTIONS

AN ANGLE-PIECE FOR MAGILL ENDOTRACHEAL TUBES

AS Dr. Magill[1] has pointed out, endotracheal anæsthesia by means of a single rubber tube is more satisfactory if there is no leakage of gases between the tube and the glottis, and he recommends packing off the pharynx with gauze to prevent this leakage. When using gas-oxygen-ether anæsthesia for abdominal surgery it is even more important to prevent this leakage, and a number of anæsthetists have found that this can equally well be achieved by passing an endotracheal tube by the nasal route, replacing the facepiece of the gas machine, and securing it on the patient's face with a Clausen's harness. This obviates the necessity for packing, and is a much simpler procedure than is necessitated by passing the inflatable intratracheal cuff of Guedel and Waters.[2] It is a method which can be used for all operations below the level of the mandible, and whose only contra-indications are when there has been bleeding from the nose on intubation or when the pharynx is full of secretions.

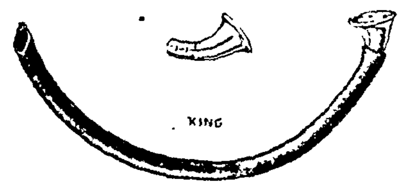
There are, however, three objections to the use of any of the existing patterns of angle-piece for this purpose:—

(1) When the facepiece is removed at the end of the anæsthetic a Magill or Challis or Rowbotham pattern angle-piece is often found to have bruised the upper lip or the nose.

(2) There is a tendency for any of these models to touch the sides or cushions of the facepiece and thus obstruct the free airway.

(3) Not infrequently some of the lubricating vaseline works its way between the tube and the angle-piece, and the latter becomes disconnected. In such a case the tube can quite easily slip down the nose, and may have to be recovered with a pair of forceps.

To obviate these difficulties I have devised a small metal funnel, shown in the accompanying photograph, whose narrow end fits into the tube. This end is provided with knocked-up teeth which take a firm grip of the inside of the tube. The middle of the stem is curved at an angle of about 200°, so that it fits the curve of the nasal fossa, while the wide end is rounded off and presents no sharp edges which can bruise the face.



Since this method is chiefly useful in adults I use two sizes of these connexions: the smaller to fit a No. 6 Magill tube, and the larger a No. 9. To ensure an adequate airway the minimum internal bore should never be less than 3/16 in. These end-pieces are large enough to admit of the passage of the cleaning-brush, and are intended to be left in place during cleaning and boiling throughout the "life" of the tube.

This method, as Magill[1] and Tovell[3] have pointed out, is equally useful with a Schimmelbusch mask if open ether is being administered, but the tube is less liable to become obstructed by the gamgee or other face-pads if this type of angle-piece is used. It is made by A. Charles King, of 34, Devonshire-street, W.1.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 8, 1934

THE WORLD WE LIVE IN

Any common man who hears or reads Sir James Jeans's presidential address this week to the British Association at Aberdeen may be excused if he feels a little bewildered. Is this, he may well ask, the physicist's most up-to-date summary of the most exact of sciences, or is it Alice in Wonderland, or is it someone in a dark room looking for a black cat which isn't there ? Something perhaps of all three, but probably mostly a demonstration of the scientific philosopher at his best, groping about for an explanation of the results of observation and experiment which he knows by revelation to be there but which he cannot clearly grasp, still less define and make available for others. Sir James's address might have been written by a religious mystic who was not quite sure what particular gospel he ought to preach. Theoretical physics, he says, is concerned with appearances rather than reality, and it has two lots of appearances. In the one the world is made up of particles which exist in time and space. In the other it is composed of a system of waves, or perhaps more nearly as a system of waviness for which ordinary space and time provide no adequate background; it may need six dimensions of space, and as there is no justification for identifying any particular three of these with those of ordinary space the wave picture comes to lie entirely outside space and is purely a construction of our minds. Experiment and mathematics are all on the side of the wave structure and yet the particles cannot be abandoned, for they represent the grains or units which pervade the whole of nature from the indivisible quantum of energy to the indivisible live organism.

The physicist's trouble is that no one has yet had the luck or cunning to hit on the idea which will bring together these two interpretations into one and provide an explanation of the universe as a consistent whole. Sir James does not doubt that such a synthesis is possible, but he goes on to point out that it may be expected to come from ourselves rather than from outside. The old physics thought that it was studying something which had an objective existence of its own—and most of us still so think of the world. But the new physics—if indeed it still be physics—holds that the nature we study does not consist so much of something we perceive but of our perceptions. In the old physics the student's mind was a spectator, in the new it is an actor; the perceiver and the perceived are interacting parts of a single system, and no clear distinction can now be drawn between mind and matter. If this is so, and if nature consists of our own mental constructions, how is it that we all make the same constructions and see the same moons and the same mountains ? It is not, we think, quite certain that we do; myopes and the colour blind suggest that there may be a good deal more variability than is apparent. But assuming a general uniformity, Sir James proposes an attractive explanation. Physically, he points out, the wave explanation takes no notice of individual particles, and innumerable photons come together as a beam of light, electrons as an electric current, and cells into a live organism.

If this is true of the objects perceived it may be equally valid for the perceiving minds. In space and time we are obviously distinct individuals; beyond these limitations we may be the components of a continuous stream of life. And so once again the mathematician comes round to the biological point of view, and now he is no less of a mystic. But Sir James is no biologist, else surely he would not have repeated Sir James Ewing's gloomy misconception, emitted at the Yale meeting two years ago, that man's control over nature has outstripped his moral control over himself. No naturalist could believe that, nor is it consonant with the plain experiences of life, and we could wish that Sir James Jeans had not felt in duty bound to come back to earth at the end of a noble sermon.

TUBERCULOSIS AMONG NURSES

> 304. The fear of infection is difficult to combat, though reports of infection with tuberculosis of the nursing staff of sanatoriums are so rare as to be negligible. Since tuberculosis is notifiable, statistics bearing on this aspect of recruitment should not be difficult to collect, and their publication might help to convince parents that their daughters are no more liable to contract tuberculosis than they would be in any other branch of nursing.

This paragraph from the final report (1932) of The Lancet Commission on Nursing deals quite frankly with a matter of public interest. The risk of infection taken by nurses whose duties bring them into contact with tuberculous patients must always exercise the minds of those responsible for training. So far however no very clear leading as to the prevalence of the infection has been forthcoming. Dr. J. A. Myers, Dr. H. S. Diehl, and Dr. H. D. Lees[1] have recently explored the question from a new angle by comparing three nursing schools in the United States, one having a tuberculosis service of 30 beds amongst its nursing duties, the others having tuberculous patients to nurse from time to time but having no definite tuberculosis service. Judged by the standard of tuberculin tests of probationers followed through to their final year of training, school 1 with the nursing service comes off very badly. The positive reactors in this school increased from 40 to 100 per cent., whereas in school 2 the reactors remained more or less stationary and in school 3 only increased from 25 to 45 per cent. The authors have no doubts as to the significance of these positive reactions. They say "the hospitals that have infected for the first time or reinfected their students [i.e., nurses] have committed a serious offense against them. A good many of these girls will suffer from clinical tuberculosis as the decades pass, and some of them will die from that disease." This is hard hitting, but the authors support their views with the fact that more than 11 per cent. of the nurses starting negative to tuberculin in 1929 are already suffering from clinical disease. At the same time this particular school is perhaps not to be regarded as typical but rather to be held up as a warning to thoughtless administrators. J. Heimbeck's[2] figures for Oslo, so often quoted, show that out of 282 nurses who began their training with a positive Pirquet reaction, 1·4 per cent. subsequently developed tuberculosis, whilst of 299 with a negative reaction 22 per cent. developed the disease.

---

[1] Jour. Amer. Med. Assoc., June 12th, p. 2086.

In dealing with the number of actual breakdowns from tuberculosis amongst nurses we are on safer ground than with the positive reactors. In this country figures were long ago published showing the proportion of resident medical officers, dispensers, nursing staff, female servants, and porters at Brompton and Victoria Park hospitals who contracted tubercle. The results were regarded as highly reassuring, but it must be borne in mind that diagnosis before the discovery of the tubercle bacillus was not very precise. In Germany, following upon Cornet's work on transmission of bacilli by dust, a hospital inquiry was instituted by the Prussian Minister concerned, with the result that a high mortality amongst the Catholic nursing orders was revealed. In 1910 J. E. Squire, in a paper read before the Royal Society of Medicine, collected the data then available; of 234 nurses who had worked at Ventnor and Crooksbury 3 (or 1·2 per cent.) were then known to have had a breakdown. After the war the subject was approached again, and in a more systematic manner, both in Europe and America. For the six-year period 1918–1923 O. Scheel found[3] that among 2913 nurses in Norwegian communal hospitals there were 30 cases of pulmonary tuberculosis (including miliary), 27 of pleurisy, 3 of renal, and 3 of osseous tuberculosis, making a total of 63 (or 2·2 per cent.). In this record the incidence of pleurisy was greatest in the first year of the nurse's service, and of other forms in the third year. One of the most thorough investigations[4] is that of E. L. Ross for Canadian hospitals. A preliminary inquiry had shown in 1926 that out of 1514 women treated in a group of Canadian sanatoria 99 were nurses. Ross compiled a record of 60 tuberculous nurses; he found that 40 had broken down during training and 20 afterwards, 10 of the latter within one year and 5 within three years—that is to say, of 800 nurses trained during a four-year period in the province of Manitoba approximately 6 per cent. became sanatorium patients directly from their training schools or within a year of completing their training. These 60 nurses came from 20 different hospitals; only rarely did a sanatorium nurse break down with tuberculosis. In America J. A. Britton and Bollman (quoted by E. K. Geer) found 2·2 per cent. of all nurses employed in Chicago had tuberculosis, S. J. Shipman and E. A. Davis 2·6 per cent. in the University of California training school over a period of six years, and Geer himself 5·5 per cent. in St. Paul, Minnesota (but only 1·6 per cent. in a later series). An inquiry in a New Zealand hospital by D. W. Carmalt Jones[5] and a committee of the hospital staff shows an incidence of 3 per cent. per annum during two years, all cases being pulmonary tuberculosis. In Germany H. Much (quoted by Geer) found the incidence in the Eppendorf Hospital up to 1918 was 1 per cent.; after the war it rose to 4·6.

As far as we are aware no recent figures are available for this country with the exception of a brief record[6] of nurses under the Welsh National Memorial Association published in 1926—11 tuberculous breakdowns in 996 nurses (1·1 per cent.). It would appear however that the incidence of clinical tuberculosis amongst nurses generally ranges between 1 and 6 per cent. While that may be true—as well as vague—we cannot draw deductions until we know the incidence of tuberculosis amongst the young adult female population in the districts from which probationer nurses are drawn. Very few of the writers on the subject have attempted this; those who have (e.g., Carmalt Jones) suggest that the figures for nurses may not be in excess of their non-nursing similars—in other words, tuberculosis amongst nurses is part of the general problem of the undue prevalence of tuberculosis amongst young adult females. This is the first point for further investigation. Some of the records quoted are compiled for the years of training only, others include follow-up records for various periods after the completion of training. It is obvious that the nurse is exposed to special risks, but the old danger from the diminution of resistance by excessive fatigue is now less frequent, while food and sleeping accommodation are usually better than in former days. Against this must be set the fact that nowadays nurses begin their training early in life. Ross noted that the breakdowns appeared to have no special relationship to any particular part of hospital work, though there was a general impression amongst the nurses themselves that night duty had had an unfavourable effect. Sanatoria have as good a record as general hospitals, indeed, in some cases better; probably because, as Ross pointed out, undiagnosed cases of infective tuberculosis are more common in the latter, whilst an open-air régime is the rule in the former. Fortunately, in the case of the nurse early diagnosis is generally assured. Ross noted that as many as 38 of his 60 cases had been diagnosed within two months of developing symptoms, a much better record than that of young adult female patients in general. The prognosis therefore is also better.

[6] Tubercle, 1926, vii., 334.

The practical issues are various. Two of these are seen in the questions: Should young women with a family history of tuberculosis be accepted as nursing probationers? Should ex-tuberculous patients be offered posts? Some sanatoria are prepared to accept the risk of a further breakdown, whilst general hospitals in most cases definitely decline to take the risk. The presence of obsolete tubercle in nurse applicants who have never had an actual breakdown raises an issue closely related to that of HEIMBECK's tuberculin-positive nurse. Is it better for a nurse to have a positive tuberculin or a negative reaction on starting training? C. J. JACOBSON[7] in recording 5·2 per cent. of Danish nurses with tuberculosis was unable to satisfy himself on this point. A positive reaction before training generally means obsolescent tubercle; a positive reaction acquired during training is more likely to signify active disease. X ray records should prove more valuable than tuberculin tests in the decision. We shall not get far until many hospitals compile records of their nurses, including a follow-up inquiry, and pool their experience.

THE CAUSATION OF SQUINT

WHAT is the primary cause of concomitant internal squint? DONDERS taught that it is hypermetropia, resulting in a want of balance between the linked reflexes of accommodation and convergence. The theory is sound so far as it goes, and the prescribing of spectacles is, and will doubtless remain, an essential preliminary to treatment in all applicable cases. Many cases, however, occur in emmetropes or quite low hypermetropes and, in general, when an internal squint is associated with hypermetropia the extent of the former by no means shows the correspondence with the degree of the latter that the theory demands. A second well-established cause is a defect in the power of fusing the images which fall upon the retinæ of the two eyes. In 1903 Mr. CLAUD WORTH published an important book in which he maintained that this is the essential condition applicable to all cases. By inventing the amblyoscope he laid the foundation for the modern orthoptic treatment of squint, and though 20 years later at a meeting of the Ophthalmological Society he admitted[8] that the proportion of cases in which fusion training is applicable is much smaller than he at first thought, we may agree with him that in suitable cases and at the right age this treatment yields results which could not have been obtained by any other means. Most of the surgeons who spoke at this meeting agreed about the theoretical value of the amblyoscope, but for practical purposes used it merely as a means of diagnosis. Since then many new instruments have been invented for training the sense of fusion, and some of them are in daily use at the orthoptic training clinics of ophthalmic hospitals. For an estimate of the value of these devices on the one hand, and of the practical limitations of their usefulness on the other, our readers will be grateful to Mr. L. H. SAVIN, whose postgraduate lecture appears at the front of our present issue.

Although it is probably true as maintained by WORTH that all cases of concomitant squint are accompanied by a defective development of the fusion sense, yet it is open to question whether he was correct in maintaining that this is the essential cause in all cases. Speaking at the discussion in 1921, already referred to, Mr. BISHOP HARMAN maintained that the most important determining cause was defective muscle balance. He cited some cases of extreme esophoria continuing into adult life without causing squint, and suggested that the reason why these cases are so rare is that most of them are lost in the all-obscuring condition of manifest squint. Heredity is an important factor in many cases, and examples more or less similar to Mr. SAVIN's curious case of congenital squint in twins will be within the experience of many ophthalmic surgeons. Finally, as Dr. W. S. INMAN has so often insisted, the psychological element must not be ignored. Squint often varies with the emotional state of the child, especially about the time of onset, and may even disappear spontaneously. Miss M. A. PUGH, who has had considerable experience at the Moorfields clinic for the orthoptic training of squint, has gone into the causation in 500 cases.[9] Of these, refractive error was the primary factor in 62 per cent., defects in the fusion sense in 15 per cent., psychological factors were predominant in 21 per cent., the remaining 2 per cent. being put down to physical defects. Miss PUGH further subdivides the 103 psychological cases thus. Imitative squint 7 per cent.—in one pair of brothers both squinted, the elder one had a large refractive error and the younger one was emmetropic. The younger one squinted a week after the elder one. Jealousy squint 10 per cent.—a frequent cause is the advent of a new baby; the elder child will mope and be unhappy and will suddenly squint. The wish seems to be to bring the focus of attention back to the patient. Fear or shock squint 26 per cent. —as when a child was frightened at night by a drunken father and woke up on the following morning with a marked and constant squint. In these ways nearly half the cases in this group are accounted for. The remainder occurred in children who were either themselves "difficult" or whose home surroundings were unfavourable. It may be doubted whether it is really possible to say what is the primary cause of squint in the great majority of cases, but among the causative factors the psychological cannot safely be neglected.

OUR ELDERS AND BETTERS

A letter lately appeared in the *Times* suggesting that the medical profession is unduly severe on patients over seventy. The writer, himself a doctor, took the view that after this age response to treatment is poor and habits are already moderate, so that insistence on a strict régime may, to no purpose, make life not worth living. He got scant thanks, however, for this humane thought; one septuagenarian reader sent an answer which implied that he, at all events, is willing to try anything once; and a surgeon was provoked to declare that he had found two classes of patients almost immune from the perils of surgical attack—namely, Quakers and those over 80. The fact is that the old will stand a good deal more than we usually give them credit for. Dr. F. W. Bailey,[1] of St. Louis, points out that as people tend to lead quieter, and therefore (he considers) more normal, lives as they grow old, they become less subject to such ills of youth as acute appendicitis, ruptured duodenal ulcer, acute pancreatitis, acute cholecystitis, and specific bloodstream infections. On the other hand, they are exposed to greater danger from circulatory and renal changes, enlarged prostate, malignant degeneration, fibrosis, and fatty degeneration, and unfortunately there are plenty of occasions on which acute surgical emergencies are superimposed upon degenerative changes, and timely surgery becomes desirable. As a rule, however, the patient is serenely ready to chance it, like the old lady with acute obstruction whose case is described by Dr. H. C. Colman on page 576. The aim, in such a case, is not to rejuvenate the patient but to return him to his normal senile state. "When surgery is necessary in the very aged," Dr. Bailey says, "prolonged bed rest, sudden change of environment and diet and an abrupt curtailment of previous habits which are not directly inimical to their illness, should be avoided and the maintenance of an agreeable psychic atmosphere encouraged." He thinks that in all serious cases a pre-operative transfusion of blood should be given, or, where that is impossible, intravenous glucose. Serious ailments should never be allowed to develop beyond the margin of safety, and minor ailments should not be left untreated merely because the patient is old. He finds that patients are more grateful, on the whole, for the relief of a minor painful disability than for successful treatment of something more serious. This is worth bearing in mind, for the old have as much right to be comfortable as the young.

If the aged offer few terrors to their surgeon they usually expect to find a good listener in their physician. He can always retaliate, however, by putting the patient on a diet, and that outlined by Dr. Robert Hutchison in the "old age" number of the *British Journal of Physical Medicine*,[2] though plain to the point of grimness, has probably helped many an antique digestion to work smoothly. He recommends, for breakfast, dry toast and butter, a lightly cooked egg or a little white fish, and one cup of tea or coffee; for the midday meal, two courses only, fish and meat, fish and a sweet, or meat and a sweet—the sweet to be milk pudding, baked custard, junket, or stewed fruit. For tea there is one cupful of weak tea and no solid food; and this is followed by a light evening meal of white fish and a potato, or bread and milk, or a boiled egg, and at bedtime a cup of soup or Benger's food, or a little whisky and water and a biscuit. Happily Dr. Hutchison adds that such a scheme must be used with elasticity. In some people "appetite and digestion remain unimpaired up to an advanced age and for such fortunate ones the ordinary diet of a healthy man is permissible though strict moderation should be exercised in its use."

There is no unison, of course, among the oracles in reply to the question: "When does old age set in?" One speaker, discussing Dr. Bailey's paper, maintained that a man was old when he gave up tennis and took to golf—a decision which many will contemplate with alarm. Dr. Bailey puts the limit, with liberal exceptions, at 60, Dr. Colman at 70; while Sir Humphry Rolleston, in his "Medical Aspects of Old Age," offers evidence in favour of the classical statement that the circulatory system, more often than any other part of the body, sets the upper limit of the human life span. But even the doctrine that a man is as old as his arteries has its pitfalls; the late A. P. Graves, the Irish poet, when he was forty visited his doctor, who alarmed him by saying: "Mr. Graves, you have the arteries of a man of eighty." He lived to be nearly a hundred, and somewhere in his eighties had the pleasure of hearing his doctor exclaim: "Mr. Graves. you have the arteries of a man of forty!"

IN MEMORY OF THEODORE WILLIAMS

Generous gifts for the advancement of medicine are made known in the will of the widow of Dr. Charles Theodore Williams, who died in July at the great age of 90 years. Theodore Williams, who was born in 1838 and died in 1912, was a student of Pembroke College, Oxford, and throughout his life remained a devoted son of Oxford. He founded four university and two college scholarships in human anatomy, physiology and pathology, including bacteriology in relation to medicine, and shortly before his death he was elected an honorary fellow of Pembroke. He was also in his lifetime a benefactor of the Royal College of Physicians of London, of which he became fellow in 1871, councillor in 1891, and censor in 1899. He gave £1000 to the endowment fund of the College and was instrumental in founding the Bisset Hawkins memorial medal. He was also for a time president of the Medical Society of London. The bequests now announced include £30,000 to Oxford University, to be expended by the faculty of medicine for the promotion of medical education; £5000 to the Royal College of Physicians, to be devoted to the exercise of hospitality and to the maintenance of its dignity; and £100 to the Medical Society of London. Mrs. Williams has also left to Pembroke College a portrait in oils of her husband, by Herbert Olivier, and the residue of her estate to promote its prosperity.

ANNOTATIONS

AEROPLANES AS CARRIERS OF INFECTIOUS DISEASE

THE temporary failure of international coöperation in politics throws into relief the success of international coöperation in preventive medicine. Its latest achievement is the Sanitary Convention for Aerial Navigation,[1] now signed and ratified by most of the important countries of the world, notable exceptions being the South American republics and the Dutch East Indies. The Convention is comprehensive and adequate and provided that the High Contracting Parties carry out their work properly it should go far to allay the fears of the many hygienists who see great danger of infectious disease being spread by aeroplanes. Of its two parts the first contains some general provisions dealing with the establishment of "sanitary aerodromes" and other matters, while the second sets out regulations governing the "Big Five" diseases—plague, cholera, typhus, small-pox, and (with a special chapter to itself) yellow fever. It is left to the authorities of each country to decide whether "sanitary aerodromes" shall be established, but the attendance of a medical officer at all "authorised" aerodromes where required for the purposes of the Convention is obligatory. Sanitary aerodromes will have a staff of medical officers and sanitary inspectors, a place for medical inspection, equipment for the taking of pathological specimens, facilities for the isolation, transport, and care of the sick and of contacts, and apparatus for disinfection, disinsectisation, and deratisation where required. Aircraft will not be required to carry bills of health but facts of public health importance, which are to include the appearance of any of the Big Five in the area from which the aircraft has come, are to be entered in the journey log-book. Although any territory may if it thinks fit carry out sanitary measures on arrival of aircraft from an infected "local area," it is before departure that the special measures (inspection, disinfection, &c.) enjoined for plague, cholera, typhus, and small-pox must be taken. These follow the same lines as in the International Sanitary Convention of 1926, and it is chiefly in connexion with yellow fever that further stringent provisions are laid down.

The special dangers of yellow fever lie in the wide distribution of its mosquito vector, the highly infective nature of the virus, and the existence of large "silent" areas in which the native population has been infected. One such area was described in our last issue by Dr. T. F. Hewer, who showed that the disease has been or is endemic in a wide zone in the Anglo-Egyptian Sudan where its presence has been unsuspected. As the Imperial Airways route to the Cape runs through this area it is gratifying to learn that all the measures prescribed by the Convention are already in force there. They include a general provision that signatories shall "take the necessary steps to ascertain whether yellow fever exists in their territory in a form which, though not clinically recognisable, might be revealed by biological examination." In regions where yellow fever has occurred or exists in endemic form there shall be established "anti-amaryl aerodromes" which in addition to the equipment of a "sanitary aerodrome" shall be situated at an adequate distance from the nearest inhabited centre and shall have mosquito-proof dwellings and water-supply. Failing the establishment of an anti-amaryl aerodrome all air traffic from such an area shall be suspended. When yellow fever is discovered in a region, the following measures are to be taken as late as possible before the departure of aircraft. (1) The aircraft and cargo will be inspected for mosquitoes and if necessary disinsectised. (2) The passengers and crew will be medically inspected, those who have been exposed to risk of infection being required to remain under observation either at the aerodrome or elsewhere until six days from their exposure. (3) The names of passengers and crew, with all information available about their exposure to infection, will be entered in the log-book. On arrival in a region in which yellow fever is not endemic but might develop, the aircraft and passengers and crew may be inspected and any person who has not completed six days since his last possible exposure to infection may be kept under observation for not more than six days.

These are stringent regulations and may somewhat hamper the development of air transport in the large region of Africa where yellow fever is now known to be endemic. On the other hand, the danger is a very real one[2] and it cannot be suggested that the precautions are excessive. The appearance of yellow fever in a country such as India would be a very serious matter indeed. It is also to be hoped, as Dr. Hewer suggests, that protection by vaccines[3] may soon be so far perfected as to allow of relaxation of the regulations to persons in a hurry. In any case it was well that the Rockefeller Foundation decided to open a special campaign against yellow fever many years before the dangers from air travel were generally recognised, since it is owing to these workers' efforts that the menace of the "silent" endemic areas was discovered. As the late Sir Walter Fletcher wrote[2]: "It is no stretch of fancy to say that the discovery of the true nature of the disease and of its preventability by vaccination may have come just in time to save us from a world disaster of unthinkable magnitude."

MEDICAL EXAMINATIONS IN DUSTY INDUSTRIES

INTEREST attaches to the principles underlying an order[4] made by the Home Secretary which came into force on Sept. 1st. This order deals with the initial examinations of workmen who seek to be employed in occupations with exposure to injurious dust under the silicosis and asbestosis compensation schemes. It amends a previous order[5] by laying down with greater precision the circumstances with which anyone must comply who is seeking employment in the scheduled industries: the refractories, sandstone, pottery, and asbestos. First, in his own interest, the worker is to be refused employment if his physique falls short of certain medical requirements with regard to development and the absence of pulmonary or cardiac disease. Secondly, in the interest of his fellow workers who, by reason of their exposure to the specific occupational dusts, are unduly predisposed to succumb to tuberculous infection, he is to be refused employment if he is suffering from tuberculosis. Precedents are here being set which may with advantage to the individual and to the community be more widely used in the future. The order of 1931 which is now amended also establishes periodic medical examinations year by year during employment in a scheduled occupation. At these examinations suspension from work may be enforced, if lung disease is found, in the interests of the worker and of his fellows. The way in which these examinations provide valuable data for studying the cumulative effect of the specific dust hazards and the clinical progress of the resulting pulmonary damage is well set out in a recent article[6] by Dr. T. Ferguson on silicosis among sandstone workers in Scotland and the North of England. He shows how sandstone dusts generally render the lungs liable to dyspnœa, bronchitis, and the like, but only certain stones originate the specific silicotic condition; furthermore, wide individual differences exist in capacity to deal with inhaled silica.

CHILDREN IN THE ALPS

THE council of the Queen Alexandra Sanatorium Fund has decided on an important change in policy. The fund, which owes its origin to the appeal for the foundation of an English sanatorium in Davos made by the late Lord Balfour of Burleigh 30 years ago, has investments valued on the Stock Exchange at £64,000 and an annual income of about £2400. Since the sanatorium was given up as a war-time necessity it has been the custom to allocate the income to enable patients of small means suffering from curable tuberculosis to stay long enough in Davos to make a substantial recovery. Last year the number of suitable cases applying for grants was not very large, and it was possible to extend the grants for more than the usual five or six months on medical advice in Davos—an innovation which has the warm support of the London Council; but those who administer the fund have recognised that a limited stay in the Alps, particularly if, as at present, it must be followed by a return to straitened conditions at home, does not produce the best possible return for expenditure. This may be a heartless view of the situation, for there is no question that whatever the effect on physical signs the fund has been able to infuse some cheerfulness and happiness into many lives; there can, however, be little doubt that a strict analysis would prove disappointing, although grants have not in principle been made to patients in an advanced state of the disease. For the last two years the council has had an object-lesson of a different kind in the Davos valley. Owing to the generosity of the president of the Birmingham Children's Hospital (himself a Swiss subject) and the enlightened imagination of its staff, a group of 40 or more Birmingham children have had the opportunity of spending several months in the alps, with results which have been critically watched and assessed by a number of British and foreign pædiatricians. About one-half of these children had had various forms of surgical tuberculosis; the remainder illnesses such as asthma, interstitial pneumonia, recurrent bronchitis, debility, and malnutrition after prolonged ill-health. When last reported, of the 80 children who had been to Switzerland, 41 were discharged "cured" after a stay averaging seven months, and at a cost per patient per week of £2 2*s*. 8*d*.

The experiment is said to have exceeded the expectations of its promoters, and it was this object-lesson which induced the council of the Queen Alexandra Fund a year ago to adopt the principle of helping children. At that time negotiations for collaboration with the Birmingham scheme did not mature and the money was allowed to accumulate, so that for the coming year there is a larger balance available for this purpose, and in fact the council has agreed to allot, if suitable cases offer, as much as half its available income for the purpose. No hard-and-fast rules have yet been laid down as to the qualifications for a child candidate. There is perhaps even now insufficient exact information about the value of the climatic factor in the cure of childish ailments to form a final opinion, but the late Prof. Leopold Moll, from his experience in organising recreative holidays for children of 6 to 12 years old in the Italian, Swiss, and Austrian Alps, formed opinions which must command respect.[1] For children of weak constitution with secondary anæmia, with bronchial asthma, and especially with infiltration of the bronchial glands, he held the alps superior to the seaside, and in his last published work he was impressed with the large percentage of children who could be rid of a relapsing bronchial catarrh by a winter cure in the high alps. The fund's honorary examining physicians in London will decide on its merits any application received for help from the fund, which now has the benefit of the advice of Prof. L. G. Parsons, who was elected a member of council at the recent meeting. It might be thought that there would be difficulties in inducing parents to part with their delicate children to the care of strangers for so long a period, but that has not been the Birmingham experience, and the two institutions in Davos, to one or other of which the children would be sent, have a reputation for homeliness which will soon reassure the faint-hearted.

Practitioners with youthful patients who would, they think, benefit under the scheme should apply for further information to the hon. secretary of the council, Mr. A. Stanley Herbert, 25, Birchin-lane, London, E.C.3, or to the local secretary, Mr. W. G. Lockett, Davos-platz, Switzerland.

MR. SERJEANT SURGEON KNIGHT

A CORRESPONDENT asks for information about serjeant surgeons in general and Dr. John Knight in particular. The serjeant surgeons of England have succeeded each other in an almost unbroken series from 1461 until the present time. They were generally two in number, although occasionally an additional one was appointed or the emeritus title was bestowed on someone whom the King wished to honour. The serjeant surgeons ranked above the King's principal surgeon. It was their especial duty to attend the King on the field of battle. For reward they received a yearly salary of 40 marks (£26 13*s*. 4*d*.) with a "bouge of Court," which was an allowance of meat and drink "with wine, wax and all requisites for carrying out their cures." The wax seems to have been used for embalming the bodies of deceased members of the royal family. Mr. Serjeant Surgeon Knight complained in 1662 that he had received the usual fee for embalming the body of the Duke of Gloucester, but was ordered to divide it with Richard Wiseman, surgeon in ordinary. Various additional privileges appertained to the office in earlier times. The serjeant surgeon was entitled to be considered a past master of the United Company of Barbers and Surgeons. When the company was dissolved in 1745 he was always appointed to the honourable and lucrative office of examiner in its successor the Surgeons' Company. The privileges were curtailed little by little, the official remuneration was consolidated and reduced, until in the end the honour alone remained.

---

[6] Jour. of Indust. Hyg., July, 1934.

[1] THE LANCET, 1933, i., 710.

Something is still known of John Knight. He attended Charles II. on his voyage from the Hague to Dover in 1660, and thus became known to Mr. Samuel Pepys, who dined with him on Dec. 30th, 1662. The diary records—

> "Thence to a Barber's and so to my wife and took her at noon to Mrs. Pierce's by invitation to dinner, where there came Dr. Clerke and his wife and sister and Mr. Knight, chief surgeon to the King, and his wife. We were pretty merry, the two men being excellent company."

Knight was constantly occupied with matters connected with the sick and wounded during the Dutch wars and the records of St. Bartholomew's Hospital contain a letter from the Duke of Monmouth, dated Sept. 10th, 1678, asking that sick and wounded soldiers may be received into the hospital on the recommendation of Mr. Serjeant Knight, chirurgeon generall. He may perhaps have been in attendance on his royal master during the Commonwealth period, for on Jan. 5th, 1661, he applied to the governors of St. Bartholomew's Hospital for the minor office of "guide" to the Lock Hospital in Old Kent-road. He brought with him a letter of recommendation from King Charles and was twice interviewed with a view to his election. He seemed to look upon the post as a sinecure and was not chosen. The governors saved their faces by replying to the King that "they had a respect and tenderness to His Majesty's displeasure if they should have conferred the said place upon the said Mr. Knight, hee being constantly soe neer the King's person and the bussines of the said place soe offensive and nautious." It often proved the first rung on the ladder to success, for the guide became assistant surgeon and in due course full surgeon to the hospital.

Knight is still remembered at the Barbers' Hall in Monkwell-street, where he was twice Master of the Company. He restored the priceless cup given by Henry VIII., and he persuaded Charles II. to present the acorn cup in commemoration of his escape at Boscobel. It is also stated that Knight identified the bones of the princes in the Tower and was instrumental in getting them buried in Westminster Abbey in an urn designed by Christopher Wren.

ACETYLCHOLINE IN RHEUMATISM

THE use of histamine in arthritis—given by ionisation or injection—has won much support.[1] Another substance capable of increasing the local circulation of blood is acetylcholine, and like histamine it has been applied to rheumatic joints by ionisation. The actual drug used by J. Kovacs[2] was acetyl-beta-methylcholine, a choline compound which is said to be more slowly destroyed in the body than acetylcholine, while its vasodilatory action is more prolonged and its side-effects are almost negligible. Ionisation is carried out with an asbestos fabric paper pad soaked in a 1 per cent. solution of the compound, and applied under the positive pole of the circuit, a large moist pad electrode being applied to the back of the patient and connected with the negative pole of the battery. The local effects noted were increase of skin temperature up to 10° F., sweating, reduction in swelling, and increased mobility of the joint. If large areas were treated general effects—such as flushing, sweating, increase in pulse-rate and slight fall in blood pressure, salivation, and evidence of increased intestinal peristalsis—might be observed. The results of treatment were best in patients with rheumatoid arthritis. Reduction of pain, swelling, and stiffness was noted in a majority of these after six or eight sessions at the rate of two a week; the patients had been selected for treatment because other methods had failed to help them. In smaller groups of cases of osteoarthritis, bursitis, sciatica, and neuritis encouraging results were also obtained. However, Kovacs wisely concludes that before the value of this form of treatment can be accurately measured, observation of patients over long periods will be necessary.

A PIONEER OF CANCER RESEARCH

THE death of Prof. Jensen, director of the serological institute of the Royal Veterinary College of Copenhagen, removes a historical figure from our midst. Born on March 16th, 1864, he came as a young man under the influence of C. J. Salomonsen and of B. Bang, and took part in the development of what was then the new science of bacteriology. He was interested mainly in the bacterial infections of animals, especially domesticated animals, and published numerous papers on this subject. But important as this aspect of his work is, it is overshadowed by the impetus he gave to the investigation of cancer by his publication in 1903 in the *Centralblatt für Bakteriologie* of a paper entitled "Experimentelle Untersuchungen über Krebs bei Mäusen." Having found repeatedly mice with malignant new growths he had tried to transmit the disease to other normal mice, but at first without success. Eventually, in 1901, he succeeded in transmitting a spontaneous mouse carcinoma to other animals and in propagating the tumour through 19 generations of mice. This tumour, which Jensen freely distributed to other laboratories where its propagation was continued, came to be known as the "Jensen mouse carcinoma." Jensen at once proceeded to investigate the nature of the process involved in this transmission of cancer. He showed that it is possible only in animals of the same species, that it demands the existence of living cells, and that the tumour develops in the new hosts from surviving cells which have been inoculated. The transmission is due, therefore, to a process of transplantation, and not to a process of infection. These observations were of fundamental importance and they have been amply confirmed by subsequent investigators.

CARL OLAF JENSEN

Jensen was by no means the first to have succeeded in transmitting a malignant new growth from one animal to another of the same species. He mentions himself the previous successful experiments of Hanau in 1889 with a rat sarcoma, of Moran in 1894 with a mouse carcinoma, and of Velich in 1898 with a rat sarcoma. Simultaneously with Jensen, Leo Loeb, in 1901, had also recorded the successful transmission of rat sarcomas. But these experiments had aroused little interest in the medical world and had been forgotten. The reason for this unfortunate attitude was that clinicians and human pathologists were convinced that cancer was a disease peculiar to the human species, and that these tumours in animals had no bearing on the cancer problem as it appears in man. Hanau was so disappointed at the neglect of his work, whose importance he fully realised, that he committed suicide. But by the end of the century veterinary pathologists had accumulated a formidable mass of evidence demonstrating the occurrence of cancer in animals. In this country Sir John McFadyean had protested against the statement of clinicians that cancer did not occur in animals. In 1903 E. F. Bashford, the director of the newly founded Imperial Cancer Research Fund, had published a paper emphasising the importance of investigating cancer as a biological problem on a basis of comparative pathology, and in the following year he had demonstrated the occurrence of cancer with all its characteristic manifestations throughout the vertebrate kingdom. Jensen's work was certainly more thorough than that of his predecessors, but it also had the merit of coming at the psychological moment. Thus the experimental investigation of cancer was initiated.

---

[1] See THE LANCET, 1933, i., 920 and 988; 1933, ii., 1018; 1934, i., 1226, 1228, and 1366.

[2] Amer. Jour. Med. Sci., July, 1934, p. 32.

Subsequently Jensen made two further contributions to the cancer problem. In 1909 he published a paper on "Übertragbare Rattensarkome." In this paper he described the tumour now so well known as the Jensen rat sarcoma. In the following year he discussed the occurrence of tumours in plants which resemble in their properties the malignant tumours of animals. His work was instrumental in establishing the transmission of cancer. Ten years after the publication of his first paper dealing with this aspect of the disease his colleague in Copenhagen, Prof. J. Fibiger, demonstrated its experimental production.

SKIN DISEASES OF DOGS

WHEN dogs develop skin lesions, such as eczema, ringworm, or mange, the owners usually want to know whether they themselves are likely to catch the infection. Holmes,[1] in reviewing the subject, points out that true eczema in the dog is non-infectious; he attributes it mostly to external irritation by dirt, parasites, impacted anal glands, and like causes. Improper feeding, and possibly renal disease, are regarded as predisposing factors; there is also a dry form of eczema common in certain breeds of dog, which probably originates from endocrine derangement. Removal of the cause of irritation and symptomatic treatment are generally effective. In ringworm, on the other hand, contagion to man is common. It occurs in the dog in dry and purulent forms, and disappears readily if infected areas are cleaned and treated with iodine, but some months must elapse before the danger of secondary lesions is quite over. Of mange also there are two kinds—due to different parasites—the sarcoptic and the follicular. The former, caused by *Sarcoptes scabiei*, is readily contagious to human beings, as was illustrated in a case reported in our columns not long ago.[2] Diagnosis, in the dog, depends upon the demonstration of the acarus, and this can be done without undue waste of time by the sugar flotation technique.[3] Treatment consists of clipping the whole dog and applying sulphur incorporated in an oily dressing. Treatment, if carried out whole-heartedly, is usually successful in four to six weeks. About follicular mange unfortunately very little is known, though it is all too common, especially in certain breeds of dog. The condition is characterised by the presence of a mite, *Demodex folliculorum*, in the deep layers of the epithelium; but as the same or a similar species is a regular inhabitant of the human skin, especially in "blackheads," it would be rash to regard it as the actual cause. The general opinion is that it is not transmissible to man, but in animals it is a serious matter; indeed in the old days it was considered incurable, and destruction of infected animals was usually recommended. In reviewing the subject recently, however, Sen [4] points out that although no specific treatment has yet been devised, the position is by no means hopeless; and, especially in the non-pustular forms, a cure can be effected in a useful proportion of cases. Innumerable types of treatment, both internal and external, have achieved popularity, and it may well be that recovery, when it occurs, is independent of specific treatment. Meanwhile it appears that any measures that tend to improve the general health of the dog may help to bring about recovery from follicular mange.

THE DIAGNOSIS OF PERNICIOUS ANÆMIA

IT might be thought that in the limelight thrown on pernicious anæmia by Minot, Murphy, and others since 1927 the disease would seldom escape recognition. Certainly some of those who suffer from it are embarrassed by the diagnostic and therapeutic enthusiasm of their medical and even lay advisers. Nevertheless Dr. E. Meulengracht,[5] whose work on pernicious anæmia has attracted wide attention, says that of over 200 cases admitted to his hospital about half had been given some other label before they reached his hands. One of the signs suggestive of pernicious anæmia, to which Meulengracht attaches importance, is premature whitening of the hair. Beginning sometimes as early as the twenties or thirties, it often gives the patient a peculiar stamp; and incidentally it is a feature apt to run in families. As regards the diagnostic value of gastric achylia, he considers that in the absence of helminthiasis if there is no gastric achylia the patient is certainly not suffering from pernicious anæmia. He has never seen an exception to this rule, and as for recorded cases of the kind he is inclined to dismiss them as figments of the imagination. He is also sceptical of the diagnosis of pernicious anæmia when the patient is young. His youngest patient was twenty-eight years old when the disease was first diagnosed, and among the 213 cases only 21 were under the age of forty.

* * *

DR. MAURICE FISHBERG, who died in New York on August 31st, will be gratefully remembered in the medical profession as the author of a text-book on pulmonary tuberculosis which for matter, manner, and sense of proportion left little to be desired. Its value was recognised by running into four editions. Dr. Fishberg was born in Russia 62 years ago, and went to America when he was 18 years old, qualifying in medicine at New York University in 1897. He became chief physician to the Montefiore Hospital and clinical professor of medicine in the University. His other strictly medical work was an American edition of Gley's "Internal Secretions." But perhaps his chief interest in life was a study of the physical anthropology of the Jewish race, a sphere in which his views did not meet with general acceptance.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XVII.—PROGNOSIS IN EPILEPSY

THERE is probably no other condition in which the prognosis is more anxiously enquired for, nor any in which under certain circumstances it is more difficult to forecast.

The reason for anxiety is obvious. The difficulty in giving a prognosis is to be found in the fact that epilepsy is not an entity; many writers and teachers have emphasised this, and suggested that we should speak of "the epilepsies" rather than of epilepsy. This of course refers to what one is familiar with under the title of "idiopathic" as distinct from symptomatic epilepsy. As we are still ignorant of the ætiological factor in most cases of epilepsy, it is clear that the prognosis in such cases must be doubtful. The effect of treatment must be awaited before it is possible to forecast the future course of the disease.

LENGTH OF LIFE

Does epilepsy tend to shorten life? The answer is that it certainly does so in severe cases, but that early death as the result of a fit is rare. It is certainly possible for some accident to occur which may have a fatal ending during the course of a fit. There are occasional examples of a fit proving fatal to others; witness a recent case in which a car, driven by a person who had a fit, ran into a crowd of people and killed some of them. Status epilepticus is a rare and often fatal condition. Cases in which epileptic dementia occurs do not as a rule reach the allotted span of life. Many of them die of tuberculosis. In mild cases, however, it is not unusual for the patient to reach old age; indeed there is a tendency with advancing age towards spontaneous cure.

DAMAGE TO STRUCTURE OF BRAIN

In certain cases there has been some damage to the structure of the brain. I do not include among these cases where a brain tumour is present, or where the fits are the expression of syphilitic disease. In the first group the prognosis is that of the brain tumour; in the second the outlook is usually good when adequate treatment is adopted. The cases to which I refer are those which follow in the path of diplegia or hemiplegia occurring as the result of developmental defect or birth injury. In such cases there is always the possibility that fits will follow. The prognosis varies a good deal with the mental condition of the patient. If there is mental deficiency, the prognosis as regards the fits is always bad. If there is no mental defect, the probability of epilepsy developing is less and the prospect of the control of the fits under treatment better. The same criterion applies to children who develop fits following encephalitis, with or without hemiplegia. In adults fits may occur as a sequel to thrombosis of the Sylvian artery which has resulted in hemiplegia. The fits are as a rule infrequent and are usually controlled well by treatment, which must however be continued faithfully for a sufficient period—that is for as long as two years after the last fit. With the use of the barbiturates this can be done with less annoyance to the patient than was possible with bromides.

IDIOPATHIC EPILEPSY

In so-called idiopathic epilepsy there are many factors which will help to justify a bad prognosis, but unfortunately few which can be relied on to justify a good one. When the fits have started early in life, when they are frequent and severe, and when in addition there are stigmata of degeneration present, the prognosis is uniformly bad. Among stigmata we may note misshapen ears, deformed teeth in poorly developed jaws, Gothic palates and eccentrically shaped skulls. When some degree of mental deficiency is present as well, it merely serves to emphasise the hopeless prognostic outlook. A history of epilepsy in the antecedents, of insanity, alcoholism or drug addiction are factors of grave prognostic significance, as too may be consanguinity in the parents.

CONVULSIONS DURING INFANCY

Convulsions during infancy tend to affect the prognosis adversely in those developing epilepsy later in life. We must not be too pessimistic, however, in our prognosis in such circumstances, as some cases in which the outlook appears most discouraging do well under treatment. The converse unfortunately is also true, and a patient of fine physique and development, and with a clean sheet so far as family records go, may fail to respond to treatment in a satisfactory manner. Aldren Turner found that the percentage of cases arrested was much the same whatever the family record, but that those with no hereditary history showed a higher percentage of improved cases and a lower percentage of confirmed cases, than did patients with definite neuropathic antecedents. Special note should be made as to whether the family record shows evidence of any toxic idiopathy, or whether the patient exhibits such himself. In these cases, and where asthma and epilepsy may alternate in the same patient, the attacks are almost certainly allergic in origin. Careful research on these lines and appropriate treatment should result in marked improvement or cure.

THE TYPE OF DISEASE

The type of disease is of some importance in prognosis. It is well known that in petit mal it is more difficult to influence the frequency of the attacks than where grand mal attacks only occur. The introduction of the ketogenic diet has, according to American reports, resulted in marked improvement in children suffering from petit mal, as many as 31 per cent. of cases in children under 15 being free from attacks as the result of treatment. I do not know of any statistics based on the treatment of a large number of cases by this method in this country, but my own experience of it has not been so encouraging as that of the American observers. Mention must here be made of the condition known as pyknolepsy, in which children suffer from a very great number of daily attacks of very transient nature, so slight indeed as entirely to escape observation unless they are watched for most minutely. These attacks seem to be uninfluenced by any form of treatment, but the ultimate prognosis is good. Cases of grand mal only are more responsive to treatment as a rule than are cases of petit mal, whilst those who suffer from both grand mal and petit mal form an intermediate group. In the latter group, however, should the attacks be frequent, the probability of dementia occurring sooner or later is greater than in the other two groups.

Patients whose attacks are *nocturnal only* are more happily situated than those whose attacks occur only by day, but there is some evidence to *suggest that, in the former group, the attacks are less* likely to be arrested as the result of treatment.

AGE-INCIDENCE

The age-incidence of the disease has some bearing on prognosis, for where epilepsy begins under the age of 10 the prognosis is usually worse than at any other age. Cases which occur at puberty are much more numerous than those which occur at the climacteric, though the outlook for the latter is better than for the former group. With advancing years as is well known, the tendency to develop "idiopathic" epilepsy diminishes. In what may be called senile epilepsy, taking the age of 50 (for this purpose only) as the beginning of the senile period, the prognosis is probably better than in any other group.

It is a truism that the longer the fits have lasted, the less chance there is of their arrest, and the prognosis so much the worse; epilepsy not being a self-limiting disease, but rather the reverse. Every effort should therefore be made to control the fits from the first.

TRAUMATIC EPILEPSY

Traumatic epilepsy is a condition in which fits develop as the sequel to a brain injury. It does not seem that those cases in which fits occur at the time of the injury are more likely to develop epilepsy subsequently than when this is not the case. The injury to the brain may affect any part of it. I mention this because I have met with a fairly widespread belief that unless the motor centre is injured epileptic attacks will not occur as a sequel. The attacks may be of any variety, either focal (Jacksonian) or generalised. Grand mal, petit mal, or both may occur in this group of cases. Statistics vary as to the proportion of cases of head injury in which epilepsy follows as a sequel, but it is much smaller than one might expect. Percy Sargent found only 800 in 18,000 cases of head wounds. Bathe Rawling, in a smaller group of cases, found a much higher percentage of epileptic incidence—namely, 25 per cent. in a series of 425 cases. In any particular case of head injury the odds are against the development of epilepsy as a sequel. When it does occur, it will be found that in many cases the fits can be controlled by adequate medical treatment. In some instances, as Foerster and Penfield have shown, surgical intervention with removal of scar tissue will result in cessation of the fits. Where fits occur in association with severe injury of the brain, the probability of dementia occurring is considerable. In such cases the fits are likely to persist in spite of treatment.

THE UREA-CLEARANCE TEST

By E. Hinden, M.B. Camb., M.R.C.P. Lond.
FORMERLY HOUSE PHYSICIAN AT ST. GEORGE'S HOSPITAL, LONDON

This paper contains a discussion on the urea-clearance test as elaborated by the work of Addis and Van Slyke. The observations recorded were made on 2 normal controls and 16 patients in St. George's Hospital.*

It has long been known that the efficiency of the kidneys to keep the blood constituents at a constant level is seriously damaged in Bright's disease, and a need was felt for some method of expressing in numerical terms the remaining power of the kidney. Such a method would materially assist the physician in following the course of a case of nephritis, and would be invaluable for prognosis; and some such test, no matter how rough, is essential before many surgical procedures may be undertaken. In some cases, in which an acute illness, such as scarlet fever, is followed by an acute nephritis which clears up but for a slight persistent albuminuria, an expression for kidney function is needed before it is possible to say whether the kidney is permanently damaged.

In searching for some one constituent to use as an indicator of kidney function, attention was soon directed to urea. This substance is physiological (that is, it is not foreign to the normal environment of the working kidney), it is present in blood and urine in easily measurable quantities, it is a non-threshold body, and it is non-poisonous, so that for purposes of experiment it may be given in large quantities. At first it was proposed to use the urine urea alone; but this is liable to so many *fluctuations* owing to food, exercise, and urinary volume that the results obtained are not consistent. Modifications of this test, however, such as the urea percentage in urinary samples obtained after taking urea by mouth, are still in practice. Then it was proposed to use the blood-urea alone; this was soon abandoned, for it was found that the blood-urea did not rise after one kidney had been removed and the functioning tissue had thus been reduced to half. This showed that the blood-urea level could not be used as a measure of kidney function.

On theoretical considerations alone, it appears impossible to separate these two factors. The environment in which the kidney works is the blood stream, and it is evident that the results of its labours will depend upon the concentration of the urea in that stream. It is also clear that the concentration of the urine will not be, in general, independent of the volume of the urine. It was these considerations which led many workers to investigate the relations between all these factors.

The first to publish results was Ambard.[1] He published two numerical laws, expressing a relation between the blood-urea, the concentration of urea in the urine, and the amount of urea passed by the kidneys.

His laws were as follows: When the concentration of urea in the urine was constant then the blood-urea varied as the square root of the urea passed; and when the blood-urea was constant then the quantity of urea passed varied inversely as the square root of the concentration of the urea in the urine. Nowadays it is usual to express all the data in terms of blood-urea (=B), concentration of urea in the urine (=U), and the volume of urine passed in unit of time (=V). The usual unit of time is one minute. Expressed in these quantities Ambard's law becomes: $\frac{U^{\frac{3}{4}}V^{\frac{1}{2}}}{B}$ *is constant. This constant can be worked out for normal individuals, and then the value obtained* in cases of nephritis compared with it. This method was much used by French clinicians during the first decades of this century.

---

* The 2 controls and 5 of the patients were seen by me, and I collected the specimens from them. The details of the other 11 cases were collected from the medical register of the hospital. All the biochemical analyses were performed in the hospital biochemical laboratory.

In America, Addis and Watanabe tried to verify this work. They discovered [2] that the law did not hold good in very many cases, and concluded that Ambard only obtained the agreement he did because his material was so scanty. They found that the law did not even give the trend of results—i.e., according to the law, when the blood-urea is constant, if the concentration of urea in the urine rises then the total quantity of urea passed should diminish, whereas it often increases. They performed many experiments, both on rabbits and human beings, in an attempt to formulate a law which would give better agreement.

After much testing, Addis and his co-workers came to the conclusion that the ratio—urea in urine : blood-urea—was constant both for the individual and for the species, provided certain conditions were in force. The most important of these conditions was that the kidneys should be working at full load. It is known that there is a large reserve power in the kidneys, so that unless they are exercised to their full extent slight damage will not be apparent. Hence it is important to give urea and water by mouth, and so cause a forced diuresis. They found that the ratio fluctuated with the urine volume, but not regularly so, and that it was much more stable when the urinary volume was high—another reason for encouraging diuresis.

As an example of the importance of giving urea, they worked out the ratio on a rabbit before and after ligating one ureter [3] and found no difference; but on comparing the ratio before and after the operation, having given urea in each case, the ratio was depressed to half its former value. This was confirmed in a later piece of work.[4] Here it was shown that when recovery after nephrectomy has taken place, the urea excretion can be as large as 98 per cent. of the normal, even though the amount of functioning kidney tissue, as measured by the weight of the remaining kidney post mortem, was only 66 per cent. of the total kidney tissue before the operation. The ratio was the only numerical evaluation of function that was depressed by the operation.† Finally, all this has since been confirmed on dogs.[5]

Let us consider the meaning of this ratio with regard to the working kidney. The ratio is the result obtained by dividing the total quantity of urea excreted by the kidneys, in one minute, by the quantity of urea contained in 100 c.cm. of blood. It is therefore equal to the number of cubic centimetres of blood cleared of urea in one minute. Thus, expressing Addis's results in words, it means that when the kidney is working at full pressure, then the quantity of blood cleared of urea in one minute is fixed, and is independent of the concentration of the urea in the urine. In a number of normal human beings this number came to 75–76 c.cm., and this has been taken as the normal figure for kidney efficiency. It is important to realise that this figure, and its explanation, as the amount of blood cleared of urea, is independent of any theory as to how the kidney performs its work. It must not be taken as meaning that actually 76 c.cm. of blood flow through the kidney, and that this quantity is completely cleared of urea; there is evidence, based on urea estimations of the blood in renal artery and vein,[7] that only 50 per cent. of the urea is cleared. This would mean that 152 c.cm. of blood flow through the kidney, losing half their urea while so doing. This figure for the renal blood flow is confirmed by the figures of the creatinine clearance.[8]

In another series of experiments, Addis measured the value of this ratio on rabbits of different sizes, on rabbits after experimental nephritis, and after nephrectomy, and showed [9] that the value of the ratio was almost perfectly proportional to the weight of the kidney tissue, as measured post mortem. He found, too, that in human beings this ratio was not quite constant, but differed according to the size of the individual.[10] This was confirmed by McKay,[11] who showed that the ratio varied with the surface area of the body, and that the kidney weight also varied directly with this expression; this was confirmed by Van Slyke [12] working on children. He showed that the ratio was proportional to the surface area, and that the weight of the kidneys was proportional to this and not to the body-weight.

It appeared, then, that in this ratio clinicians possessed a numerical expression of the functioning power of the kidney. In order to make sure that it did not depend on factors outside the kidney, a further series of observations was taken on this ratio under different conditions. Thus it was found that both adrenaline [13] and pituitrin [14] affected it somewhat, while the ingestion of salt [15] and dextrose [16] had no effect. The taking of food increased the ratio, but only after the fourth hour; this appears to be due to the protein alone,[17] for it has been shown that the purin diuretics have no effect on the ratio,[18] while fasting [19] and low protein intake [15] lower it. In confirmation, high protein feeding raises the ratio.[20] It was shown, too, that vigorous exercise would lower the ratio to 50 per cent. of its normal value,[21] although it appears that mild exercise in normal people might raise it [22]; but in nephritics even mild exercise depresses the ratio considerably.[23]

TECHNIQUE

In order to get comparative results, Addis and his workers then formulated the following technique, which keeps all the foregoing factors constant:—

1. The test is done when the subject is in bed.
2. In order that the effects of food may be eliminated, the test is done first thing in the morning, and no breakfast is given.
3. Fifteen grammes of urea are given at 7 A.M. in 1000 c.cm. of water. Then, till 12 noon, the subject drinks 500 c.cm. of water hourly. This raises the blood-urea and causes copious diuresis.
4. Urine is collected for each of the hourly intervals, from 9–10, 10–11, and 11–12. Blood is collected about half-way in each hourly interval.

The chief objection to this technique is that it involves the patient being in hospital overnight, and three blood collections. This first condition makes it difficult to carry out the test in private practice. Also, in cases of nephritis, it disturbs the patients to collect the urine so frequently, and some of them, especially women, find difficulty in emptying the bladder completely while lying down. It must be emphasised that consistent results are obtained only when the physician himself collects the various specimens; otherwise it often happens that the urines are not collected at the proper times. Often the patient cannot empty his bladder just at the right moment; but this is immaterial if the actual time is noted, as what is wanted is the minute volume, not the total quantity passed.

---

† Addis explains the fact that the remaining kidney was as much as 66 per cent. of the two together, before operation, on the grounds of compensatory hypertrophy. It is known [6] that this hypertrophy can take place under certain conditions. Even so, the value of the ratio was 78 per cent. after nephrectomy, instead of the expected 66 per cent. This was explained by Oliver in the same paper, who showed, on careful sectioning of the remaining kidney, that the hypertrophy affected chiefly the glomeruli and the first part of the convoluted tubules—i.e., just the secreting parts of the kidney. This means that the true functional hypertrophy was greater than the gross hypertrophy, as measured by the increase in weight of the kidney. There was no evidence of hypertrophy in the dog,[5] and here the weight of the remaining kidney was 54 per cent. of the total renal tissue, and the ratio was 56 per cent. of its value before the operation.

It must be mentioned that some other workers attempted to verify Addis's work,[24] but did not find consistent results. On close examination of their data it appears that they left the collection of the specimens to nurses, and did not force diuresis by withholding urea. These factors are quite sufficient to invalidate their results; hence their criticism of Addis lacks weight.

In order to simplify the technique Van Slyke and his co-workers [25] undertook a complete re-examination of the whole problem. They investigated the relations between the blood-urea (=B), urine-urea (=U), and urine volume (=V) when the kidney was not working at full load. They also made the correction for surface area, by estimating the surface of the subject from the height and weight, comparing this area with the normal of 1·73 sq. metres, and dividing the urine volumes by the factor so obtained. They considered the relation between V and the ratio U : B. They gave the term "clearance" to the quantity of blood cleared of urea in 1 min.=UV/B. They found that, provided V was more than a limiting value, this clearance was constant both for the individual and for the species. In a later piece of work [26] they showed that for most individuals this limiting value was 2 c.cm. Incidentally, this confirms Addis's work, for the diuresis produced by 15 g. of urea always raises V above this figure, and Van Slyke's clearance is the same as Addis's ratio, which is therefore also shown to be constant. This limiting volume they name the "augmentation limit."

But it was further discovered that even when the urine volume fell below this limit, there was still a relation between the clearance and the urine volume. It was found that the clearance varied as the square root of V. From this it follows that, in order to compare different individuals, it is first necessary to find out what their clearances would be at some standard volume of urine per minute. The standard volume which they chose for this purpose was 1 c.cm. per minute, for this simplifies the arithmetic of the calculation, and also is the average normal urinary output (for 1 c.cm. per min.=1440 c.cm. daily, which is approximately the normal output). The clearance calculated to this level of volume they called the standard clearance, written C_s, and it is numerically obtained by the formula $UV^{\frac{1}{2}}/B$ (for if UV/B varies as $V^{\frac{1}{2}}$, then $UV^{\frac{1}{2}}/B$ must be constant). The value of C_s for the normal individual is 54 c.cm., although Bruger and Mosenthal [22] obtained higher figures. The clearance obtained when the minute volume is above the augmentation limit they called the maximum clearance, written C_m. Its value for the normal individual is 75 c.cm. The close similarity between this standard clearance formula of Van Slyke and Ambard's law is apparent when they are compared: the one is $UV^{\frac{1}{2}}/B$, the other $U^{\frac{3}{4}}\,V^{\frac{1}{2}}/B$; and as U varies from 1–2 usually their value is nearly equal. It can also be shown that the two values for the clearance are mutually consistent. Thus, let us imagine a case where V was just about 2 c.cm. per minute. Then we could calculate the kidney efficiency from either formula, and the ratio between these two values would be $UV/B : UV^{\frac{1}{2}}/B$, or $V^{\frac{1}{2}} : 1$; and as $V=2$ this would equal 1·4 : 1. But the ratio of $C_m : C_s$ is 75 : 54, or also 1·4 : 1.

It is clear that now we have a much simpler method of estimating kidney function. It is sufficient to keep the subject quiet, and there is no need to give urea or to attempt diuresis (in many nephritics it is not possible to cause diuresis). All that is necessary is to collect two consecutive specimens of urine at hourly intervals, and to obtain one specimen of blood mid-way between these two; then, if V is greater than the augmentation limit of 2 c.cm. per minute, the formula for maximum clearance is used, and the result compared with 75; otherwise the standard clearance is calculated, and the results expressed as a percentage of 54.

This technique was adopted in all the cases here collected. In order to make sure that there would be no complications due to food the test was done in the morning before breakfast. At 9 o'clock the patient emptied his bladder, and that was discarded; then the urine was collected at 10 and again at 11 o'clock. A sample of blood was taken at 10 o'clock. In each case if the patient did not empty his bladder at the precise time then a careful note was taken of the hour, and so the minute volume could be calculated. In some cases 15 g. of urea was given beforehand in a quantity of water.

Comparisons have been made of this test with others. Thus the rise of plasma sulphates runs parallel with a fall in clearance,[27] but the series was too small to allow conclusions to be drawn. It is much more delicate and accurate than the uric acid level.[28] Anæmia runs parallel to the older tests for kidney function,[29] but this test is more delicate than the older ones, so that it gives evidence of kidney impairment before the blood does. Figures obtained by considering the creatinine clearance correspond very closely to those given by urea clearance, but the estimation is much more difficult to carry out.[30] Bruger and Mosenthal [31] and Van Slyke [32] both find that this test is the best and most delicate of all those in common use.

FINDINGS

Before considering the results obtained in this series a brief review of the literature may be appropriate. The first to be noticed is the work of Addis, who followed up several cases from the onset of the disease to the termination in death or recovery.[9] Van Slyke and his co-workers trace 67 cases of Bright's disease [33] for long periods. There it is shown that in acute nephritis the clearance always fell to 50 per cent., and may fall as low as 20 per cent., but this fall has no prognostic importance; they were, however, able to draw the important conclusion that if no improvement took place in four months the case was certain to end fatally. It was not possible to draw inferences in the other types of Bright's disease. Life could be maintained comfortably on 15 per cent. of functioning tissue, but uræmia is certain when it drops as low as 5 per cent. It is also known that the blood-urea does not rise till the clearance falls to 50 per cent.[34] Van Slyke has since worked out a quick colorimetric method of evaluating the clearance.[35]

Other workers have since published series of cases. In the United States Bruger and Mosenthal [36]; in South America, Schultz Ortiz [37]; in England, Poulton and Ryffel [38]; and in Italy, Lazzaro.[39] All these workers confirm Van Slyke's conclusions. The value of the test in pregnancy and the puerperium has been pointed out by several American investigators.[40 41 42 43] In this last paper, however, Cantarow and Ricchiuti find low values during normal pregnancy, which values rise to the normal during the puerperium; this was not found by any other worker in this field. In children the test is useful but difficult to interpret,[44] probably owing to the difficulty of finding the augmentation limit.[45] Finally, tribute to the test in urological surgery has been paid both in America [46] and in this country,[47] though opinion is not unanimous on its being the best.

The results obtained at St. George's Hospital are set out in Table I. I wish to thank the members of the honorary staff for permission to quote cases.

TABLE I

Case.	Clearance.	Percentage of normal.	Case.	Clearance.	Percentage of normal.
1	S.	103	9	S.	66
2	S.	93	10	M.	100
3	S.	30	11	M.	26
4	S.	26; and 1 wk., later,	12	S.	9
	M.	21. and	13	S.	22
	S.	26	14	M.	15, and
5	S.	19; and 2 wks., later,		S.	18
	M.	42	15	M.	20
6	S.	20, and	16	M.	83, and
	M.	12: and 6 wks., later,		S.	91
	S.	11	17	S.	60
7	S.	45; and 1 wk., later,	18	M.	22
	M.	51			
8	M.	26, and			
	S.	11			

S. = standard ; M. = maximum.

In those cases where only one number stands in the "percentage of normal" column, it means that both specimens of urine were standard or maximum, and the number given is the average of the two estimations obtained.

These cases fall into three groups, according to the degree of impairment of the renal efficiency. (Table II.)

TABLE II

GROUP I. Kidney function normal.		GROUP II. Moderate impairment.		GROUP III. Severe impairment.					
Case.	P.N.	Case	P.N.	Case	P.N.	Case	P.N.	Case	P.N.
1	103	7	48	3	30	8	18	14	16
2	93	9	66	4	24	11	26	15	20
10	100	17	60	5	32	12	9	18	22
16	87	..	..	6	15	13	22	..	..

P.N. = Percentage of normal (averaged).

In each case two specimens of urine were obtained, so that two estimations of kidney function were made for each test. In the majority of cases both these estimations were either standard or maximum, but in five cases one was standard and the other maximum. Estimations have throughout been expressed in percentages of the normal, so that it is possible to compare results obtained in either of these forms. In two cases (Nos. 6 and 8) the differences are considerable: the figures are 20 and 12, and 26 and 11. Both these patients are females, and the error is probably due to incomplete emptying of the bladder on the first occasion. The test was repeated later on No. 6, and the result obtained then agreed with that given by the second specimen of urine on the first occasion, bearing out this theory as to the error. In four cases (Nos. 4, 5, 6, and 7) the test was repeated after an interval. In Nos. 4, 6, and 7 the second result was very close to the first, but in No. 5 there was a wide divergence, from 20 at the first to 42 at the second occasion. This cannot be explained by an improvement in the clinical condition, which actually deteriorated. There was probably some error in the actual performance of the test. The correction for surface area was neglected. This does not appear to have invalidated the results, for they closely follow the clinical findings. In the case of No. 16, a youth aged 13, a figure of 86 per cent. would have been nearer 100 per cent. if this correction had been made.

Nos. 1 and 2 were normal controls, and their figures, 103 and 93, are well within the limits of normal variation. No. 16 was suspected of chronic nephritis on the grounds of an attack of scarlatinal nephritis and occasional albuminuria. The test showed perfect function. No. 10 was suspected of nephritis because he had persistent pains in the back and was puffy under the eyes. The clearance was normal, and radioscopy showed lumbar osteo-arthritis. All these cases have normal function, and clinically also there was no nephritis.

The next group show moderate impairment. No. 17, with a clearance of 60 per cent., had signs of nephritis, in that there was persistent albuminuria, but the blood pressure was low and there were no other signs of disease. No. 9 was a surgical case, who showed 66 per cent. of function; in accordance with this, prostatectomy was perfectly successful. No. 7 had definite signs of general arterial disease in his legs and thorax, and actually died of a coronary thrombosis. He showed a trace of albumin in his urine, and his clearance was 48 per cent. of the normal. It is noteworthy that his blood-urea, without the ingestion of urea, was 0·044 per cent., which is only just outside the bounds of normality, while as shown by the test he had only 50 per cent. of functional renal tissue.

All the other cases show marked impairment of function, and there was corresponding clinical evidence of advanced nephritis. No. 3 had bilateral hydronephrosis and polycystic disease. He had a clearance of 30 per cent., and clinically was very ill. No. 4 had severe nephritis of the "nephrotic" type, and her clearance was about 23 per cent. of the normal. In her history after leaving hospital she showed a tendency to low-grade septic conditions. No. 5 was a severe nephritic, with a clearance of about 20 per cent. at first, which rose later to 40 per cent. No. 6 was in the terminal stages of acute hæmorrhagic nephritis following tonsillitis. Her clearance at first was 16 per cent., falling six weeks later to 11 per cent. A few months later she died in uræmia. No. 8 was first diagnosed as nephritis during a pregnancy. It is not possible to say from the history whether she had nephritis before her pregnancy or whether it was the latter event which started the kidney trouble. When seen in hospital she had advanced nephritis clinically, and her clearance was about 18 per cent. No. 11 was in hospital over one year ago with severe nephritis. On admission this time her clearance was about 25 per cent. Her illness started six years ago with scarlatina. No. 12 was a very severe case, with a blood pressure of 235/155. Her clearance was 9 per cent., and her vision was failing. Probably she was near uræmia. No. 13 was a nephritic, with a history of decapsulation performed 13 years ago. He showed signs of nitrogen retention, and his clearance was 22 per cent. No. 14 is very similar. Her clearance was only 17 per cent., and her blood pressure 240/140. No. 15 had scarlatina 12 years ago. He had signs of advanced kidney disease, with nitrogen retention. His clearance was 20 per cent., and five weeks later he died in uræmia. Post-mortem findings include small atrophic kidneys and an enlarged heart. No. 18 had severe nephritis, with a clearance of 22 per cent. It was not certain whether his disease was due to the syphilis from which he was suffering or whether it was caused by the arsenical treatment he had been having.

SUMMARY AND CONCLUSIONS

The development of laws concerning kidney excretion is described, leading up to Addis's ratio and Van Slyke's modification of it. This worker showed that if the urinary volume was greater than the "augmentation limit" of 2 c.cm. per minute, then the expression UV/B was constant, and, if not, then $UV^{\frac{1}{2}}/B$ was constant. It was further shown that the amount of functioning kidney tissue was proportional to the value of this constant, and therefore in cases of nephritis it gave a valuable measure of the renal damage. It is, however, not safe to trust to one single estimation if it gives a low value.

Various workers have shown that this estimate of kidney function follows the clinical condition of the patient better than any other. The value of the estimation afforded by the test is greatest in cases of moderate impairment, for most other tests show no difference at all in these circumstances. Thus it has been shown that at least half of the functioning tissue must be destroyed before the blood-urea rises. Eighteen people were subjected to the test, and in all cases the test was an accurate picture of the clinical condition.

HERTFORD BRITISH HOSPITAL, PARIS.—This hospital, which was founded and endowed by the late Sir Richard Wallace, has had an annual deficit since 1930, due to the increased cost of living and the necessity of providing additional accommodation. The fall in the exchange value of the pound has now reduced the income by about 40 per cent. and there is an annual deficiency of £2000. The hospital gives *its services to all* subjects of the Empire living in, or visiting, France.

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF SURGERY

Prof. G. GREY TURNER, *the president, took the* chair at a meeting of this section when a paper on

Physical Efficiency after Operations for Hernia

was read by Mr. MAX PAGE (London). In five years' operations at St. Thomas's Hospital, he said, the relative incidence had been 11 inguinal hernias, 1·4 femoral, and 1 ventral. He therefore took inguinal hernia as his text. In spite of all the consideration given to it, agreement about the best method of treatment had not been reached, largely because the information about late results was inadequate or inaccurate. A close and critical follow-up of all cases would reveal a far larger proportion of recurrences than was *generally* believed. His own confidence in the operation had been shaken by his experience with the Metropolitan Police; for in the five-year period 1929–34, of 241 operations performed on police officers, 11·5 per cent. were for recurrence. Further investigation suggested that the true rate was even higher. Block's analysis of continental figures gave a recurrence of 34·8 per cent. after two years, and this author declared that 40 to 45 per cent. of recurrences were avoidable. The majority seemed to be internal direct hernias, and the suture material used *seemed to have little influence. After quoting* the numbers in other reports, Mr. Page admitted that he really did not know quite what he wanted to prove. The *astonishing differences between the* statistics he had quoted could hardly be laid at the door of any special technique. His own conviction was that recurrence was commoner and more difficult to avoid than was generally thought. The factors influencing success were the technique and its failures, post-operative pulmonary complications, operation on double hernias, and congenital feebleness of the musculature.

Mr. G. L. KEYNES (London) *declared that the only* possible attitude was to aim at complete physical *efficiency and deal with almost* every hernia. No patient should be condemned to wear a truss after operation, and every patient, except possibly the old and infirm, should be able to carry on with his work. Out of 10,000 or 12,000 patients whom he had attended at the City of London Truss Society, only 500 or 600 had had recurrences. There was too much *dependance on standardised operations*, and the surgeon must possess a sufficiently large operative repertory for all cases. Incorrect diagnosis between direct and indirect hernias was a prolific cause of recurrence. All recurrence was due to failure in technique, for if the tissues were not strong enough a more elaborate operation was called for. The allegation of a hereditary tendency was merely an attempt to justify failure. He showed a number of *slides of various conditions* many of which illustrated the use of Gallie's fascial suture.

Mr. T. A. HINDMARSH (Newcastle-on-Tyne) reviewed 154 cases operated on in hospital, nearly all labourers. Out of 102 *patients with inguinal hernia* 89 were perfectly satisfied, 9 had recurrences, and 4 had severe pain and tenderness in the scar. Twenty-three out of 26 femoral, 11 out of 13 umbilical, and 8 out of 13 ventral operations had been successful. It was nearly always *possible to succeed in the important aim* of saving the patient from wearing a truss. It was essential to remove the sac completely. Sixty per cent. of recurrences were due to suppuration and infection, and a fairly large proportion to choice of a wrong type of operation. It was dangerous to tie sutures too tight, and if they were not tied carefully the conjoined tendon might be split. He considered that three weeks was not a sufficiently long convalescence. It took six weeks to get firm fibrous tissue, and he would therefore advocate three weeks in bed, followed by ten days on a couch and then by six weeks' progressive exercise. If the anæsthetist allowed the patient to come round too soon, damage might be done on the table through vomiting before bandages were firmly applied. Excessive distention of a ventral hernia before operation should be controlled by 0·5 c.cm. of pituitary extract every three or four hours.

Mr. E. M. Cowell (Croydon) mentioned as factors in success wide resection of the hernia sac, the covering of the weak point with suitable pedunculated fascial flaps, the use of fascial sutures, and the encouragement of a return of muscle tone with suitably graduated exercises. Peebles's hernia of the linea semilunaris was rare but important. He had found 6 in 500 cases, 2 having been overlooked at the original operation. He showed slides illustrating his modification of Gallie's method by which he used a much shorter strip of fascia. He recommended that patients should be directed to contract their abdominal muscles at about the fourth day, and that they should be out of bed at the end of the week and back to work as soon as possible. His recurrence-rate was, he said, about 4 to 5 per cent.

Mr. Philip Turner (London) said that while it was important to remove the sac, it was almost as important to close the opening in the fascia through which the sac made its way. He described his operation for curing large hernias in elderly patients. He advocated the principle of plastic surgery, the replacing of tissues by like tissues. He said that the series of patients mentioned by Mr. Keynes now numbered about 100; all had been followed up, and the recurrence-rate was very small. The result showed that, if the patient's general condition was fairly satisfactory, it was possible to operate successfully on a hernia of almost any size at practically any age. In many cases a testis and the spermatic cord could be sacrificed with advantage. Hernioplasty was as effective in direct as in indirect hernia. Sliding hernias were more troublesome, but many could be treated satisfactorily in this way by cutting away redundant peritoneum, enlarging the opening in the retroperitoneal tissue, pushing back the large intestine, cutting a flap and pulling it over, and sewing up the opening in the transversalis fascia.

Mr. W. McAdam Eccles (London) spoke on his experiences 35 years ago with the City of London Truss Society. In those days operation on hernia was not nearly so common as to-day. Congenital hernia in young males should, he said, be operated on in the first few years of life or physical efficiency was in danger. A truss was not a nuisance if properly made and adjusted. Some elderly labourers were quite efficient and comfortable in trusses and were made worse by operation. Preparation and after-treatment were more important than the operation itself. The results would be better if asepsis were more rigidly observed. He recommended ten days in bed and ten days' progressive exercise about the ward. Hernia was compensated under statute as an industrial accident, and the patient should be tempted to do light work before heavy work.

Mr. R. Wood Power (Hereford) urged concentration on ventral hernia, which he said was by far the most difficult to operate on successfully. The muscle was lacking, and recurrence was high even after the Gallie graft. The graft must have no strain on it. He described a method of replacing the opening by a sliding graft from the rectus muscle.

Mr. P. H. Mitchiner (London) said that a workman could often carry on his work efficiently even if his hernia recurred. Ninety per cent. of policemen with recurrence were doing full duty without complaint. In the young man, where the inguinal ligament and conjoined tendons, together with the attached oblique and transversalis muscles, provided the mechanism for keeping the contents out of the sac, the hernia would only come down when tension on these muscles was prolonged. This strain should be removed rather by turning the end of the muscle into the scar than by an elaborate repair operation. His results showed 3 per cent. of patients with recurrence, quite a number of whom could work. Repair was necessary when tissues gave way, as in fat and elderly people. If the repair depended on scar tissue, the patient should stop in bed at least three weeks. A well-fitting abdominal belt was the best treatment of recurrence.

Dr. John Ramsay (Australia) spoke of the value of kangaroo tendon. He said that sufficient use was not made of the spare fascia, which could be rolled and folded up; if this were not sufficient, a flap could be turned off the anterior rectal sheath. Potential pouches off the posterior wall of the inguinal canal could become sacs if the peritoneum were not made smooth at the operation.

Mr. R. Kennon (Liverpool) declared that, though he might be riding for a fall, he was not at all depressed about his results, which showed some 3 per cent. of recurrence. Femoral hernia was the commonest variety in women. The direct hernia was the most difficult to deal with, and it was therefore unwise to weaken the area with scar tissue.

Prof. A. W. Sheen (Cardiff) stressed the opinion that hernia operations should only be performed by comparatively experienced surgeons. He recalled a visit from the great French surgeon, Lucas-Championnière, who had insisted on strict asepsis. This authority had divided a small part of the internal oblique muscle and had made his way to the extreme top of the sac, and had left the peritoneum smooth, displacing the neck if he wished. The filigree was valuable when good, but highly detrimental when bad; its chief use was for large inguinal hernias and, when properly applied, for umbilical ruptures.

Mr. R. B. Blair (Hull) said that recurrences among dock labourers were very few. He advised light work after six weeks and ordinary work after six months.

Mr. A. B. Rooke (Bournemouth) said that he hesitated to advise operation if there were a chronic cough. Early movement was not always harmful. When abdominal muscles were infiltrated with fat and the fascia resembled butter, the patient's condition presented an almost insuperable obstacle.

The President reminded the meeting that results were judged by the working community, who pressed for operation in almost all circumstances. The results from applying present principles were sufficiently good to encourage surgeons to continue on the same lines. In considering results it was unfair to make no distinction between the older patients, with their changed tissues, and the younger. One-third of his patients with umbilical hernia had recurrence. It was not enough to be content with an ex-patient's reply on his condition, for he was likely to overlook a recurrence; a competent examiner should see him. Operation should be advised, because if it were not done and if the hernia strangulated later, chances of relief were very remote. The true criterion of cure was absence of recurrence in later life, when the tissues deteriorated.

SECTION OF RADIOLOGY AND ELECTROTHERAPEUTICS

Dr. D. D. MALPAS (Boscombe), vice-president, took the chair at a meeting of this section at which a paper on

Radiology as an Aid to the General Practitioner

was read by Dr. DOUGLAS WEBSTER (London), the president. Radiologists, Dr. Webster believed, would become more useful to their colleagues and the community when they regarded themselves primarily as physicians. The value of a diagnostic method depended on the light it could throw on obscure clinical problems, and especially on its ability to provide pathognomonic signs. Radiology had brought forward a greater number of such signs than all the previous centuries of clinical observation. Instances of these were bronchiectatic cavities, horizontal fluid levels, and gastric ulcer craters. Radiotherapy had also made immense advances and new discoveries were being made almost yearly, especially in the field of inflammatory infections. X rays and radium were the only agents known to have an influence on malignant growths. The first criterion of the value of radiology was that it must be good. There had been far too much imperfect radiology: hundreds of military recruits, for instance, had been rejected for a non-existent "peribronchial phthisis." Haenisch had recently held that the problems of correct interpretation were so great that there could be no "minor roentgenology" corresponding to "minor surgery" or "minor pathology." Dr. Webster, on the other hand, maintained that nearly all fractures and dislocations, many foreign body localisations, and much of the fields of elementary thoracic and genito-urinary diagnosis could be called minor roentgenology. If no distinction were to be made, he asked, how would it be possible to prevent technical assistants, radiographers, or general practitioners from practising radiology to a greater or lesser degree? Granted that interpretation was a medical prerogative, technical and elementary diagnostic radiology could not be restricted to medical specialists. On the other hand, there could be very little minor radiotherapy except in connexion with certain skin diseases. He considered that unqualified practice in radiology should be forbidden by law, just as the prescription and administration of drugs were forbidden.

Radiology had recently, he said, been recognised as a specialty by the institution of diplomas and by the insistence on the training in it of students. Dr. Webster laid stress on the need for a reasonably full and precise training of students; if the curriculum was over-burdened, he argued, much of what was unnecessary in it should be excised to make room. Unless the achievements of radiology were so exhibited as to make a wide appeal to the general practitioners of each country its diagnostic and curative possibilities would largely remain as locked-up capital. Private practitioners had the unique position of being the first to see most of the patients. They were thus able to advise medical, surgical, or other specialist treatment. Their coöperation must be solicited if the general level of health were to benefit by new knowledge. Much delay in diagnosis was due to ignorance of the possibilities of radiology. Some patients suffered for years from undiagnosed gastric symptoms and others spent years of ill-health with Graves's disease, leukæmia, and menorrhagia before radiotherapy was adopted. The most important sphere in which the coöperation of the general practitioner was essential was in the early diagnosis and treatment of cancer. Many patients were already at an inoperable stage at diagnosis, and many others were not good operative risks or were unwilling to submit to operation. The possibilities of radiotherapy should therefore be widely known. The first treatment was the all-important treatment, and it was quite indefensible to delay an appeal to the radiotherapist until surgery had proved a failure. Active campaigns in radiology had resulted in Sweden in a material raising of the general public health. A similar campaign in this country would have equal value.

Dr. E. KAYE LE FLEMING (Wimborne) set out the point of view of a general practitioner who regarded all kinds of specialist treatment as primarily arising from the needs of the general physician and closely associated with and dependent upon his interest and coöperation. The relationship of the general practitioner with the radiologist was not so close as with the surgeon, but was more intimate than with specialists, such as the bacteriologist or pathologist, who gave their reports in writing. He advocated a closer personal contact, fearing that from the peculiar nature of radiology there was a danger of the tie becoming weakened or lost, to the disadvantage of all concerned. The science of radiology, especially radiotherapy, was technically outside the sphere of knowledge of the general practitioner. Its application was advancing so rapidly that the busy practitioner could not keep pace with it. It was, moreover, an expensive specialty, and unless the practitioner had good knowledge of the nature of a treatment and its probable efficacy he must hesitate to recommend it.

He then enumerated the main departments in which the general practitioner found the radiologist's help of particular value: bone injuries and displacements, the thorax, and the abdomen. X rays gave great assistance in locating fluid in the pleural cavity, and the skiagram of the heart, especially with a fixed method of procedure, added appreciably to the physician's knowledge. Records of the bismuth meal examination were sometimes too expensive, and a series of drawings from screening, with regional photographs, would often be sufficient. In treatment, he asked for information on the possibilities of X rays in Graves's disease. The general practitioner, he said, was keenly interested in the production of sterility in the female, and wanted to be able to tell a patient what the treatment would entail in the way of time and money. It was always important for the practitioner to know the cost- and time-factors in specialist treatment. He asked whether radiologists viewed with disquiet the giving of radiation to prevent conception on the request of a practitioner of repute. He himself had never in his professional experience felt the need of any amendment of the law in relation to sterilisation and abortion. Practitioners well knew the success of radiology in malignant skin disease, but were less familiar with its value in other conditions. He asked how far he could rely on a speedy cure of multiple warts on the hands or of patches of psoriasis. At present the treatment of carcinoma of the breast involved much cost and time; nevertheless, Dr. Le Fleming hoped that radium would some day displace the knife and greatly lessen the need for subsequent X ray exposure. In conclusion, he pressed for closer coöperation among radiologists in order to harvest their common experiences and results, and for a more systematic presentation of these results to the general practitioner, more particularly in post-graduate studies.

Dr. Franklin Wood (London) spoke on a series of 678 cases referred for X ray examination last year by the general practitioners of a certain area. They represented roughly, he said, the proportion of cases of the given types which required X ray examination in an average practice. Fractures came first with 388, and chest conditions came second; after these in order were arthritis, dental disorders, urinary disorders, and barium meal examinations. Pain, he said, was not always referred to the fracture, and diagnosis of cranial fractures required special skill. The radiogram would show every alteration in the heart and lungs. The condition of "radiological pneumonia" consisted of areas of congestion or consolidation and was seen after influenza; it corresponded to no physical signs or symptoms. Emphysema produced widening and asthma narrowing of the bronchi. He deprecated the use of softer rays in chest work, showing how the shadows of the heart and diaphragm obscured a large area of the lungs and blurred the apices. In pregnancy it was easy to make out the contour and diameter of the inlet and the character of the fœtus. He described methods of radiopelvimetry. In pseudo-pregnancy, he said, a radiogram of the abdomen gave useful reassurance. Lipiodol was valuable not only in the diagnosis of sterility due to obstruction of the tubes but also in its treatment; five patients out of eight treated had since become pregnant. Only the general practitioner could help the radiologist to see the late results of cases and therefore to correlate the clinical and the radiological findings.

Dr. H. G. Dain (Birmingham) said that except in gross lesions radiology could not be expected to give the whole diagnosis. The young doctor was apt to leave out the clinical examination. Radiology was most often useful for settling the general practitioner's doubts of his diagnosis, and often saved a second operation. When referring patients, the general practitioner should give the radiologist an idea of his difficulty, and in return the radiologist's report would be enlightened by this clinical knowledge. The chief uses of radiology were first of all its protective legal use to the general practitioner. Unfortunately no doctor was safe until the patient had been radiologically examined, though many of such examinations were clinically needless. Secondly, an enormous proportion of sprained ankles and wrists were really fractures. Here, although the X ray findings might not modify the treatment, they would affect the prognosis. Thirdly, X rays enabled the practitioner to watch the progress and healing of arthritic or tuberculous joints. In the fourth place, radiology was valuable for detecting infected foci; it had saved the removal of many teeth and was not, as some believed, a means of having teeth extracted. It gave a much more accurate idea of the patient's chances in a chest case, and with the new contrast media its use in the diagnosis of gall-bladder and kidney complaints was increasing. Difficulties in technique constituted one of the main drawbacks, and among the chief of these was variation in the angle at which the film was taken. In treatment one of its most outstanding successes was in ringworm. He was not satisfied with its value in Graves's disease, but deep therapy was effective in many malignant conditions. After mammary excision its results were disappointing.

Dr. W. B. Prowse (Brighton) said that the radiologist relied on the general practitioner to educate patients to appreciate the proper position of radiology and of the radiologist as consultant. The radiologist was a medical man practising in a technical field, not a technician. It was a misfortune that radiology dealt largely in pictures, the value of which in the public eye overshadowed that of the radiologist's intelligence. Patients were apt to consider the picture the chief part of their money's worth, as something which they could take to another doctor or osteopath. The radiologist's fees were not high compared with those of other specialists. More films of barium meal examinations were necessary, and they could not be replaced by screen drawings. In disagreement with Dr. Le Fleming he considered that radiological evidence was often useful in appendix cases. In deciding on treatment, the course should be adapted to the patient. The general practitioner should place all reliable data in the hands of the radiologist, preferably by interview.

Dr. Andrew Baxter (Alderley Edge, Cheshire) said that he always endeavoured to be present at the consultation with the radiologist. In his experience, post-operative radiotherapy in breast cancer saved the patient from secondary trouble. Radiology might save operation, as in intestinal obstruction in an old person where malignancy was suspected, but did not exist. He agreed with the full instruction of students, saying that the more a general practitioner knew of a specialty the more likely he was to consult a specialist. He urged a campaign in connexion with post-graduate work.

Dr. G. B. Batten (Dulwich) pointed out that a radiologist learnt to interpret only by long personal experience and experiment, and by following up patients to operation and autopsy. Dr. Stanley Melville had added much to radiological knowledge by attending the post-mortem examination of all patients who had died after examination for chest disease. Knowledge of the technique of radiology was, however, useless and dangerous in the hands of students and did harm by making them think of radiologists not as physicians and surgeons but as picture-takers. The general practitioner who purchased an X ray outfit was likely to become a menace to his patients.

Dr. J. F. Brailsford (Birmingham) held that the student should be taught what the radiograms meant. This would enable him to appreciate the nature of living organs as he could not by other means. There was no objection to the medically unqualified radiologist, who kept his job because he turned out first-class work. Radiotherapy could be extremely valuable in some cases of Graves's disease: patients might occasionally be burnt on the neck, but they were at any rate alive. It was impossible to cut down expense by limiting the examination, for scanty examination meant misdiagnosis. Contract work was apt to lead to mistaken economy in this direction. Clinical examination was becoming neglected. A negative report of a first examination did not necessarily mean that the patient was healthy. When the radiological appearances were typical in the absence of clinical signs, the general practitioner could not afford to neglect them.

Dr. **Roy Ward** (London) said that as early diagnosis was the most important single factor in the treatment of cancer, progress would be limited until there was a closer liaison between the patient, the doctor, and the treatment centre. At present patients failed to come for examination through ignorance or because they were afraid of cancer being diagnosed. The general practitioner must help centres to follow up their patients. The use of radiotherapy in menorrhagia was not dependent on a gross lesion. Operation was better than X rays for sterilisation, as it saved the ovaries. The choice of treatment in early operable cases of breast cancer had not yet been put on a satisfactory basis. For the thin, flat breast radiotherapy was better than surgery, but in the fat, pendulous breast it was difficult to distribute the needles properly and operation had advantages, especially if the incision were made over a wide area of skin.

Dr. C. H. C. **Dalton** (Ipswich) said that students should be instructed in what radiology could do. If instruction were deferred until the post-graduate stage, the great majority would not receive it. Every radiologist ought to serve at least one year as a resident before he took the diploma.

Dr. S. L. **Mucklow** (Cheltenham) suggested as one advantage of an interview between general practitioner and radiologist that analogies were often suggested with former cases.

Dr. **Le Fleming**, in reply, said that one great use of an X ray film was to impress the patient with the need for proper treatment. A disadvantage of post-operative radiation was that it concentrated the patient's mind on the possibility of recurrence.

Dr. **Webster**, also in reply, advised radiologists not to base their reports on the screening, because the film often showed appearances that the screen missed. This was especially true of fractures, where the legal danger came in. Modern safety apparatus, in which the current could not be passed until the filter was inserted, abolished danger to the skin. A new method was being perfected by which Graves's disease might be cured in a few weeks. The radiologist and the general practitioner could coöperate usefully in periodical medical examination for preventive purposes.

SECTION OF PUBLIC HEALTH

The president of the section, Dr. T. **Carnwath** (Ministry of Health), having briefly introduced the speakers, Dr. R. A. **O'Brien** (Beckenham) opened a discussion on

Immunisation in the Prevention of the Specific Fevers

in a paper dealing mainly with recent advances in the production of diphtheria prophylactics. The original toxin-antitoxin or toxoid-antitoxin mixtures with which so much of the earlier work was carried out were, he said, with the exception of toxoid-antitoxin floccules (T.A.F.)—a potent prophylactic which does not give rise to reactions—gradually being replaced by toxoid. Considerable use is also being made of alum-toxoid. Toxoid given in three or even two well-spaced doses has been found to make well over 90 per cent. of Schick-positive reactors negative within a few weeks. Except in very young children toxoid is apt to give rise to local reactions. Various ways may be adopted to circumvent these. Some give a full dose of 1 c.cm. of toxoid to children under 5 years of age. In the case of older children, the Moloney-Fraser intradermal sensitivity test with diluted toxoid is applied; negative reactors are immunised with full doses of toxoid, positive reactors with T.A.F. The so-called universal dose of toxoid (0·1 or 0·05 c.cm.) may be given to all children. Dr. G. Chesney of Poole injects all children with a small detector dose to identify those likely to suffer reactions. Discussing alum-toxoid, which although a powerful antigen tends to produce lumps and on occasion sterile abscesses at the site of injection, Dr. O'Brien said he was not wholly convinced that it will displace formol-toxoid. He thought however that, until it was possible to eliminate the pseudo element from antigens, the local swelling and general malaise which may follow the inoculation in sensitive people would not entirely disappear. There was no evidence that prophylactics made from the classical Park-Williams 8-strain did not give adequate protection against infection with the *gravis* strain of *C. diphtheriæ*.

Contrary to Dudley's experience at Greenwich, Dr. O'Brien had been unable to collect evidence in this country, or in the United States of America, that immunisation produced an increased carrier rate amongst the immunised who might therefore constitute a danger to non-immunes. About immunisation against scarlet fever there was little or nothing new to report. Scarlet fever formol-toxoids had been produced, he said, but, unfortunately, as the intensity of formalinisation is increased the toxicity is reduced and so also the immunising efficiency. Work was still being carried out but, so far, a satisfactory scarlet fever toxoid was not available. In the vaccine prophylaxis of whooping-cough, Dr. O'Brien considered that the work of Madsen in Scandinavia and Sauer in America offered considerable hope. He concluded by stressing the difficulties of the immunologist in obtaining access to adequate clinical material. Progress would be faster, he said, if under proper safeguards trial could be made of different antigens on large groups of children.

Surgeon-Captain S. F. **Dudley**, R.N. (Chatham), said that in his experience at Greenwich Hospital School negative Schick reactors might lapse to the extent of 10 per cent. in from six months to two years. Infection with the diphtheria bacillus, however, rapidly raised the antitoxic titre of the blood so that most of the cases of sore-throat in lapsed immunes were so trivial as to be clinically unrecognisable as diphtheria. He insisted upon the importance of not claiming that a school population was immune until there was evidence that the Schick tests had become negative. There could be no greater set-back to the progress of immunisation, he remarked, than the occurrence of severe or fatal diphtheria amongst those who were alleged to be immune. Since carriers were Schick-negative reactors, artificial active immunisation increased the number of those who, instead of developing clinical diphtheria following infection, became carriers. Captain Dudley believed that absolute immunity was not attainable, but active immunisation reduced morbidity, even following *gravis* infections, to a negligible figure. In conclusion he referred to recent important work by Colonel M. Perry and his co-workers at the R.A.M.C. College on T.A.B. vaccine. The Rawlings (1900) strain of *B. typhosus* had, with the lapse of years, lost virulence. It had now been possible to rejuvenate the strain and it had further been shown that vaccines prepared from virulent strains were no more likely to give rise to reactions following inoculation than were strains possessing only a low degree of virulence.

ULTRAMICROSCOPIC VIRUSES

Dr. Wilson Smith (Med. Research Inst., Hampstead) discussed the methods of immunisation available for those specific fevers which are caused by ultramicroscopic viruses. An acceptable method must be absolutely safe and produce no disturbance of health. It should be painless and result in a high grade of lasting immunity. There were several difficulties. No virus was known to produce an exotoxin, and thus those controlled trials with neutral innocuous toxin-antitoxin mixtures which were possible in the case of diphtheria were not feasible. Since viruses could not be grown upon lifeless media, pure sterile suspensions of known density, like T.A.B. vaccine, could not be made. Virus vaccines contained a little virus and a great deal of something else which might reduce, if it did not destroy completely, the efficiency of the vaccine. Owing to their very small size, it might be quite impossible to administer enough bulk of the dead virus to produce an adequate immunological response and, further, in the case of certain human diseases no other animal species had been found susceptible to infection by the causative virus. Nevertheless, important advances had been made during the last few years by indirect methods. Killed virus vaccines might produce no immunity or immunity which was slight and transient. The latter might be converted into solid immunity by giving subsequent doses of the living virus, possibly fatal to the normal animal. Formolised and carbolised vaccines had been extensively used for dog distemper and cattle plague and in human rabies were employed with great success. Field trials of similarly prepared yellow fever vaccine during an epidemic were unconvincing. These vaccines were unstable and might also be rendered quite useless if the viricidal chemicals were added in too great a concentration. Methods valid for one virus might be invalid for another.

In some cases, Dr. Smith thought, really killed viruses might be antigenically active and improved methods of concentration and purification might lead to their greatly extended use. By passage of the living virus through an unusual host it might be so modified as to produce in the human being a mild disease—e.g., vaccinia—but the modified virus was not sterile and hence scarification, even with its lack of precise dosage, was the only advisable means of administration. T. M. Rivers had cultured vaccinia virus in chicken embryo medium and had produced a satisfactory degree of immunity in 100 out of 118 infants. Culture vaccine might be injected intradermally without disadvantage. Further, W. D. H. Stevenson and G. G. Butler (The Lancet, 1933, ii., 228) had produced, he said, a highly potent and sterile vaccine by growing the virus on the chorio-allantoic membrane of the developing chick embryo. One egg would yield sufficient virus for the vaccination of 200 individuals. M. Theiler by the intracerebral inoculation of mice had prepared a modified strain of yellow fever virus which had been used for the inoculation of human beings. In this disease Dr. Smith thought it was preferable to adopt the method employed so extensively in animal diseases, such as dog distemper—i.e., the combination of virus with immune serum. The attack of yellow fever resulting from the injection of mouse-brain virus and convalescent serum together is mild, and extensive trials have shown that the immunising response is satisfactory. Dr. Smith mentioned briefly the use of convalescent serum in the prophylaxis of measles and its possibilities in poliomyelitis, chicken-pox, and mumps.

Dr. E. H. R. Harries (North Eastern Hospital) described some of the main indications for active and passive immunisation in the practice of the fever hospital. It was essential to immunise the staff against small-pox, diphtheria, scarlet fever, and, on occasion, against infections of the enteric group. Natural Schick-immune or lapsed artificially immunised nurses never, following infection with the diphtheria bacillus, experienced more than a highly modified and trivial attack which cleared up spontaneously. Immunisation of nurses with toxoid was valid against *gravis* infections. Natural Dick-immunes possessed solid immunity and did not contract clinical scarlet fever. Occasionally, artificial Dick-immunes appeared to lose immunity to an extent which permitted a clinical attack of the disease. Until the optimum range of skin test doses was known, active immunisation against scarlet fever in public schools with their high proportion of original Dick-positive reactors who might relapse could not be advised. Dr. Harries showed that the active immunisation of nurses against scarlet fever did not increase the incidence of streptococcal tonsillitis among them. Prophylactic *passive* immunisation against diphtheria, scarlet fever, and measles was of great value in obviating the spread of cross-infection in fever hospital wards. During the recent measles epidemic, when it was essential to maintain the maximum turnover, Dr. Harries had, by the injection on admission of a combined prophylactic of diphtheria and scarlet fever antitoxins contained in 5 c.cm. of concentrated serum, been able to secure the almost complete freedom of measles wards from these cross-infections. Analysis of some 900 consecutive cases so protected showed no instance of anaphylaxis and a late serum rash rate in about 9 per cent. It was further shown that sensitisation was negligible in frequency and degree. He discussed the value and dosage of adult immune measles serum.

Dr. C. W. Hutt (Holborn) gave statistical details of the progress of diphtheria immunisation in the large cities, headed by Birmingham with some 70,000 immunised children.

Dr. E. H. T. Nash reported the further progress of his immunisation campaign in Heston and Isleworth. He stressed the importance of propaganda.

Dr. Nancy Howell (Acton) had, during the last 18 months, immunised 6000 school-children including 69 per cent. of those in infants' departments. No cases of diphtheria had been admitted to hospital for some time. A gratifying result of a local anti-vivisectionist campaign had been a large immediate accession of children to the immunisation clinics.

Modern Sanatorium Treatment

In a paper read in his absence Dr. A. S. MacNalty (Ministry of Health) insisted upon the importance of early diagnosis and the proper selection of patients for sanatorium treatment. He noted a tendency to disparage sanatorium treatment and to exalt collapse therapy. There should be full coördination between the tuberculosis officer and the medical superintendent. Facilities for observation and hospital treatment were essential. Collapse therapy should only be carried out in really suitable cases. The criterion of temperature was all-important. Fever was the first indication of infection and should be met by absolute rest in hospital. Correct coördination between the hospital and sanatorium would obviate the admission of unsuitable cases to sanatoria. With the recurrence of activity the sanatorium patient should return to hospital. Careful study of the individual patient was essential. There must be a proper régime and facilities for prolonged stay. After discharge the ex-sanatorium patient should be secured as regards maintenance and should be kept under supervision for five years. Village settlements met these requirements.

Dr. F. G. CHANDLER (London) and other speakers also advised caution in the selection of cases for collapse therapy. It should not be lightly undertaken. The tuberculin era was recalled and fears expressed that another valuable mode of therapy might fall into disrepute as a result of indiscriminate use.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

A NOTABLE HEALTH SURVEY

A RECENTLY completed health survey of the State of New Mexico is of unusual interest from two points of view. In the first place, something over one-half of the population of this State consists of "Spanish-Americans"—the original Indian population inter-bred with Spanish conquistadores. The U.S. Census Bureau classifies them as white Americans, so that it is impossible from the mortality statistics published in Washington to distinguish between the rates for Spanish-Americans and for their "Anglo-American" neighbours. The New Mexico survey is the first extensive study of health among these original inhabitants of the south-west. In the second place, New Mexico has been for a generation the mecca of the American consumptive. Thousands have travelled from all parts of the United States to seek health among the New Mexico mountains. Many have died there leaving their families in the State. Many have recovered complete health and are now prominent bankers, lawyers, physicians, and merchants of the State. What has been the effect of this influx of active cases of tuberculosis upon the indigenous population? These interesting aspects of New Mexico's health problems, together with the fact that the bureau of public health in this State is administered on a civil service basis and is therefore reasonably efficient, induced many of the national health organisations to participate with the New Mexico Tuberculosis Association in the study.

The survey was made under the general direction of Dr. Carl Buck, field director of the American Public Health Association. It covered 18 out of 31 counties. Most of the work, however, was done in five counties carefully selected to include the different racial and occupational groups to be found in the State. In all, 4755 school-children received Mantoux tests, 4076 were examined for nutritional defect by the new A.C.H. method, 4000 had their eyes examined by experts from the National Society for the Prevention of Blindness. A careful search was made amongst the adult contacts of children giving positive Mantoux tests for open cases of tuberculosis. This was in addition to health examinations given at random in the adult population. More than 5000 adults selected at random had blood samples taken for Wassermann and Kahn tests, and in some cases for further serological study. More than 7000 premises were studied for sanitary facilities.

Mora County, populated almost entirely by Spanish-Americans, provided 1646 specimens of blood of which 1023 were from adults. The rate of syphilis among adults was found to be 8·0 per cent. The rate among children (under 17 years of age) was 2·0 per cent. No difficulty was experienced in tracing possible sources of infection. The cases found positive seemed not to be disturbed either that they had acquired the infection nor at the implications of having acquired it. An interesting account of this part of the survey has been published by Dr. Walter Clarke (Ann. Internal Med., May, 1934).

It is estimated that there are not less than 20,000 cases of active syphilis in the State. An accurate census, taken by the U.S. Public Health Service, of all cases of syphilis under treatment by the doctors and institutions of the State on Dec. 1st, 1933, showed 1011 cases actually under treatment. From this it follows that only 1 out of every 20 cases of syphilis in the State is under medical treatment. Judging from the findings in Mora County and from other available data, it is probable that the proportion of Spanish-Americans receiving treatment is even much less than the 1 in 20 average for the State.

Of adults examined at random, 8·6 per cent. were diagnosed either as having active tuberculosis or as suspicious. Among the families whose adult members were given physical examinations and found to be free from tuberculosis, 12·8 per cent. of the children gave positive Mantoux tests. On the other hand, in families in which active tuberculosis was found, 32 per cent. of the children gave positive reactions. Since tuberculosis was found to be three times as common among the Anglo-Americans as among the Spanish-Americans, one might easily suppose that more Anglo than Spanish children would show positive Mantoux tests. Remarkably this was not the case. The Anglo-American group of children showed 13·2 per cent. Mantoux positive, the Spanish-American 22·9 per cent. From this it appears that while the existence of open cases of tuberculosis in the family is an important factor in the spread of infection there must also be other factors of even greater social import. Will these other factors, whatever they are, also tend eventually to produce a large number of active cases among the Spanish-speaking people?

Public health officers in the south-west will watch with interest the research now being pursued in Cattarangus County, N.Y., where 500 children (300 reactors, 200 non-reactors) have been under close observation for a total of 1742 person-years. About half of the reactors have been followed into adolescence. Five of them are now negative to tuberculin. Only three have developed adult tuberculosis, two of them after continued or renewed exposure to positive sputum in the home, and the third after strenuous competitive athletic sports.

The survey of the sanitation of homes in New Mexico discloses primitive methods of waste disposal and water-supply among the Spanish-speaking people. Ninety per cent. rely on outdoor privies, while 4·2 per cent. have no system of human waste disposal at all. The Anglo-Americans enjoy only slightly better conditions, 71 per cent. using outdoor privies, while 15·9 per cent. have sewer connexions. Less than 10 per cent. of the privies in either group were found to be flyproof. In 15 per cent. of the premises surveyed (9 per cent. Anglo, 27 per cent. Spanish) there was a cesspool or privy, usually the latter, within 50 feet of the source of drinking water. Five per cent. of the Anglo-Americans and nearly 10 per cent. of the Spanish-Americans get their drinking water from streams or from irrigation ditches.

PARIS

(FROM OUR OWN CORRESPONDENT)

OF WHAT DO PARISIANS DIE ?

"OUR study presents, in brief, a promenade through a vast cemetery harbouring numberless Parisians who have disappeared during the three five-year periods, between 1909 and 1923." With this pictorial introduction, Dr. G. Ichok begins an analysis in the *Annales d'hygiène publique* of the main causes of death in Paris over three periods of equal length before, during, and after the war. As the population of Paris has shown little tendency to expand in the period under review, Dr. Ichok's uncorrected figures give a truthful enough picture of the relative importance of the various causes. It should be noted that the present tendency of many French doctors not to notify explicitly the causes of the deaths of their patients is hardly at all reflected in the present study which deals with Paris alone and with a period when ignorance had not yet become a studied policy. In fact, among a total of 672,137 deaths registered between 1909 and 1923 there were only 4917 not specified. Old age as a cause of death has increased slightly, but what is truly remarkable is the fact that there are three women for every man dying of old age. For this sex inequality Dr. Ichok has no explanation. Turning to deaths from suicide, he publishes a table in which nine variations of suicide are classified. The years 1914–18 distracted the would-be suicide, and the diminution survived the war. But there is one exception—viz., suicide by drowning—for which the figures for the three periods are 152, 108, and 305 respectively. On the other hand, accidental drowning is about 50 per cent. less common after 1919 than it was both before and during the war. Dr. Ichok is inclined to explain this paradox by assuming that many a suicide by drowning before and during the war was glossed over with the diagnosis *submersion accidentelle.* As for tuberculosis as a cause of death, we find the paradox of tuberculosis of the lungs declining from about 47,000 to about 33,000, while tuberculosis of the larynx shows a rise from 585 to 697 in the period under review. These opposite movements probably reflect fashions in notifications rather than any basic change in the behaviour of tuberculosis in these two organs ; and it would be getting nearer to the truth if the larynx were not dissociated from the lungs. With regard to the digestive system as the seat of fatal disease, it is noteworthy that the deaths from ulcer of the stomach numbered 354, 454, and 736 respectively in the three periods. In compensation for this abrupt rise is the diabetic mortality, the figures for which are 2312, 1846, and 1563 respectively.

MEDICAL PLETHORA AND A PROPOSED REMEDY

Dr. Portmann, senator and professor of medicine, has suggested a scheme for relieving congestion in the medical profession by the simple expedient of limiting the number of entrants. He has even prepared a draft of a law to this effect. According to the first article the Minister of Education will decide each year how many medical students may register as such, and how many may proceed from the first to the second year of their studies. According to the second article, the would-be medical student's inclusion in, or exclusion from, the list of candidates for a medical career would depend on the number of marks scored in certain examinations. They would, in other words, become competitive. In the *Concours médical* Dr. G. Duchesne deplores his colleague's lack of historical sense. For 50 years or more French doctors have not ceased to bewail the discomforts of a competition thrust on them by the overcrowding of the profession. In 1899 a prize was offered by a leading French medical journal for the best essay on this problem and its solution. Though Dr. Duchesne did not win this prize, his essay was published by the journal in question in 1900. Looking over it again, after an interval of 34 years, Dr. Duchesne was struck by the similarity of his scheme of reform to that of Prof. Portmann. But in the interval, Dr. Duchesne has lost confidence in the wisdom of such short cuts by discriminatory legislation. How, he asks, would it be possible to ascertain what is the number of doctors that would be necessary and sufficient for the needs of the community ? And how are doctors to be distributed in the many branches of their profession ? And what would happen if the limited number of students allowed to qualify as doctors were all to choose to settle in Paris, to the neglect of the rest of the country ? Nothing less than an arbitrary geographical distribution of doctors would solve this difficulty, a pretty solution indeed for a liberal profession !

SYSTEMATIC MEDICAL SUPERVISION OF MEDICAL STUDENTS AND NURSES

The extension of the system of periodical medical examinations to medical students and nurses is yielding instructive and sometimes disconcerting results. They are curiously similar, whether the examinations have been made in Yale, Oslo, Upsala, or Munich. At the Boucicaut Hospital in Paris, in the course of the past eight years, Dr. Courcoux and his colleagues have thoroughly overhauled more than 300 students and 380 nurses. A radioscopic examination of the lungs and heart was supplemented by a radiographic examination when there was any suspicion of tubercle. This comb-out not only yielded a couple of cases with tubercle bacilli demonstrable in the sputum, but also several cases of old pleurisy and radiologically demonstrable morbid changes in the lungs. The danger of the former to their neighbours, and the need for both groups to take special care of themselves, require no emphasis. But a more surprising result of these systematic examinations was the observation from time to time that the apparently robust, who passed the first examination with flying colours, collapsed soon afterwards with signs of acute tuberculosis. The by now classical skin tests of Hamburger and Monti in Vienna at one time lulled the world into a false sense of security with regard to the immunity of young adults to tuberculosis by their finding that 94 per cent. of the Viennese children between 11 and 14 were already tuberculin-positive. Dr. Courcoux and his colleagues have checked up these figures by tuberculin skin tests which they have included in their medical examinations of students and nurses during the past two years. They found that 23 per cent. of the students and 21 per cent. of the nurses were still cuti-negative. Yet most of these negative reactors came from urban, not rural homes. The precaution was taken of enjoining on these presumably susceptible persons the necessity for beginning their hospital work in services in which exposure to tuberculous infection would be least likely, but the repetition of the medical examinations, including skin tests, not only showed that more than half of them soon became cuti-positive, but also that several of them showed other and more disquieting signs of a recent infection. Commenting on these observations at a meeting of the *Société d'études scientifiques sur la tuberculose*, Prof. Bezançon stressed their importance in favour of the conception of tuberculosis as a contagious disease, at a time when there is a return on the part of many to Villemin's belief in tuberculosis as an expression of heredity.

IRELAND

(FROM OUR OWN CORRESPONDENT)

A NEW PUBLIC HEALTH MEASURE

IMMEDIATELY before the adjournment of the Dáil the Minister for Local Government and Public Health introduced a Local Government (Amendment) Bill, the text of which has now been circulated. It contains provisions which empower the Minister to divide rural sanitary districts into two or more sanitary districts, each of which will rank as a county health district. The Minister will only take such action at the request of the county council. The county council will continue as the sanitary authority of each newly constituted district. Pending a statement from the Minister on the second reading of the measure its objects are not clear. Few of the counties in the Irish Free State are too large to be dealt with as a single area, and a multiplication of small sanitary districts may lead to unnecessary duplication of machinery. At present only two-thirds of the county areas in the State have medical officers of health, and a multiplication of areas is likely to delay still further this essential step in administration.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 25TH, 1934

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 1964; diphtheria, 967; enteric fever, 51; acute pneumonia (primary or influenzal), 368; puerperal fever, 43; puerperal pyrexia, 116; cerebro-spinal fever, 15; acute poliomyelitis, 34; acute polio-encephalitis, 2; encephalitis lethargica, 6; dysentery, 5; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 3rd–4th was as follows: Small-pox, 0; scarlet fever, 1158; diphtheria, 1409; measles, 353; [illegible]; puerperal fever, 19 mothers (plus 7 [illegible] lethargica, 269; poliomyelitis, 5; [illegible] At St. Margaret's Hospital there were 18 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 9 (1) from measles, 5 (0) from scarlet fever, 9 (1) from whooping-cough, 24 (3) from diphtheria, 54 (14) from diarrhœa and enteritis under two years, and 11 (0) from influenza.

The deaths reported during the week as due to diphtheria exceed the sum of those due to measles, scarlet fever, and whooping-cough. The fatal cases of diphtheria were widely distributed, no more than 2 being reported from any great town, but Portsmouth, Liverpool, Newcastle-on-Tyne, Sheffield, and Birmingham each reported 2 deaths. The two fatal cases of enteric fever outside London occurred at Hull. Birmingham, with 6, showed the highest deaths from diarrhœa, Leeds following with 5, Liverpool and Newcastle-on-Tyne with 3.

The number of stillbirths notified during the week was 249 (corresponding to a rate of 38 per 1000 total births), including 34 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdrs. G. E. D. Ellis to *Victory* for R.N.B. and H. L. Douglas to *Pembroke* for R.N.B.

Surg. Lt.-Comdrs. E. B. Pollard, J. C. Souter, J. W. Cussen, R. G. Anthony, D. C. Drake, E. J. K. Weeks, and A. A. Pomfret to *President* for course; C. Keating to *Pembroke* for R.N.B., and to *President* for course; C. H. Birt to *Pembroke* for R.N. Hospital, Chatham, for course; W. F. Walsh to *St. Angelo;* T. W. Froggatt to *Godetia;* and J. C. Gent to *President* for course.

Surg. Lt.-Comdrs. (D.) L. B. Osborne to *Drake* for R.N.B. and A. W. Wallace to *Resource.*

Surg. Lts. B. S. Lewis to *Dolphin;* S. R. G. Pimm to *Victory* for Haslar Hospital for course; J. L. S. Coulter to *Centurion;* M. J. Brosman to *Fowey;* and S. R. G. Pimm to *President* for course.

Surg. Capt. P. E. Maitland, retired, has been awarded a Greenwich Hospital pension of £50 a year, from March 20th, in the vacancy created by the death of Fleet Surgeon R. H. Nicholson, retired.

Surg. Comdr. G. Kirker to *Drake* for R.M. Infirmary, Plymouth.

Surg. Lt.-Comdrs. (D.) H. E. Rose to *Defiance* and J. L. Edwards to *St. Angelo* for Malta Hospital.

Surg. Lt. D. B. Jack to *Bideford.*

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. H. A. M. Whitby to be Surg. Lt.-Comdr.

Surg. Lts. J. D. Simpson to *Vernon;* K. W. Martin to *Victory;* and W. D. M. Millar to *Victory* for R.N.B.

Proby. Surg. Sub.-Lts. D. Shute to *Pembroke;* P. M. Inman to *Effingham;* and J. Scott to *Drake* for R.N.B.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. R. C. Hallowes, D.S.O., retires on ret. pay.

Maj. L. T. Poole, D.S.O., to be Lt.-Col.

Maj. L. A. B. Moore relinquishes his commn.

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Off.: Lt.-Col. L. G. Gibson, Lt.-Col. F. L. Bradish, D.S.O., and Lt.-Col. W. C. Smales, D.S.O.

ARMY DENTAL CORPS

Maj. R. M. King to be Lt.-Col.

TERRITORIAL ARMY

Maj. S. J. C. Holden to be Lt.-Col.

R. M. Allardyce to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS

The King has been graciously pleased to confer the Efficiency Decoration upon the undermentioned Officers under the terms of Royal Warrant: Lt.-Col. C. H. Budd and Maj. V. H. Wardle.

ROYAL AIR FORCE

Dental Branch.—Flight-Lt. G. A. Ballantyne is promoted to the rank of Squadron Leader.

INDIAN MEDICAL SERVICE

The appt. of the undermentioned officers is confirmed: Captains: B. M. Rao, A. N. Duggal, B. S. Sandhu, B. N. Khan, I. Bakhsh, C. H. Dhala, M. Ata-Ullah, S. Ahmad, C. C. Kapila, and V. M. Albuquerque.

The undermentioned appts. are made: To be Lts. (on prob.): W. J. Virgin, J. Brebner, H. W. G. Staunton, and J. D. Gray.

The undermentioned officers have vacated appts. in India: D.A.D.M.S.: Maj. R. F. Walker.

The undermentioned appts. have been made in India: A.D.M.S.: Col. L. V. Thurston, D.S.O., Brit. Serv. and Col. A. E. S. Irvine, D.S.O., Brit. Serv.

DEATHS IN THE SERVICES

The death occurred at Dymchurch, Kent, on August 31st, of Lieut.-Colonel Alban Anderson Meaden, R.A.M.C. (retired). Born in 1876, he was the eldest son of the late Rev. R. A. Meaden, and was educated at Highgate, St. Bartholomew's Hospital, and London University. He qualified M.R.C.S. in 1902, gained the Lawrence gold medal and scholarship in 1903, and entered the R.A.M.C. in 1904. He served through the European War and was created D.S.O. in 1916. He retired in 1931.

The death occurred on Sept. 3rd at Bexhill of Colonel Alan Edmondson Tate, C.S.I., C.M.G., R.A.M.C. (retired). He was the son of the late Rev. C. R. Tate, Rector of Trent, Somerset. Born in 1859 and educated at Merchant Taylors' and Bishop Stortford Schools, he qualified M.R.C.S. and L.S.A. in 1882. He entered the R.A.M.C. in 1883, became colonel in 1912, and retired in 1917. He served with the Burma expedition, 1886–89 (medal with two clasps), with the Chitral relief force, 1895 (medal with clasp), and in the South African war, 1899–1901 (Queen's medal with six clasps). He served in Mesopotamia and India 1915–19 and received the C.M.G. in 1916, and in 1919 the C.S.I. He was on the staff of the *commander-in-chief in India 1903–07* and hon. surgeon to the Viceroy of India 1912–17. He was also deputy assistant director-general of Army Medical Services at the War Office in 1908–09. He married in 1889 Zaidee, daughter of the late Mr. Frank White, of Loughborough.

CORRESPONDENCE

EXTRAPERITONEAL OVARIAN GRAFT CYST

To the Editor of THE LANCET

SIR,—In THE LANCET of July 14th (p. 74) Mr. J. S. Hall gave a very interesting account of cyst formation in ovarian grafts, and pointed out that very few cases have been recorded. Here is a recent case of my own.

Mrs. S., aged 36, was admitted to hospital on Dec. 21st, 1933, complaining of pain in the right iliac fossa, dysuria, frequent menorrhagia, and vomiting. She had had two previous operations, one in 1929 for dilation and curettage, the other in 1931 when the cervix was amputated. On examination the uterus was bulky and irregular, and there was a tumour in the pouch of Douglas. On Dec. 27th I opened the abdomen and found numerous adhesions surrounding an appendix which had been the seat of recent inflammation. The appendix was removed. The uterus contained a large number of fibromyomata, and there was an ovarian cyst on the right side the size of a grapefruit. The left ovary was also cystic. A panhysterectomy was performed, and three slices of the left ovary, each about 2 cm. long and 3 mm. thick, were transplanted into the rectus sheath on the right side. Convalescence was uneventful, and the patient was discharged on Jan. 20th.

I saw her again in February, when she complained of a painful swelling in the right rectus sheath. On Feb. 15th, under local anæsthesia, I removed one of the grafts. There was a small collection of blood-stained fluid about it, but no true cyst wall could be seen. The pathological report was: "The greater part of the transplant shows necrosis and loss of cell outline. There is a small area of proliferation of young blood-vessels into the centre, while the extreme edge of the tissue submitted appears to have escaped." On July 16th she complained of tenderness over two "lumps" in the right rectus sheath. They were about the size of pigeon's eggs, but she agreed not to have them removed when assured that they were not due to "cancer." She was entirely free from menopausal symptoms, but complained of some premenstrual pain over the tumours.

(I am indebted to Dr. R. A. Grant, medical superintendent of the Birkenhead Municipal Hospital, for permission to publish this case, and to Dr. J. M. Ritchie for the pathological report.)

The points of special interest are these: (1) The ovary from which the graft was taken was the seat of the disease. (2) Cyst formation occurred in all these pieces of graft. (3) There have been no menopausal symptoms. (4) The section showed, as is usual, some necrosis and new blood-vessel formation, but no definite cyst wall was seen. I believe, as Mr. Hall suggested, that these cysts are not true ovarian cysts but rather false cysts, the walls being formed by the surrounding tissue and the fluid by the rupture of Graafian follicles, the contents of which have not been absorbed. This theory is supported by the pathological findings, and it seems possible that the difference between the osmotic pressure of the liquor folliculi and the tissue fluids not only prevents the absorption of the liquor folliculi but may even cause an increase in the cyst contents. The fact that the ovary from which the grafts were taken was diseased does not affect the theory, and indeed it is probable that a diseased ovary is always used for transplantation, as otherwise the operation would not be required. It is, I think, unnecessary to remove these cysts unless the symptoms that they produce warrant it, and this is more especially so when menopausal symptoms have been avoided.

I am, Sir, yours faithfully,

H. A. KIDD, F.R.C.S. Edin.,

Deputy Medical Superintendent, Birkenhead Municipal Hospital.

August 23rd.

ACRIFLAVINE FOR SCHISTOSOMIASIS

To the Editor of THE LANCET

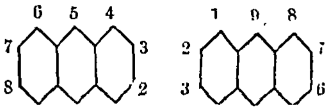
SIR,—Dr. A. C. Fisher's proposal in your issue of April 28th to treat schistosomiasis with acriflavine has stimulated many medical centres in Egypt to try it. To my surprise all of them treated their cases with trypaflavine with the idea that it is a synonym of acriflavine, and their failure may be attributed to this fact and to different dosage. Trypaflavine is a yellow powder with the formula 3 : 6 diamino-10-methylacridine chloride; acriflavine is a brick-red powder with the formula 2 : 8 diamino-10-methylacridine chloride. I am using a big bed-time dose of acriflavine—30 c.cm. of a 2 per cent. solution in water for adults weighing over 60 kilos, 15 c.cm. for youngsters and boys weighing 25–35 kilos, and 5 c.cm. for young children weighing 10–20 kilos. With these doses vomiting occurs in 40 *per cent. of* the cases but only ten hours after the dose has been given. Even very weak and debilitated patients stood this dose well; vomiting and some diarrhœa occurred, but there were no colicky pains or *jaundice*. Among 100 cases so treated over 50 per cent. are cured—ova absent or all dead. It is rather too early to speak about ultimate results. I am treating with encouraging results cases rejected by the Bilharzia Hospital as unfit for *tartar emetic* because of heart failure, liver cirrhosis and insufficiency, kidney troubles, or advanced anæmia. Some of the cases were treated in hospital, but the majority at home without special precaution.

Acriflavine is so quickly absorbed by the intestinal mucous membrane that little of it reaches the rectum where the worms may carry on. This led me to give rectal enemas, 300 c.cm. of a 1 in 500 solution every night, and it was when the drug was excreted in the urine curing bilharzia both of rectum and bladder. This route of treatment is suitable for cases which vomit badly and refuse oral treatment on this account. Recently I have been trying salol-coated or keratin-coated pills, with extract of gentian as the vehicle.

I am, Sir, yours faithfully,

M. A. EL MONEIM EL DIWANY,
Principal Medical Officer, Shebin-el Kom
July 30th. General Hospital, Egypt.

*_** Our correspondent is not correct in regarding trypaflavine as in any way essentially different from acriflavine. The confusion is due to the unfortunate fact that two systems of numbering have been employed to indicate the positions of substituted groups in the acridine molecule. The method of enumeration recognised by the B.P. 1932 is that given in Richter's "Lexikon der Kohlenstoff-Verbindungen," and shown in Formula I. An alternative method used—notably in France and in America (U.S. Dispensatory 1926)—is given in Formula II.



The variation in colour to which our correspondent refers may be due to the fact (of which we are informed by Messrs. May and Baker Ltd.) that commercial samples of these products consist of a mixture in varying proportions of the hydrochlorides of diamino-methyl-acridinium-chloride *and diamino-acridine*; which may also explain the differing therapeutic results.—ED L.

VACCINES IN PEPTIC ULCER

To the Editor of THE LANCET

SIR,—During the past few years the view that gastric and duodenal ulcers are due to an intestinal infection has slowly gained ground. Prof. D. P. D. Wilkie,[1] of Edinburgh, has demonstrated similar streptococci in the walls of the ulcer and gall-bladder in the same case. Dr. A. F. Hurst [2] has noted that duodenal ulcer is almost always associated with constipation. In the handbook of Vaccine Therapy,[3] issued by Parke Davis and Co., written by members of the Inoculation Department of St. Mary's Hospital, it is stated that long-chained non-hæmolytic streptococci are always present in cases of gastric and duodenal ulcer, and that these streptococci are not a normal inhabitant of the bowel.

Working with the vaccine prepared from these streptococci, during the past 18 months I have been able to demonstrate the fact that in a series of 22 cases the patients were hypersensitive to this vaccine —intestinal streptococci—to a remarkable degree. As a general rule a dose of 100 organisms is sufficient to cause a serious reaction. In fact, after a few of these reactions I have been compelled to commence with a smaller dose—20 or even 10 streptococci—and to make increases in this small initial dose every two or three days until improvement or reaction follows. Once there is a definite improvement the dose is cautiously increased until the improvement lasts for about a week, and the same dose is then administered at weekly intervals without any attempt to increase it unless the favourable response becomes shorter in duration. If a reaction follows any dose, a week is allowed to elapse and the next dose is drastically reduced, according to the severity of the reaction.

It is almost unbelievable to anyone who has not tried it that these doses should produce such marked results. One can only suppose that the result is produced by some kind of allergic response in a body sensitised to this particular bacterial poison. In actual practice the difficulty with these minute doses is not that they are without effect, but that they produce too violent reactions. The patients are, in my experience, hypersensitive—not only in the stage when an actual ulcer has been demonstrated by the X rays, but also before such ulcer can be demonstrated by the X rays, and after the ulcer has clinically healed. I have also found—as one would expect, according to the *infective theory—that in* the small number of cases I have tested, this hypersensitiveness to these intestinal streptococci is present in every case of *chronic appendicitis and cholecystitis*, and the common clinical complaints of "heartburn," "waterbrash," and so-called gastritis. The theory *that these are all local exhibitions of one underlying* streptococcal infection seems to be correct, and vaccine therapy is worthy of an extended trial with *a larger series of cases*.—I am, Sir, yours *faithfully*,

Tutbury, Staffs, August 20th. J. N. GALE.

PERSPIRATION SENSIBLE AND INSENSIBLE

To the Editor of THE LANCET

SIR,—In his first Lettsomian lecture, published in your last number, Dr. C. E. Lakin has defined insensible perspiration as "the escape of water vapour by osmosis through the skin. It is thought," he adds, "that the sweat glands play no part at all in this process." Hancock, Whitehouse, and Haldane (Proc. Roy. Soc. B., 1930, cv., 43) say that the loss of water by evaporation of water which has permeated through the general surface of the skin, and by evaporation or trickling down of sweat secreted by sweat-glands, does not necessarily correspond with what is known as insensible and sensible perspiration. They write :—

> "*In dry moving air or air at the low atmospheric* pressure of a high altitude, evaporation from the skin may be so rapid that when the sweat-glands are secreting very actively, or even to their utmost capacity, the general surface of the skin may be dry, so that all the perspiration is insensible, though far the greater part of it is due to secretion of sweat."

The condition of sweating was recently dealt with by Prof. B. A. McSwiney in his Samuel Hyde lecture to the Royal Society of Medicine (see THE LANCET, 1934, i., 641). It seems to me that Dr. Lakin's use of the term "insensible" perspiration is confusing. The term refers to the condition where there is no visible sweating; but under certain conditions even though the sweat-glands are secreting actively perspiration appears to be insensible.

I am, Sir, yours faithfully,

J. T. IRVING.

The School of Medicine, Leeds, Sept. 4th.

JOHN KNIGHT, SERJEANT SURGEON

To the Editor of THE LANCET

SIR,—The distinguished royalist, Dr. John Knight, is the leading figure in an historical paper which I am endeavouring to complete. Dr. Knight was made serjeant surgeon by Charles II. and appointed to be the King's principal surgeon. He was also commissioned by the same sovereign to be surgeon general of the Forces, and in that character did service in arranging for the care of the sailors wounded in the sanguinary naval battles fought off the East Coast in the second and third Dutch wars, and for the care of the sick soldiers engaged in the expedition to the Spanish Netherlands in 1678.

For the purpose of my paper I am seeking information bearing upon the history of the office of serjeant surgeon. An interesting article upon the serjeant surgeoncy appeared in the *Medical Times and Gazette* of Oct. 19th, 1867; oddly enough the article does not name Dr. John Knight among the holders of the office. It occurs to me that other articles upon the subject of the office must have been published from time to time and particularly upon occasions when distinguished surgeons in modern times have received the Royal Grant which appears to be conferred by letters patent.

---

[1] Brit. Med. Jour., 1933, ii., 767.

[2] In Price's Text-book of Medicine, London, 4th ed., p. 582.

[3] Vaccine Therapy, Parke Davis and Co., 1931, p. 62.

The importance, the dignity, and the antiquity of the office alike suggest that some book may have been written about it giving, amongst other things, biographical material concerning the holders of the serjeant surgeoncy from early times.

I am, Sir, yours faithfully,

August 31st. E. M. C.

PANEL AND CONTRACT PRACTICE

Amendments to the Regulations

The Insurance Acts Committee has been considering the draft of the new consolidated edition of the medical benefit regulations, which contains certain amendments of existing procedure. The first of these deals with excessive prescribing. At present an insurance committee "shall make a recommendation" to the Minister about the withholding of money, even in cases where it has been found that excessive cost of prescribing has not been established. It is now proposed to insert after the word "shall," "if such decision is that excessive cost has been imposed upon the funds available for the provision of medical benefit." The second amendment concerns the procedure to be adopted when questions as to scope of the service are submitted to referees under the Act. The Ministry have agreed to the two modifications suggested at the last panel conference. The third amendment deals with arrangements for practice on retirement or death. The present wording states that "the representative of a deceased practitioner may *within the period for which the committee may permit the practice to be carried on by a deputy* require the committee to give notice, &c. . . ." It is agreed to alter the italicised words to "*within any period for which the committee shall have permitted.*" This is to make it clear beyond doubt that in the case of the death of an insurance practitioner the right to nominate a successor to the practice under this clause does not extend to a period of (say) two months, if no deputy has been appointed. The fourth amendment deals with the period within which, after fees have been accepted for services outside the Act, form GP 45 has to be submitted; at present only two days are allowed, and the time is to be extended to seven days. The fifth amendment concerns the arrangement for carrying on a practice during a practitioner's absence. At present the practitioner is required to inform the committee of the nature of any standing arrangements made with any other practitioner or practitioners, but does not require him to make such deputising arrangements. The new clause makes this quite clear: "A practitioner shall make all necessary arrangements for securing the treatment of his patients where he is unable for any of the causes mentioned above to give treatment personally, and shall inform the committee of any standing arrangements for that purpose."

Agreement on Certification

As a result of conferences up and down the country during the year, culminating in a central conference convened in March, agreement has been reached between approved societies and the Insurance Acts Committee on various points of difficulty in certifying incapacity. The agreement requires no alteration of regulations, but will only become effective through general adoption by both sides. The Ministry of Health, whilst appreciating the efforts of both sides to solve their difficulties, will insist on the proposals going to the consultative council for approval. The resolutions relating to the certification of pregnancy have already been set out in these columns (1934, i., 919); further resolutions on final certificates are now to be submitted to the conference. Postdating by three days is to be allowed in urban as well as rural areas; any alteration on certificates should be initialed to aid in detecting unauthorised alteration of dates. With regard to industrial diseases the resolution suggests that, although insurance practitioners are not required to decide whether an incapacitating disease is occupational or not, the note "? occupational" might be added to the certificate whenever the practitioner is of opinion that the character of the patient's employment may be a contributory or causative factor. For alternative employment the practitioner may communicate with the society intimating his opinion that the time was approaching when the member might be capable of some other kind of work, and asking what the society proposed to do in the matter. Of special interest is the suggested letter to be sent to doctors by secretaries of approved societies on the question whether a reference to the regional medical officer is desirable. The letter runs:—

DEAR SIR,

re — — — — — — — — — — — — — — — —

— — — — — — — — — — — — — — — —

Serial No. — — — — — —

The above insured person is a member of our society, and is receiving from you certificates of incapacity for work.

After a review of the case we are considering the reference of our member for examination by the regional medical officer, but in order to prevent unnecessary reference to this officer we shall be obliged if you will be good enough to inform us by return of post if a final certificate has been issued by you, or is likely to be issued by you in the next few days.

We realise that there is no obligation upon you to supply information to us, but it is hoped that in the interests of all concerned you will favour us with a reply.

To save you trouble we have made provision below for your reply, and we shall be grateful if you will use this and return the entire form in the enclosed envelope.

Yours faithfully,

Secretary.

Dr. — — — — — — — — — — — — — — —

— — — — — — — — — — — — — — — — —

I issued a final certificate on — — — — — — — — — — — —

Do you consider that any advantage would be gained by a reference to the R.M.O.? — — — — — — — — — — — — — —

Any other observations which you may wish to offer the society.

— — — — — — — — — — — — — — — — — — — —

— — — — — — — — — — — — — — — — — — — —

— — — — — — — — — — — — — — — — — — — —

Signature — — — — — — — — — — — — — —

The form of this letter, as also the previous resolution on alternative employment, appear at first sight to be so obvious a method of dealing with the situation that one asks immediately why it has not been adopted before. The answer is professional secrecy —and this difficulty is still present. The relationship of doctor and patient is such that without the patient's consent the doctor cannot answer such letters from an approved society. He can send a report, as he does now, to another medical man who is to give an opinion on a particular case, because those reports are confidential and are not disclosed to the society that is making the reference. The R.M.O.'s report is made to the society as a result of his own examination of the case, and with the help of the information conveyed in the medical attendant's report.

The report of the Insurance Acts Committee does not say whether legal opinion has been taken on the matter. It is obvious that if an insurance practitioner did communicate to an approved society facts about a patient without his consent which resulted in losing benefit, that quite clearly would be a breach of professional secrecy. On the other hand, these communications about patients might be answered in secrecy. But is it the I.A.C.'s considered policy to ask the conference to sanction secret communication about patients between the attending doctor and the society's officials? At the present time the difficulty is surmounted by marking the certificate confidential and handing it to the patient. This method could be adopted by sending to the patient the letter asking for the doctor's report. He would then know what was taking place, and by sending it himself to the approved society he would absolve the doctor from the breach of professional secrecy. With regard to the information sought by this letter, while it may help the society to know that a final certificate has been issued, few doctors and fewer patients will think there is anything to be gained by a reference. The patient may resent the suggestion that his doctor does not know all about his case, and will certainly dislike the implication that he is drawing sickness benefit when he ought to be back at work. The doctor in most cases will simply regard the reference as another report to write.

OBITUARY

ERIC DANVERS MACNAMARA, M.D. Camb., F.R.C.P. Lond.

Dr. E. D. Macnamara, who died in London on August 24th after a short illness, was educated at Peterhouse, Cambridge, where he took his B.A. in 1890, and at the Westminster Hospital from which he graduated L.S.A. in 1895 and M.R.C.S. in 1897. He then entered the medical department of the Royal Navy, serving in the Boxer rising, and being present at the relief of Peiping, for which he was awarded a medal with clasp. After five years service he returned to civil practice as medical registrar at the Westminster Hospital, taking the higher medical diplomas, and becoming assistant physician to the hospital, lecturer on medicine in the medical school, and finally dean of the school. During this period he was for a short time physician to Paddington Green Children's Hospital, and began the association with the West End Hospital for Nervous Disease which lasted throughout his life. In 1912, shortly after being elected F.R.C.P., he resigned his appointments at Westminster to succeed C. A. Mercier as physician for mental diseases to Charing Cross Hospital, and lecturer on psychological medicine in the college. He lectured also at Bethlem Royal Hospital, examined in psychology for the Conjoint Board and the University of London, and was a visitor for Middlesex under the Mental Deficiency Act. During the war he served in the medical department of the Admiralty as well as in the R.A.M.C. When increasing private work led him to give up his Charing Cross appointment he still remained active on the staff of the West End Hospital.

Although always more interested in psychopathology and psychiatry than organic neurology, Macnamara was nevertheless a very sound neurologist and diagnostician. His early experiences as assistant physician at Westminster had given him a wide knowledge of general medicine which enabled him to take a sound view of his special subjects and his individual cases. He was the author of no textbook but he was a frequent writer on neurological and psychological subjects to medical journals. He contributed to Latham and English's "System of Treatment" articles on morphinomania and insomnia; to the "Dictionary of Practical Medicine" articles on general paralysis, alcoholism, and functional insanity; and to Price's "Text-book of the Practice of Medicine" the article on psychological medicine. Everything he wrote had a distinction of style and an easy competence which made reading a pleasure.

Macnamara's personal qualities endeared him to his friends. Beneath his unassuming, somewhat reserved manner lay a charming personality and one of ready sympathy. "One could always," a colleague writes, "talk over difficulties with Macnamara, and be sure of common sense and helpful advice. Much of his work at the hospital was unobtrusive and entirely unselfish. He would serve on committees without demur, and on the committee of management of the hospital his services were invaluable. Although cautious in his decisions and somewhat conservative in his ideas, he had a vein of humour which belied his grave demeanour." A colleague in the R.N. medical service who remained a lifelong friend also testifies to the ability and sympathy which Macnamara possessed and devoted in such full measure to the department of medicine which he made his own. To an extensive knowledge of men and matters he added an enjoyment of life and an outlook on affairs which made him a delightful companion. It is, he adds, no exaggeration to say that Macnamara's name and work will long be remembered with gratitude by patients, students, and colleagues alike.

Dr. Macnamara married in 1904 Frances Mary, daughter of the late Dr. W. Simpson Craig, and sister of Sir Maurice Craig. He leaves a widow and two sons.

DAVID DUNCAN MAIN, F.R.C.P., F.R.C.S. Edin.

Dr. David Main, formerly principal of the Hangchow Medical Training College, who died at Buxton on August 30th, was an Ayrshire man, being born at Kirkmichael in 1856. At the age of 16 he entered a shipping business in Glasgow, but under the inspiration of Moody and Sankey he later decided to work as a missionary, and in 1877 he went to Edinburgh to prepare himself for the work by becoming a doctor. He qualified in 1881, and with his wife was immediately sent to Hangchow, where he served for 46 years. In spite of political disturbances, when the station either had to be closed down or work was carried on under military protection, when hospitals had to be given over to wounded and Red Cross services mobilised, Dr. Main created one of the finest medical organisations of the mission field. His work among the lepers, the opium addicts, and those suffering from tuberculosis led him to obtain the funds to found hospitals for patients suffering from these diseases. His care for the general health of the population called into being a home for incurables, convalescent homes, a maternity hospital, and a mental hospital.

He was eager that Chinese doctors and nurses should be trained, and so there were schools for midwives and dispensers, for male and female nurses, and in 1924 a gift of £10,000 from Lord Maclay enabled him to open the Hangchow Medical Training College, accommodating 135 resident students, with a staff of 25 foreign and Chinese teachers and doctors. At the close of his service there were 500 beds at the station instead of 16. Over 4000 in-patients and 60,000 out-patients were treated in a year, and over 1000 major operations performed. The institution was aptly called in Chinese the Hospital of Universal Benevolence. In 1926, at the time of Dr. Main's retirement, there were serious uprisings against foreigners, and in 1927 the whole work had to be closed down: but 18 months later it was possible gradually to open it up again.

Dr. Main's translations into Chinese include Whitla's "Dictionary of Treatment," Caird and Cathcart's "Surgical Handbook," and Playfair's "Midwifery." His years of retirement were spent in Edinburgh.

MEDICAL NEWS

Microchemical Club

The second meeting of this club will take place at Reading on Sept. 29th. At 11 A.M. the club will meet at the University for the discussion of papers, while in the afternoon a visit will be paid to the National Institute for Research in Dairying, Shinfield. The hon. secretary may be addressed at that Institute.

St. Mary's Hospital

A post-graduate course open to all medical practitioners will be held in this hospital from Friday, Sept. 28th, to Sunday, the 30th. The annual dinner for past and present students will take place in the library of the new medical school, adjoining the hospital, on Saturday, Sept. 29th, at 7 for 7.30 P.M. The chair will be taken by Dr. F. Montague Smith.

National Children's Home and Orphanage

Dame Janet Campbell, M.D., will open a new wing at the Sanatorium, Harpenden, on Saturday, Sept. 22nd, at 2.45 P.M. Sir Thomas Barlow, M.D., F.R.S., who has just celebrated his eighty-ninth birthday, is to take the chair.

St. George's Hospital

A post-graduate course for old students has been arranged by this hospital, and will be held from midday on Friday, Sept. 28th, till midday on Monday, Oct. 1st. Dr. W. Langdon Brown, regius professor of physic in the University of Cambridge, will deliver the inaugural address and present the prizes in the board room at 3 P.M. on Oct. 1st. The address will be entited "We have Reason to Think," and Sir Humphry Rolleston is to preside. The annual dinner will be held at Claridge's Hotel on Saturday, Sept. 29th, at 7.15 for 7.45 P.M., with Mr. W. Fedde Fedden in the chair.

Fellowship of Medicine and Post-Graduate Medical Association

A lecture-demonstration will be given by Dr. Clark-Kennedy at the Medical Society of London, on Tuesday, Sept. 11th, at 2.30 P.M., and will deal with chronic cough. On Sept. 18th he will lecture on hemiplegia. There will be a "refresher" course in medicine, surgery, and the specialties at the Westminster Hospital, from Sept. 17th to 29th. Other forthcoming courses include diseases of the chest at the Brompton Hospital, and proctology at the Gordon Hospital, both from Sept. 24th to 29th; diseases of children at the Queen's Hospital, Oct. 1st to 13th; dermatology at St. John's Hospital, Oct. 1st to 27th; an evening course on physical medicine at the St. John Clinic and Institute of Physical Medicine, Oct. 1st to 27th; cardiology at the National Heart Hospital, Oct. 8th to 20th; and medicine, surgery, and the specialties at the Metropolitan Hospital, Oct. 8th to 21st.

Kirk Duncanson Research Fellowship

The council of the Royal College of Physicians of Edinburgh will shortly award a whole-time fellowship of £200 per annum to a research worker. A part-time fellowship of £100 a year will also be awarded. Applications should be sent to the secretary of the college, 9, Queen-street, Edinburgh, not later than Sept. 15th. Particulars appeared in our advertisement columns last week.

Instruction in Contraceptive Methods

A lecture on the Theory and Practice of Contraception will be given to medical students and practitioners by Dr. Gladys Cox on Friday, Sept. 14th, at 6 P.M., at the Walworth Women's Welfare Centre, 153A, East-street, S.E.17. Practical demonstrations will be given on Fridays, Sept. 21st and 28th, at 6 P.M. and 7 P.M. These courses are given under the auspices of the Society for the Provision of Birth Control Clinics; they are open to students who have completed their gynæcological course and to medical practitioners, and to cover expenses a fee of 5s. is charged. Tickets for the lectures are to be applied for in advance, and those wishing to attend are asked to indicate as soon as possible the day and time they propose to attend.

A number of lectures on the theory and practice of contraception will also be given this autumn at the North Kensington Women's Welfare Centre, 12, Telford-road, London, W.10. The first lecture for post-graduates will be given by Dr. Cecile Booysen on Friday, Sept. 14th, at 5 P.M., and the first lecture for medical students by Dr. Helena Wright on Monday, Sept. 24th, at 5.30 P.M. Dates of demonstrations will be arranged at the lectures, and a fee of 5s. will be charged. Particulars of later lectures and other information may be had from the secretary of the clinic.

NOTES, COMMENTS, AND ABSTRACTS

OLD AGE*

By Horace C. Colman, M.D.

No satisfactory definition of old age has been produced. Whatever our age may be, we feel that old age is many years ahead; but for a working formula nothing is better than the Psalmist's three score years and ten. The patients I am thinking of are mostly those who have passed that milestone and yet show no signs of incapacitating disease. Even in these days of wandering after false gods or from consultant to consultant, there are still whole families whom we may regard as patients, our patients, well or ill. These old patients form no inconsiderable proportion of our visiting list, for among them are many who, though not obviously ill, like a regular visit from their family doctor; and that is a cause for thankfulness in every way.

You will agree with me that visits to old patients are often those you look forward to enjoying, and that from them you have learned a great deal not only medical, but of life in general. These people do not expect miracles, and most of them are very grateful for anything you do for them. All this applies to some in the humblest circumstances as much as to the better-off.

In my young days I learned something very valuable from a dear old lady. It was thought well that I should be introduced to her when she was not really ill. At the end of our consultation she said, "Well, I think you are quite a nice young doctor, but how times have changed! When I was younger, my doctor always felt my pulse and looked at my tongue." When we start practice fresh from hospital and a surfeit of acute illness we may very likely feel that old people and their ailments do not matter much; we may think that very little can be done for them, and that very little can be learned from them. It is well if we discover our error early.

One old lady once said to me, "You will find that your patients, when they get past 70, do not behave in illness in the way you would expect." Experience has proved this to be true. Do we not often see an old patient successfully go through an illness which by all the rules should have been fatal; or another resist for a long time the attack of some illness that ought rapidly to have proved fatal? On the other hand, some apparently trivial ailment has rapidly ended life, almost before one had realised that the patient was ill.

Patience and Prophecies

What can we learn from our old patients? Not all of them are dear old things. Some are very much the reverse, and from them we have to learn patience while they recite their tale of woe and their list of grievances. I have a vivid recollection of one old man who had been extremely successful in business, and who had everything that would make his declining years comfortable and happy. Yet he could find no pleasure in anything but reciting his woes, and seemed possessed by a grievance against Providence that such a man as he should be allowed to grow old. He kept a diary. I had to listen weekly to the details of his functions for the previous seven days, the amount of sleep, the exact hour at which he waked, and the biscuit he ate on waking, &c. Nothing would persuade him to take a favourable view of anything. One could only endure with patience and be thankful that one only visited him and did not dwell with him. A visit could not be terminated in less than 30–40 minutes, and one left feeling that at least that fee was earned.

One can learn also never to prophesy too confidently about the future, and to remember that mistakes in treatment are more easily forgiven than mistakes in prognosis. I had long promised an old man that, should he ask me if he were going to die, I would give a truthful answer. The test came when he was nearly 90 and ill with pneumonia, with a high temperature, respirations of 48, and pulse 140. To his question I replied that I did not think that he could possibly live 48 hours. The prospect pleased him so well that he improved from that hour, and he lived another four years. One can learn never to give up hope.

A question that is sometimes asked is whether we are ever justified in depriving a patient of hope. My own view is very seldom, unless it is obvious that adjustment of his affairs may save great distress to those who are left behind. But when we do feel justified in buoying up our patient's hopes, we should take some near relative into our confidence.

Even the most desperate cases recover sometimes. One old woman always protested when her daughter sent for me that it was nonsense sending for me as she was a done old hulk, and ought to be allowed to die. When sent for when she was 88 I found her with a complete obstruction. I told the daughter that an operation might save her life, and in any case would make her end easier. I said I thought she should have the chance, though I felt sure she would not take it. The daughter agreed with me, and was sure she would not take her chance. The old lady was lying in an old-fashioned box bed and was very deaf. There was nothing for it but to climb into the bed and practically to lie down beside her and bellow into her ear. Like a shot she replied, "Well, if you think so, you had better get it done at once." The daughter collapsed into a chair behind me, but I am glad to say the old lady spent 11 days in hospital and returned home to enjoy a year of complete comfort before influenza quietly removed her.

One can learn also to admire and respect an indomitable spirit rising supreme above poverty and real hard work.

An old woman had known poverty so extreme that she and her brothers and sisters gathered wool from the hedges for her mother to spin, and gleaned in the cornfields and kept the straw for their mother to make hats for them, married a widower who developed locomotor ataxia and went blind. She nursed that man, led him about, and in his old age catheterised him for seven years, kept pigs and hens, and took in washing, and for many years never had more than three consecutive hours' sleep in bed. To the end, which came when she was 87, she kept up a cheerful outlook on life that made friends for her all round, and I am glad to remember that she had a few years of peace and quiet after she buried that unfortunate husband.

Management of Old Age

Now let us turn to what we can do for our old patients. We can do a great deal, both in the way of helping them to keep well, and when obviously in their last illness by making their remaining life tolerable.

To illustrate my last point I may refer to an old woman who came into my hands lately. I found an emaciated patient with a very sore mouth, diarrhœa, a foul discharge, and ulcerated skin, altogether in utter misery. Examination showed a large rectal cancer and a recto-vaginal fistula. Douching and an ointment at one end and a simple treatment of the mouth, together with opium, to which I shall refer later, converted a miserable, querulous woman to a placid contented invalid, who died peacefully and without distress. Incidentally she developed a painless gangrene of a toe, and I have discovered that the two affections are often associated.

Old people, when they are feeling in good form, like to kick over the traces occasionally, and often the best thing we can do for them is to protect them from too fussy relatives. Even if they get thoroughly

ADDRESSES AND ORIGINAL ARTICLES

ARTERIAL HYPERTENSION *

BY O. L. V. DE WESSELOW, D.M. Oxon.,
F.R.C.P. Lond.

DIRECTOR OF THE CLINICAL MEDICAL UNIT AT ST. THOMAS'S HOSPITAL; PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LONDON

AT the moment the question of the origin of the hypertensive states is the subject of keen controversy and of extensive research. There is an increasing tendency to limit the part played by the kidney in the production of a raised arterial pressure and even to deny that any form of hypertension is of renal origin: the possibility of an endocrine factor has assumed an increased importance with the recognition of the development of permanent hypertension in association with certain disorders of the ductless glands; with the advance of our knowledge of the chemical control of the circulation, there has been much search for possible pressor substances in the blood of the hypertensive patient; lastly hypertension has been experimentally produced in animals by the destruction of a reflex arc. The origin of the hypertensive states is, therefore, to-day a very living problem, and it is for this reason that I have ventured to review certain limited aspects of the question, fully realising that my review even of this limited field must be relatively superficial and incomplete.

The principal types of hypertension with which we meet are the hypertension of acute glomerulonephritis, the closely similar hypertension of the toxæmias of pregnancy, and essential hypertension, with its termination in malignant hypertension, essential hypertension being the commonest of all forms of raised blood pressure and its results the most disastrous. The term "essential" hypertension is in itself unsatisfactory, since it cloaks ignorance in apparent precision and leads to a unitary conception of a group of patients whose most prominent symptom, a raised blood pressure, has not yet been shown to be due to a single cause.

It is, perhaps, unfortunate that in all these forms of raised blood pressure albumin may appear in the urine, and that as a result of this, attention has from the first been focused on the kidney as a possible cause of the rise in the arterial pressure. What, then, is the present position of this renal theory of hypertension?

Compensatory Hypertension in Renal Disease

The earlier theories, which assumed that an increased resistance to the circulation of the blood through the vessels of the diseased kidney produced purely mechanically a rise in the general arterial pressure, we may regard as disproved; the vascular area occluded is too small and the interplay of the various vascular areas of the body too efficient to lead to any such result. Present-day advocates of a renal theory of hypertension would argue that defective renal function or a diminished circulation through the kidney in some way, possibly through the mediation of the nervous system, leads to a compensatory rise of general blood pressure which enhances the efficiency of the residual renal tissue.

As Verney[1] puts it "it would not be surprising to find that when this second reserve of the kidney was exhausted, and all the renal elements were receiving the maximum stimulus which under the circumstances could be given them, and yet were unable to cope with the work thrust upon them, there should be a call for external aid in the form of a rise of general blood pressure:" that is, when all the functioning glomeruli are in continuous activity, and when possibly by a shift of resistance from the vas afferens to the vas efferens the glomerular pressure has been increased to a level approximating that of the general arterial pressure, the only further compensating mechanism which can be called into play is a rise in the general arterial pressure itself. This rise will for a time compensate for the diminution in active renal units, but ultimately a further diminution in these units will upset the balance and death will then ensue. Such are Verney's conclusions from the study of the isolated kidney.

The possible mechanisms by which the compensatory rise in the general pressure might be evoked are three in number—firstly by means of some substance in the blood stream acting directly on the vessels and producing generalised vasoconstriction; secondly by some substance acting on the vasomotor centre, just as the respiratory centre is acted upon by an increase in the hydrogen-ion concentration of the blood; or lastly by afferent nervous stimuli to the centre.

That a rise in the general arterial pressure would be a valuable compensatory mechanism in advanced renal disease we may accept as probable; it remains to be determined whether such a method of compensation is actually brought into play to combat renal functional failure and, if this is the case, to what extent the various forms of hypertension are the result of primary renal damage. The fact that a mechanism of this nature would be of value is not a proof that it exists. It is of some interest to us that as long ago as 1881 Mahomed,[2] a member of this college, anticipated modern criticism of the renal theory of hypertension by suggesting that the renal lesion was not primary but secondary to the vascular changes.

His remarks on the condition which we now call essential hypertension, but which in his day was described as Bright's disease with red granular kidney, will bear repetition. "In the earlier stages the urine of what is known as chronic Bright's disease with red granular kidney is most commonly perfectly normal. Either chronic Bright's disease is not a renal disease, though it frequently gives rise to a renal affection, or else another disease must be recognised which constantly precedes and prepares the way for Bright's disease, and which may be called arterio-capillary fibrosis or any other name that may be proffered for it."

He was convinced that the changes in this type of Bright's disease were essentially vascular. More remarkable still, *considering the very inadequate means of investigation* then available, is the fact that he believed that in scarlatinal nephritis hypertension preceded the renal lesion. "In scarlatina," he says, "high pressure is recognisable in the pulse before, and experience has shown long before, any sign of failure or albumen appears in the urine."

To Mahomed belongs the credit of first suggesting that in essential hypertension the vascular lesion is primary, and that the same sequence of events occurs also in acute nephritis. The first of these suggestions had been generally accepted by the beginning of this century, but recent work has greatly strengthened the grounds on which it was based; the second remains in dispute.

* The first Croonian lecture for 1934, delivered before the Royal College of Physicians of London on June 5th. Lectures II. and III. will appear in forthcoming issues.

Renal Changes in Essential Hypertension

It is unnecessary to discuss at any length the part played by the kidney in essential hypertension. The older investigators, basing their conclusions on the absence of albumin and casts from the urine of early cases, had already recognised that the renal lesion, when it occurred, was secondary. With the development of improved methods of investigating renal functional efficiency it has become increasingly evident that in the earlier stages of essential hypertension the function of the kidney is intact, and that it may remain unimpaired until death takes place from some extrarenal cause. Using such simple methods as the determination of the specific gravity of the urine under test conditions, or the urea-concentration test, the efficiency of the kidney is found to be unaffected, nor is there necessarily any accumulation of nitrogenous waste products in the blood of these patients. The more elaborate methods of examination, which are directed to determining the *amount* of functioning renal tissue, such as the urea-clearance test, or the Rehberg method of calculating the glomerular filtration rate by means of creatinine excretion, point to the same conclusion.

In a recent study by Weiss and Ellis[3] it was found that of 17 hypertensive patients 13 showed a urea clearance approximating to the normal. Though it might be argued that in the apparently normal cases the kidneys were in fact damaged, but showed a satisfactory clearance of urea owing to the presence of a compensatory rise of blood pressure, this was not actually the case. The authors were able to lower the blood pressure very considerably by means of sodium nitrite, and at the low pressure thus produced the clearance was in many cases as complete as it had been at the high. It follows that the renal function may be entirely intact in essential hypertension, and that the normal results obtained in functional testing are not merely the result of complete compensation for an impaired renal efficiency by a rise in the general arterial blood pressure.

Without going into further details we may, I think, regard it as proved that essential hypertension may exist in individuals whose renal function is completely unaffected. Clinically support is found for such a view in the predominance of cardiac failure and cerebral vascular accidents as causes of death in these patients, and in the relative infrequency of death from uræmia; in chronic glomerulo-nephritis, on the other hand, a disease in which the renal lesion has been present from the onset, the termination is almost invariably uræmia. Pathologically there is good evidence that even in long-standing cases of hypertension the renal vessels may sometimes be entirely normal, or may show no more definite degenerative changes than in individuals of the same age with normal blood pressures, and that the glomeruli and tubules may be completely unaffected. Modern nomenclature recognises the purely secondary nature of the renal changes in these patients by employing the term "ischæmic nephritis," and the term is justified by the fact that similar renal lesions are found in patients suffering from forms of hypertension in which there can be no question of a primary renal origin.

The Blood Pressure *in Acute Nephritis*

While in essential hypertension there seems to be every indication that the renal lesion is secondary to the vascular, in acute glomerulo-nephritis we have the classical example of the sudden development of hypertension in association with symptoms of renal damage. Volhard,[4] indeed, in his account of the disease, describes the rise of blood pressure as *the* pathognomonic symptom of diffuse glomerulo-nephritis. No one who had the opportunity of observing cases of "trench nephritis" during the war can fail to have been impressed by the close relationship of the raised blood pressure to the acute stage of the disease, and the rapid fall of pressure that occurred with the onset of diuresis and the subsidence of the œdema. Of 62 patients in whom I had the opportunity of making daily blood pressure observations, in 58 there was a close correspondence between the termination of the period of raised blood pressure and the disappearance of the dropsy as determined by weighing. A similar connexion between hypertension and œdema is found in the eclamptic toxæmia of the pregnant woman, a condition which presents a close similarity to acute glomerulo-nephritis. At first sight, then, these acute renal lesions would appear to offer a convincing proof of the connexion between renal damage and a rise in the arterial blood pressure.

If, however, we go further and examine the onset of the disease and the subsequent course of these cases we find that there is considerable cause for doubt. Unfortunately the sufferer from acute nephritis rarely comes under observation during the interval between the acute infection which almost invariably precedes the renal lesion and the development of the more obvious symptoms of the disease, such as œdema. The exception is the scarlatinal patient, and nephritis is at the present time a relatively infrequent complication of scarlet fever. We are dependent, therefore, for information as to the exact sequence of events at the onset of the disease on the fever hospitals and such chance cases as may come under our observation in the general wards.

As we have seen, Mahomed believed that hypertension in scarlatinal nephritis preceded the renal symptoms, but his observations, based on palpation of the radial artery and on sphygmographic tracings, cannot be regarded as in any sense conclusive. They have, however, been recently confirmed.

Koch,[5] following the blood pressure in cases of scarlet fever and making three observations daily, found that in almost all uncomplicated cases a rise of pressure occurred between the fourteenth and twentieth days. The rise of pressure was of variable duration, lasting in some cases only for 24 hours, and during the period of hypertension albumin and more rarely casts might appear in the urine, often only in a single sample. In some cases the hypertension might occur without any albumin in the urine, but albuminuria never appeared unless the blood pressure was raised.

Observations from the Stockholm Fever Hospital[6] have confirmed his finding that the rise in blood pressure precedes the appearance of albuminuria, though it is fair to mention that Steiner,[7] whose paper is only available to me in an abstract, while admitting the rise of pressure noted by Koch in the third week of scarlet fever, finds that when nephritis occurs as a complication of the disease the urinary changes precede the rise of blood pressure.

It is probable that in many cases of the common type of acute nephritis which follows infections other than scarlet fever, cardiovascular symptoms and œdema precede the appearance of albuminuria. Such patients are rarely seen until the disease is well established, and any primary rise of blood pressure is almost certain to be missed. Enough isolated observations are, however, on record to warrant the belief that in this type of nephritis also a rise in arterial pressure may precede the other symptoms of the disease.

Kylin,[8] for instance, taking daily blood-pressure measurements in patients recovering from acute tonsillitis, had the good fortune to meet with three cases complicated by acute nephritis; in all three the disease was of a mild type, but a rise of blood pressure of about 25 mm. Hg preceded the appearance of albuminuria and cylindruria. This hypertensive, pre-albuminuric stage of the nephritis lasted for three to four days.

Wickbom[9] records a case in which the systolic blood pressure reached a level of 160 mm. Hg with generalised œdema, headache, vomiting, and oliguria, but in which no albumin appeared in the urine, though red blood-cells were found on several occasions.

Nonnenbruch,[10] studying trench nephritis during the war, found that a rise in blood pressure without albuminuria is rare, but that such cases may occur, and that the systolic pressure may reach a level of 160 mm. Hg without renal symptoms. He also observed a group of patients in whom well-marked hypertension and moderate œdema were present, but in whom albumin appeared in the urine only on a single day, or even in a single sample.

I have recently had under observation an interesting case of this type.

The patient, a male of 26 years, had suffered from a sore-throat followed by a quinsy which had kept him from work for 14 days. Three days after resuming work general œdema developed, with slight dyspnœa on exertion; he was admitted to hospital on the third day of the disease, 17 days after the onset of the tonsillitis. He then showed slight generalised œdema, a blood pressure of 170/100, and moderate bradycardia, the pulse-rate at times falling to 56. In the course of 7 days the blood pressure gradually fell to 126/70, the œdema disappearing with a well-marked diuresis, which in one period of 24 hours amounted to 3800 c.cm.; the urine examined daily showed throughout no trace of protein to the salicyl-sulphonic test, nor were casts ever found in the centrifuged sediment. The blood-urea on the day following his admission was 39 mg. per 100 c.cm., and the urea-concentration and clearance tests were within normal limits, immediately after the termination of the hypertensive period.

The preliminary infection, the symptoms, and the course of the disease were in every way typical of acute nephritis, but the renal findings were entirely negative. Just as we meet with cases of eclampsia sine albuminuria, so we may also occasionally encounter cases of the condition which we call "acute nephritis," who show no urinary changes.

PRE-ECLAMPTIC TOXÆMIA

In addition to such fortuitous observations as I have detailed, it is permissible to turn to the routine blood-pressure determinations of the antenatal clinics for information as to the probable sequence of events. The renal aspects of the pre-eclamptic toxæmia of pregnancy and of eclampsia itself bear such a close resemblance to those of acute glomerulo-nephritis that conclusions drawn from the one condition may reasonably be applied to the other. The antenatal clinic has the unique opportunity of being able to keep its patients under observation for long periods even though no pathological condition is present.

That eclampsia may occur without albuminuria has long been known,[11] and most physicians with experience of the toxæmias of pregnancy have met with cases of pre-eclamptic toxæmia in which the rise of blood pressure and œdema have preceded the appearance of the urinary changes. A careful study of the symptoms of pre-eclamptic toxæmia has recently been published by Browne,[12] who paid special attention to the order in which hypertension, albuminuria, and œdema appear. Though his criterion of what constitutes a raised blood pressure in out-patient work is perhaps unduly strict his conclusions are important. He finds that a rise of blood pressure is the earliest sign of a toxæmia in 75 per cent. of his patients, and that œdema may precede the appearance of albumin in the urine or may occur without concomitant albuminuria. Though the data at present available are, owing to the nature of the case, somewhat inadequate, the observations of those interested in the sequence of events at the very onset of nephritis and eclamptic toxæmia are strongly in favour of the occurrence of a rise in the arterial pressure before the appearance of the urinary changes.

NATURE OF THE RENAL LESION IN ACUTE NEPHRITIS

What then is the relationship between the rise of pressure and the renal lesion in nephritis? Any attempt to answer this question entails a short discussion of the existing theories of the disease, theories necessarily based upon pathological and clinical observations in the human subject, since up to the present an acute nephritis resembling that seen in man has not been produced experimentally in animals.

It is generally agreed that the disease follows an infection, after an interval, and that the pathological changes found in the kidney of the patient dying during the early stages of the attack are predominantly vascular. The glomeruli are swollen, and the capillary loops abnormally rich in nuclei, partly owing to endothelial proliferation, partly to leucocytic infiltration. The capillaries of the glomerular tuft contain few or no red blood-cells: their lumen may be dilated, but is packed with proliferated endothelial cells.[13 14] The changes in the eclamptic kidney, as described by Baird and Dunn,[15] are closely similar: the capillaries are empty of red cells and occluded by endothelial proliferation; leucocytic reaction is absent.

Volhard, who has had the opportunity of examining many samples of renal tissue obtained during decapsulation of the kidney in the acute stage of the disease, finds that the vasa afferentia of the glomeruli are patent and contain no blood, that the interlobular arteries contain hyaline thrombi with few red cells, while the large arteries are still full of blood. He insists that the failure of circulation through the loops is not caused by endothelial proliferation, since the lumen of the capillary may be patent but empty; the ischæmia of the loops is to be attributed to arterial constriction above the level of the vas afferens, and results from functional spasm and not from any actual mechanical obstruction. The glomerular changes are produced by the ischæmia.

He finds that, using suspensions of red blood corpuscles or Indian ink, and an injection pressure less than the systolic pressure observed before death, it is possible to inject all the glomeruli of a nephritic kidney, which previously were empty of blood, and concludes that the bloodlessness of the glomerular capillaries is not due to blocking of their lumen by an endothelial proliferation but to a vascular spasm. Hayman,[16] who perfused kidneys with Ringer's solution or gum acacia at varying pressure, found a marked reduction in the perfusate per gramme of tissue per minute in two cases of acute glomerulo-nephritis as compared with the normal kidney. He gives no data as to length of time which had elapsed from the onset of the disease, and it is arguable that, even though the initial absence of blood from the capillary is purely the result of spasm of the vasa afferentia, endothelial proliferation may at a later stage produce some degree of mechanical obstruction to the blood flow through the organ.

That vascular spasm, even of relatively short duration and in no way limited to the renal vessels, may lead to serious damage to the glomeruli is well shown by the case of the pharmacologist Bornstein, who administered to himself intravenously the large dose of a milligramme of adrenaline. After a period of collapse red cells, granular casts, and a large amount of albumin appeared in the urine, and a residual albuminuria persisted for some weeks.

Volhard originally assumed that a generalised vascular spasm occurred, due to unknown but entirely extrarenal causes; in this the renal vessels participated and glomerular ischæmia resulted. In some unknown manner the general vasoconstriction was to be attributed to the initial infection. Since his collaborator Bohn has claimed to have demonstrated pressor bodies in the blood of patients suffering from acute nephritis, bodies which on other grounds he believes to be derived from disintegrating renal tissue, Volhard has changed his point of view, but it will be simpler to consider his present position in connexion with the question of pressor substances in the blood of hypertensives.

A more obvious explanation of the absence of blood from the glomerular capillaries and of the changes in the appearance of the tufts is that the blood flow is obstructed mechanically by changes in the capillary walls.

> Fahr,[17] who maintains that the hypertension of acute nephritis is renal in origin, believes that the essential lesion of the disease is a capillaritis of the vessels of the glomerular tuft, which may extend into the vas afferens. Any circulatory toxin of a colloidal nature would presumably become concentrated in its passage through the tuft and would exercise its injurious effect upon the delicate vessels of the glomerulus. He believes that the changes in the glomerular capillaries are of an inflammatory nature rather than the result of ischæmia due to spasm of the afferent arterioles, and that the ultimate bloodlessness of the glomeruli is the result of obstruction to the blood stream due to endothelial proliferation, and develops hand-in-hand with that proliferation. The absence of blood from some segments of the vas afferens is due to the same cause, while the apparent patency of the lumen of glomerular capillaries, from which blood-cells are absent, is an artefact due to shrinking of the endothelium during the process of fixation. The microscopic findings in certain cases of acute nephritis which have terminated at a very early stage of the disease are believed to afford support for this view.
>
> Hückel,[18] who examined the kidneys of a patient dying within 30 hours of the onset, found the glomeruli in general well filled with blood; where they were poorly filled endothelial proliferation and narrowing of the lumen were present; the capillaries were never empty yet open, as described by Volhard. It must be admitted that the diagnosis of this much quoted case is doubtful; the kidney changes were minimal, though albumin and casts were present in the urine, the non-protein nitrogen of the blood was not appreciably raised and, though convulsions had occurred, the systolic blood pressure was only 110 mm. Hg.
>
> Dietrich,[19] during the war, obtained specimens from cases of presumed nephritis which had died suddenly very shortly after the onset of the disease: the glomeruli tended to be bloodless, but individual loops of the glomerular capillaries varied in the amount of blood which they contained; in the empty loops the lumen was apparently obliterated by endothelial proliferation, and definite leucocytic infiltration of the tufts was present. If spasm of the vas afferens is the cause of the absence of blood from the glomerular capillaries, all the capillary loops should be equally affected, and not isolated segments, as found by Dietrich.

The interpretation of the post-mortem appearances in the kidney of acute glomerulo-nephritis is obviously difficult, and it is highly doubtful whether studies of this nature will lead to conclusions which will command general assent. The essential problem is the cause of the absence of blood from the capillary loops. A generalised arterial constriction must be present to account for the raised blood pressure; the observed narrowing of the retinal arteries in severe cases, and possibly the pallor of the skin, may be taken as evidence of such a generalised spasm. The disputed point is the relationship of the vascular constriction, with the resulting rise of blood pressure, to the renal lesion. Is the arterial spasm secondary to glomerular damage and compensatory in nature, or are the glomerular changes themselves secondary and the result of ischæmia? In default of any agreement as to the significance of the pathological findings, the answer to this question must come from clinical observation of the course of the disease and from experimental work.

If hypertension does in fact precede the albuminuria it would seem that a capillaritis of the glomerular loops can hardly be accepted as the primary lesion in acute nephritis. The delicacy of the glomerular epithelium is such that its permeability to protein seems to be very readily affected; exercise, exposure to cold, venous congestion, fever, and many other causes all lead to such changes in the glomerulus as to permit albumin to pass into the urine. It is difficult to believe that the first symptom of a disease consisting essentially of a lesion of the glomerular capillaries would be other than albuminuria. Hypertension, if secondary to the renal lesion, should appear after the albuminuria, or at most simultaneously with it, but should certainly not precede the urinary change. The available data suggest, however, that the blood pressure may rise before albuminuria appears. Again, if we assume that the rise of pressure is secondary to the renal damage, and compensatory, it is difficult to see by what mechanism it is evoked. In the type of renal lesion in which there would seem to be good reason to suspect that the hypertension is secondary, gross accumulations of the nitrogenous waste products are present in the blood. In acute nephritis such accumulations are by no means the rule, and in the hypertension of eclamptic toxæmia are almost always absent. The other possibility that occlusion of the renal vessels produces by some reflex mechanism a compensatory rise in the general arterial pressure may be discounted. Occlusion of a relatively small vascular area does not of itself produce hypertension, nor does the complete occlusion of the renal circulation in bilateral cortical necrosis lead to a raised arterial tension. Eppinger[26] in animal experiments has given an apparently decisive demonstration of the effects of occlusion of the glomerular circulation upon the cardiovascular system.

> He shows that in the kidney damaged by cantharides or sublimate there is almost complete obstruction to the flow of blood through the capillaries of the glomeruli: it is no longer possible, as in the normal kidney, to inject the glomeruli by means of Indian ink introduced into the left auricle. Measuring the blood flow through the renal and mesenteric veins, he finds that the flow through the damaged kidneys falls to about one-seventh of the normal, while the flow from the mesenteric vein increases by a proportionate amount. A local shunt of the blood stream occurs and the arterial blood pressure in the brachial shows no appreciable rise. Albumin, red cells, and numerous glomerular casts appear in the urine.

In these experiments we have a condition approximating to the obstruction of the glomerular circulation which is assumed by Fahr to result from glomerular capillaritis in acute nephritis, but no compensatory rise in general blood pressure is evoked.

A UNIVERSAL CAPILLARY LESION ?

While Fahr suggests that the lesion in acute glomerulo-nephritis primarily affects the capillaries of the renal glomeruli, Kylin believes that the capillary lesion is not limited to the kidneys, but involves all the capillaries of the body. The generalised lesion is assumed to be responsible for the subcutaneous œdema; in the glomerular capillaries it leads to the appearance of albumin in the urine; further, it evokes a spasm of the arterioles with a resulting rise of blood pressure. The œdema, albuminuria, and hypertension of eclamptic toxæmia are the result of a lesion of similar type, though produced by a different toxin. The attraction of this theory of a universal capillary lesion is the explanation which it appears to offer of the œdema of acute nephritis, and the linking-up of the subcutaneous œdema with the albuminuria, as the expression of a generalised increase in capillary permeability.

The grounds on which Kylin bases his theory are the alleged rise of capillary pressure in acute nephritis, the high albumin content of the subcutaneous œdema fluid, and the microscopic appearance of the skin capillaries. He compares the action of the hypothetical toxin to that of histamine, and suggests that like histamine it may produce in weak concentration a capillary dilatation with increased permeability, in stronger concentration an arteriole constriction with associated hypertension. The comparison is somewhat unfortunate, since it has been pointed out that, while in rodents arteriole constriction may be the predominant effect, in the human being both arterioles and capillaries dilate, and it is well known that in man histamine produces a fall of blood pressure.

With a generalised increase of capillary permeability, concentration of the blood may be expected to occur, the loss of plasma volume in histamine shock sometimes amounting to as much as 40 per cent., with a corresponding increase in the hæmoglobin value. No similar concentration of the blood has been shown to occur in acute glomerulo-nephritis. Nonnenbruch,[21] it is true, reported a high red cell count in certain cases of trench nephritis, but his patients appear to have been in the nephrotic rather than the acute stage of the disease. My own experience of trench nephritis was that the hæmoglobin was invariably low early in the disease, probably owing to the presence of a true anæmia. The use of the more accurate vital red method of estimating the blood and plasma volume indicates that in acute nephritis in civilian life the plasma volume is approximately normal for the patient's non-œdematous weight, the total red cell volume being diminished.[22] In eclampsia and pre-eclampsia, in which Kylin also postulates a generalised capillary lesion, I have found no evidence of any actual concentration of the blood. In 14 cases, most of them at a very early stage of the disease, the average volume of plasma per kilogramme of corrected, non-œdematous weight was 52 c.cm. against 56 in normal, pregnant controls and the corpuscular volume, as determined by hæmatocrit, 37 per cent. Concentration of the blood, such as might be expected to occur with a general increase in capillary permeability, does not therefore appear to be present in these two conditions.

The most convincing proof of an altered capillary permeability would be a high protein content of the fluid exuded into the tissue spaces. It is unfortunately difficult to obtain data as to the actual composition of the œdema fluid in acute nephritis; in contrast to the nephritic, in whom large quantities of œdema fluid may be readily obtained from the subcutaneous tissues, puncture of the skin of the patient suffering from acute glomerulo-nephritis rarely yields enough fluid for analysis. Kylin quotes Beckmann's[23] figures as showing that a high protein percentage is characteristic of the œdema fluid of acute nephritics. This author, studying the œdema fluid in various types of dropsy, found that in nephrosis the protein content is approximately 0·1 per cent., while in acute glomerulo-nephritis the fluid contains from 1·0 to 2·5 per cent. of protein, and in cardiac dropsy about 0·5 per cent. These figures for the protein content of nephritic œdema fluid do not appear to have been confirmed by other workers.

Van Slyke[24] in two cases gives a protein content of 0·1 per cent., and in œdema fluid from a patient of my own, in whom a considerable degree of cardiac failure was present, 0·35 per cent. of protein was found. Kylin[25] himself has recently reported similar values in acute nephritis and in nephritis of pregnancy—values approximating closely to those met with in cardiac dropsy. Both plasma volumes and protein content of the œdema fluid give therefore no clear indication of grossly increased capillary permeability. In acute nephritis we find no such reduction of plasma proteins and of plasma osmotic pressures as occurs in nephrosis, and is believed by some to account for the œdema of that condition. In default of other explanation, it is suggested that the œdema of acute nephritis is cardiovascular in origin. Cardiac embarrassment is certainly a noticeable feature of many cases of acute nephritis, and definite cardiac failure may occur at levels of blood pressure which are tolerated without appreciable discomfort by the essential hypertensive, whose cardiac muscle is given ample time to hypertrophy owing to the slow rate at which the increase in the arterial tension develops. There can be no doubt that, during the process of recovery, the disappearance of the œdema and the fall in blood pressure are closely related.

Kylin also insists that the rise of pressure in the capillaries, as determined by his compression method, is evidence of a capillary lesion. The rise is stated to be present both in the frankly developed nephritis and in the pre-albuminuric stage of the disease, sometimes preceding the appearance of albumin in the urine by a week. Mufson,[26] by a similar method, has also found high capillary pressure in acute nephritis and in certain cases of pre-eclamptic toxæmia, the rise in his patients being closely associated with the presence of œdema. The mechanism of this rise, despite the presence of the arteriole constriction which the capillary lesion is assumed to evoke, is obscure. The compression method of determining capillary pressure is by no means universally accepted, and it is possible that the apparent rise of pressure in acute nephritis is merely the result of changes in the elasticity of the skin, which are known to be present in this disease, and may even precede the appearance of clinical œdema. As to the constancy of morphological changes in the skin capillaries, as demonstrated by the capillary microscope, there is at present no agreement.

Though the hypothesis of a generalised capillary lesion offers a tempting explanation of the œdema of acute nephritis, and correlates the subcutaneous œdema with the urinary findings, it would seem that definite evidence of the presence of such a lesion is still to seek. There is also no proof that the lesion of the capillaries would, as suggested by Kylin, lead to arteriole constriction and the rise of blood pressure which is the phenomenon of the disease with which we are especially concerned. If the albuminuria is to be taken as the index of the time at which the capillary lesion makes its appearance, on this theory again albumin should appear in the urine coincidently with or before the rise in blood pressure, but Kylin himself does not claim that this is the case.

Inadequate as is the available evidence, it would seem that the existing data suggest that in acute nephritis the rise in blood pressure precedes the renal damage, and that the generalised vasoconstriction is more probably a factor in the production of the glomerular lesion than a consequence of that lesion. The very fact that all attempts at experimental production of the disease by injection of bacterial toxins have up to the present failed, is against the belief that in acute nephritis we are dealing with a primary toxic capillaritis of the glomeruli, and that a lesion of this type is responsible for the other features of the disease, including the hypertension. It is undoubted that in man the infection precedes the appearance of acute nephritis, but some other factor than toxins derived from the infective focus must apparently be invoked if the typical glomerular lesion is to be produced. It is possible that this factor is glomerular ischæmia produced by arterial spasm of unknown origin.

The Blood Pressure in Persistent Nephritis

In its later stages the course of acute glomerulonephritis shows the same lack of correlation between the renal lesion and the level of the blood pressure which we find at the onset. At the termination of the acute stage the fall of pressure is often abrupt; I have seen a pressure of 180/100 fall to 98/60 in 72 hours. The ultimate level of the blood pressure is often for a time abnormally low. There is, however, no evidence that this rapid fall of blood pressure is accompanied by an equally rapid resolution of the renal lesion. As is well known, albuminuria and microscopic, if not macroscopic, hæmaturia may persist for months after the termination of the hypertensive period, even though eventually complete recovery occurs. The restoration of full renal function is also slow and gradual. The concentrating power of the kidney, as estimated by the urea-concentration test, is still impaired at a time when the blood pressure has returned to a normal level; the urea-clearance test shows a similar lag. Holton,[27] using the creatinine-clearance test, and the concentration test of Volhard, notes this slow recovery of efficiency, and finds that the blood pressure has fallen to a normal level long before the renal function is completely restored. Such findings are not easily explained on the assumption that the hypertension is compensatory for, and secondary to, a damaged renal efficiency.

The course of the blood pressure in those cases in which complete recovery does not occur and which, often after many years, terminate in uræmia is also of interest.

During the so-called second stage of chronic glomerulonephritis, before renal inadequacy has developed, the blood pressure may remain at a normal level though the lesion is active and progressive. In Volhard's series of 342 cases in the second stage of the disease, 159 showed blood pressures below 140 mm. Hg. This absence of hypertension is especially noticeable in some of those patients who pass through a period during which the symptoms are suggestive of nephrosis, heavy albuminuria, and extreme œdema, without nitrogenous retention. In such cases no evidence of cardiovascular change need be present, and in default of a history of acute nephritis the diagnosis from true nephrosis may be impossible. Later, with development of the third stage of renal inadequacy, the œdema may clear, the quantity of albumin passed in the urine may diminish, and the blood pressure rise. Hypertension is, indeed, an almost invariable feature of the third stage of the disease, the stage characterised by a grossly defective renal function. For this particular period of hypertension we may, in default of any other explanation, assume a renal origin; it is the stage of chronic glomerulo-nephritis in which the number of functioning glomeruli is enormously diminished, and in which the failure of function makes itself evident by the accumulation of waste products in the blood. In such circumstances an increase in the filtration pressure is the only mechanism which will compensate for the diminished filtering surface, though we have as yet no knowledge of the method by which the compensatory hypertension is evoked.

We have, then, in the course of glomerulo-nephritis, two periods of hypertension which may be separated by an interval during which the blood pressure is within normal limits. The hypertension of the acute stage is probably not of renal origin; its cause is at present unknown. The hypertension of the later stages is associated with evidence of functional failure of the kidney, and may be regarded as compensatory and as the result of the renal lesion.

The most convincing evidence that such compensatory hypertension may occur is to be found in the raised blood pressure of polycystic disease of the kidney. Though doubt has been cast upon the existence of hypertension in this disease, a rise of blood pressure is certainly present in the majority of the patients during the later stages.

In a small series of 14 cases which I have collected, eight patients showed definite hypertension during life, and in three others hypertrophy of the left ventricle was present post mortem; two cases were only seen in an advanced stage of uræmia, and at that time showed a normal blood pressure, possibly as a result of cardiac exhaustion: in these two patients no post-mortem was obtained. In one case only, a male of 32 years, the blood pressure was normal at a time when the patient was in vigorous health and showed no evidence of renal inadequacy. In the hypertensive cases there appeared to be a rough correlation between the degree of renal inadequacy, as estimated by functional tests, and the height of the blood pressure.

Fahr,[28] who has always insisted on the frequency of a raised blood pressure in this disease, found that in a series of seven cases six presented clinical or post-mortem evidence of hypertension, the most remarkable being a child who died at the age of 5 years from polycystic disease and who showed definite concentric hypertrophy of the left ventricle. Of 74 fatal cases of polycystic disease of the kidney, collected from the records of the Mayo Clinic,[29] 75 per cent. had shown a systolic pressure during life exceeding 145 mm. Hg, while in a control group of 74 patients of similar age and sex suffering from bilateral pyelonephritis only 25 per cent. showed a pressure above this level.

In face of such figures it is impossible to deny that there is a close association between polycystic disease of the kidneys and a raised arterial pressure, an association far too frequently present to be accidental. Of all types of renal disease in which hypertension occurs, it is possibly the condition in which there is most reason to suppose that the rise in blood pressure is secondary and compensatory, since there can be no question that the renal lesion is primary and not the result of any vascular change. In certain other types of renal lesion, however, in which a high degree of glomerular destruction with corresponding renal inadequacy and nitrogenous retention is present, it must be admitted that hypertension is not found. Of such conditions, amyloid disease of the kidney is an example; in the amyloid kidney individual capillary loops of the glomerular tufts may remain patent even in an advanced stage of the disease, but the glomeruli as a whole are severely damaged and a high grade nitrogenous retention is observed. In spite of this the blood pressure is very seldom raised,[30 31] and if a compensatory hypertension is actually evoked by renal inadequacy we must assume that in amyloid disease it is absent owing to the general cachexia; the necessary stimulus is present but the cardiovascular system of the patient is unable to respond.

Experimental Renal Damage

Direct attacks upon the problem of renal hypertension have naturally been made by way of animal experiments. It is impossible to deal with this work in any detail, but it may be pointed out that the difficulties met with are very considerable. In the first place, a chronic experimental nephritis such as is seen in man has not yet been reproduced in animals; secondly, the frequent determination of an animal's blood pressure over considerable periods of time is not an easy problem; lastly, if too much renal tissue is destroyed or removed the animals rapidly become cachectic and die.

The first experimenters to claim to have produced renal hypertension in animals were Pässler and Heinecke,[32] who, after removing three-quarters of the total renal tissue, took away further small portions of the residual kidney substance as hypertrophy developed. The majority of their animals, which survived without developing cachexia, showed hypertrophy of the left ventricle and a small rise in the systolic pressure.

Besides ablation of renal tissue other methods have been used to damage the kidney, such as ligature and embolism of the renal arteries or exposure to radiation.[33] The results obtained have been conflicting. In rabbits surviving for considerable periods with nitrogenous retention as the result of partial ablation of the kidneys, no rise occurred in arterial blood pressure as measured by compression of the main artery of the ear[34]; on the other hand, both in dogs and in rats hypertrophy of the left ventricle and hypertension have been found to follow ablation of one kidney and partial ligature of the arterial supply of the other.[35 36]

Hypertension, when produced, does not appear to have been necessarily dependent on the presence of necrotic renal tissue in the body, since it is claimed to have occurred in ablation experiments, and also to have been present in experiments in which the renal arteries had been ligatured at a time when the necrotic tissue had been completely absorbed. Probably the balance of evidence derived from such experiments, though difficult to evaluate, is in favour of the production of hypertension as the result of renal damage, and more weight may be assigned to the positive than to the purely negative experiments. The results are not, however, so clear-cut as to justify of themselves an unhesitating acceptance of a nephritic cause for hypertension and have not in any way explained the mechanism by which such hypertension is produced, though they suggest that it is usually associated with gross inadequacy of function and retention of the nitrogenous waste products.

Primary or Secondary

We may, I think, conclude that certain hypertensive states are of renal origin, or rather that no other explanation than the coexistent renal lesion can at present be suggested for the presence of a high blood pressure in certain forms of renal disease. Such hypertension may be regarded as compensatory, and probably serves a useful purpose in to some extent making good the loss of glomerular filtering surface. Seen in association with advanced inadequacy of the renal function and definite azotæmia, it certainly appears to be capable of maintaining equilibrium, since in some conditions of renal damage the accumulation of waste products may be checked and remain stationary over prolonged periods: in such patients the supervention of cardiac failure rapidly leads to increasing accumulation of waste products and to uræmia. The raised blood pressure of the third stage of chronic glomerulo-nephritis and of the polycystic kidney may be explained on these lines, and it is probable that renal hypertension of the compensatory type has been produced as the result of experimental damage to the kidneys in animals. In essential hypertension, in its earlier stages, there can be no question of such a compensatory rise of blood pressure, since a renal defect is non-existent; in the last stages of the disease, in those patients in whom ischæmic nephritis with functional insufficiency develops, a renal factor may, arguing from analogy, play some part in the maintenance of the high blood pressure. Even, however, if we may ascribe some types of hypertension to renal inadequacy, the mechanism of their production remains entirely undetermined. It is natural, since we are accustomed to think of hypertension in terms of a humoral theory, to ascribe the rise of blood pressure to the retention of some pressor body, which should normally be excreted by the kidney; but as yet, though nitrogenous retention and a raised blood pressure are associated in these diseases, no such pressor substance has been satisfactorily identified.

In acute *glomerulo-nephritis* and in eclamptic *toxæmia* we have *two conditions* which resemble each other closely both in their symptoms and in the renal findings. Pathologically both are characterised by a glomerular ischæmia, the glomerular tufts in acute nephritis showing a leucocytic infiltration which is absent in the toxæmia. Though ætiologically distinct, there seems to be every reason to believe that the relationship of the raised blood pressure to the renal lesion is the same in the two diseases: clinically data are accumulating which suggest that the rise of blood pressure is primary and precedes the glomerular lesion. From the functional standpoint, if we may take the extent to which waste products accumulate in the blood as an index of the degree of renal insufficiency present, and as related to the stimulus which evokes a compensatory rise of blood pressure, both in acute glomerulo-nephritis, and still more so in an eclamptic toxæmia, such a stimulus is slight or even absent. It would seem probable that in these two diseases the vascular disturbance precedes the renal lesion; just as in essential hypertension vascular spasm precedes and ultimately produces changes in the glomeruli, so in acute glomerulo-nephritis and in eclamptic toxæmia the vascular spasm and rise of blood pressure are primary and the renal lesion secondary. The vascular spasm remains unexplained, but its cause is to be sought elsewhere than in the kidney.

DISTURBANCES OF THE BODY TEMPERATURE[*]

By C. E. Lakin, M.D., F.R.C.P. Lond., F.R.C.S. Eng.
PHYSICIAN TO THE MIDDLESEX HOSPITAL AND THE LONDON FEVER HOSPITAL

Suprarenal Hæmorrhage

There is a rare disease met with in infants, usually during the first year of life, in which the temperature suddenly rises, a purplish mottling appears over various parts of the body accompanied by petechial hæmorrhages and which is likely to prove fatal within 24 hours. Vomiting is usually present at the onset and the condition is likely to be mistaken for the hæmorrhagic form of one of the infectious fevers. Convulsions make their appearance and are followed by hyperpyrexia. In a few hours profound collapse supervenes with cold clammy skin and a rapid feeble pulse which is unaffected by the usual remedies. That the condition in the case of children does not appear to be due to infection and yet is attended by pyrexia and even hyperpyrexia is of special interest in a study of disturbance of the body temperature. On post-mortem examination the suprarenals show a deep purple colour and are distended with blood. Under the microscope the gland is seen to be everywhere infiltrated with blood and particularly is this true of the medulla. In some cases the glandular cells are destroyed and replaced by extravasated blood corpuscles. I have met with the condition in the post-mortem room not only in infants but once or twice in adults with pneumonia. The infantile cases appear to support Cramer's contention that pyrexia is dependent upon changes in the thyroid-adrenal sympathetic system.

Pathological Changes in Fever

In considering the clinical accompaniments of fever, we said that it was usually impossible to discriminate to what extent the febrile state and to what extent the underlying infection was responsible for the various clinical manifestations. When we study the pathological results of fever the same difficulty emerges. Cloudy swelling is widely distributed and is well marked in the liver and kidneys. In more severe or long-standing infections fatty degeneration follows and in some instances focal necroses are met with. Fatty degeneration of the intima of the aorta is extremely common, but the various forms of thrombosis and the rarer mycotic aneurysms which sometimes arise are to be attributed to the underlying specific infection. A variable degree of hyperplasia of lymphoid tissue is encountered in many infections, as is also a greater or less degree of anæmia. The myocardium is subject to parenchymatous and interstitial changes giving rise in turn to low blood pressure and cardiac arrhythmia. The voluntary muscles also are affected by cloudy swelling and fatty changes and in some instances Zenker's necrosis may occur. The latter is met with more especially in typhoid fever and appears only to occur in cases where a high temperature has been allowed to persist for many days. The proliferative changes in the epithelium of the thyroid and the secretory changes in the adrenals have been referred to already. The nervous system may show degenerative changes, but this is seen more especially in those fevers such as diphtheria where the toxin of the disease-producing organism exerts a specific action upon nervous tissue. If acute parenchymatous inflammations develop, particularly in the heart and kidney, they may become chronic and result in permanent disability and ultimately in death. In fact, acute infectious diseases are responsible for many of the chronic diseases to which man is subject. Such sequelæ, it may be pointed out, are more frequent with the severer grades of infection, and young individuals recover more readily than older ones.

Stages of Fever

A febrile illness may be said to present typically three stages, known respectively as the stage of invasion, rigor, or chill, the stage of domination or fastigium, and the stage of decline or defervescence. They may all be run through in the course of a few hours as in an attack of malaria, or they may extend over a period of weeks.

In the *stage of invasion* the superficial vessels of the skin are contracted so that radiation and conduction of heat from the body are reduced to a minimum. The smooth muscle in the skin, known as the arrector pili, contracts and a microscopic quantity of sebum is expressed, closing the pores of the skin and still further limiting heat loss. The hairs of the skin are erected and what is popularly known as goose-flesh or goose-skin results. The patient complains of feeling cold, for his sensations of temperature arise in the skin and not in the viscera, and the use of a surface thermometer proves that the temperature of the surface of the body is below normal. He cowers over a fire or covers himself with rugs or blankets. His teeth chatter and he shivers with cold, thus converting stored-up energy into heat. Every available mechanism is brought into play to stop the dissipation of heat and the internal temperature begins to rise. In spite of the sensation of cold, the temperature of the interior of the body is highest during the stage of chill. In this stage then the loss of heat is diminished, the production of heat is increased, the balance is disturbed in the direction of excess, and pyrexia results.

During the second stage or *fastigium*, the temperature remains high, the skin vessels dilate, and the surface becomes hot and flushed. The shiverings are replaced by a subjective sense of heat, and in some cases the skin becomes moist and further heat is lost by the evaporation of sweat. The pulse is now full and bounding from the increased action of the heart and relaxation of the arterial wall. In this stage the increased production of heat caused by the rigor is maintained by increased metabolism of the body tissues. As we saw in our first lecture, the mere existence of an increased temperature speeds up the metabolic processes and, as a result of this, heat production is still further increased in accordance with Van't Hoff's law that increased temperature accelerates the velocity of chemical reactions. The diminished loss of heat due to the spasm of the cutaneous arterioles present in the first stage ceases with the relaxation of the vessels, but the balance is still against heat loss. The length of the fastigium is often proportional to the time taken to reach the acme. Thus in pneumonia, where the period of invasion is short, the fastigium lasts about a week. In typhoid, where four or five days are taken for the fever to reach its height, the fastigium lasts from 10 to 14 days.

The *stage of defervescence* is indicated by a falling temperature, a less frequent pulse, a moister and cleaner tongue, and a general return towards normal conditions. It may be initiated or accompanied by sweating or other evacuation. When this stage is of short duration the fever is said to fall by crisis, when of long duration, by lysis. Generally speaking, the more rapid the onset of fever the more sudden is the fall. Where the onset has been gradual the more protracted is the defervescence. As the fever declines the arteries are still further relaxed, but the heart's action is less powerful and the pulse becomes softer. Most of the acute infectious fevers are self-limited in their course and defervescence is followed by convalescence. The symptoms have now almost disappeared and the patient gradually resumes his customary strength. During the first few days of convalescence the temperature is often found to be subnormal. Too great a virulence of the invading organism or too low a resistance on the part of the patient may prolong the course of a fever, delay recovery, or result in death. A fatal termination may be ushered in by hyperpyrexia, but more commonly the temperature falls below the normal line and collapse ends the scene.

---

[*] The third Lettsomian lecture for 1934, delivered before the Medical Society of London on March 5th. Lectures I. and II. appeared in our last two issues.

Febricula

Febricula is only mentioned to be dismissed. It was commonly defined as a simple fever of not more than a few days' duration, not preceded by any one known antecedent, and not attended by any one distinctive organic lesion. There is little doubt that febricula of the old authors was really an example in a mild form of one of the common infective diseases which has aborted early in the illness before the particular disease has had a chance of running its course.

The Therapeutic Reduction of Pyrexia

The treatment of a febrile disorder will, of course, differ according to the cause, but it is sometimes necessary to take measures to control the attendant pyrexia. In any lengthy fever this is most efficiently carried out by the application in some form or another of cold. Currie of Liverpool in 1787 first recommended the cold bath treatment, but it was soon forgotten. Its reintroduction is due to Brand of Stettin in 1861. My old chief, William Cayley, was the first physician in England to introduce the cold bath in the treatment of typhoid fever and through his able advocacy its use in a more or less modified form soon became general. Prior to its introduction the so-called typhoid state was the usual accompaniment of a continued fever, in spite of treatment by various antipyretic remedies and by enormous doses of alcohol. It was found that the cold bath was followed by slowing of the pulse and by an increase in its tension, by slowing of the respiration, and improvement in the appetite. Under its use the tongue became moist, delirium disappeared, and sleep was restored to the sufferer. Statistics soon showed that by its adoption the mortality of the disease was lessened.

EFFECTS OF COLD ON THE BODY

Exposure to temperatures below −6° C. (about 21° F.) produces destruction of the tissues due directly to the cold. This is probably to be ascribed to some physical change which destroys absolutely the protoplasm of the cells. But here we are concerned only with the general consequences of cold on the body. Its first effect is to contract the musculature of the arterioles of the skin and blood is driven back into the interior of the body. The temperature sinks, metabolism is slowed in all organs, and their activity is consequently reduced. The limbs become weak and stiff and an irresistible desire to sleep is experienced. Just as pyrexia is attended by wakefulness, cold shows its counterpart in somnolence. Possibly the sleep centre which is in close juxtaposition to the heat centre in the hypothalamus is concerned in bringing about this result. Respirations are slow and shallow and the pulse becomes small and weak. If the body temperature continues to fall till 18° to 20° C. (64°–68° F.) is reached the heart stops beating and death supervenes. A perfused heart, beating well upon Ringer's fluid, slows down and stops if the fluid is cooled to 18° C. Such a heart will start beating again if the fluid be warmed, but the resuscitation of the human body is a different matter. Nothing distinctive is found on post-mortem examination and death appears to be due to the gradual slowing down of metabolic processes.

ALGIDITY

This is a valuable term which has lapsed from general currency. It was used by a former generation of physicians, particularly by Byrom Bramwell, to indicate states of general depression of the body temperature. It occurs both as an acute and as a chronic state. General algidity must be distinguished from the condition in which the temperature of the peripheral parts is lowered while that of the central or deeper parts remains normal or is elevated—a condition which may be termed peripheral depression of temperature or peripheral algidity. To quote Byrom Bramwell:—

> "Peripheral algidity with a normal temperature of the central and deeper parts is of common occurrence both in health and disease. It may result from exposure to cold. Healthy persons exhibit great differences in their susceptibility to external variations of temperature. Those whose vasomotor tone is low bear both heat and cold badly; in them peripheral depressions of temperature are readily produced by exposure to external cold, the blood in the peripheral or surface circulation being driven into the central or deeper parts, a result which is not always unattended with danger; for should the arteries—say of the brain—be degenerated, the sudden increase of pressure may lead to rupture and an attack of hæmorrhagic apoplexy. The sudden filling of the deeper vessels which so frequently results in persons of low vasomotor tone from exposure to cold, is probably a common cause of headaches. The increased effort demanded of the left ventricle in order to cope with the increased peripheral resistance due to the action of cold on the peripheral parts is in some cases the immediate exciting cause of an attack of angina pectoris." ("Clinical Studies.")

Peripheral depression with a normal temperature of the central and deeper parts is common in disease; while peripheral depression with central elevation is of frequent occurrence in febrile disorders. During the stage of rigor, for example, the rectal temperature may be rising rapidly and very much above the normal, while the patient is shivering with cold and the temperature of the peripheral parts subnormal. In cholera, too, the surface temperature may be greatly depressed while the central (rectal) temperature is normal or much above normal. In some cases of sclerema neonatorum remarkable differences have also been noted between the peripheral and central temperatures. Many other examples of a similar kind might also be mentioned.

Acute general algidity, that is to say an abrupt depression of the body temperature, is seen in prolonged exposure to severe cold. Recovery has been reported in persons who have missed their way on mountain paths and have been found with temperatures in the neighbourhood of 78·5° F. A drunken man is especially liable to experience a marked fall of temperature if exposed to cold or inclement atmospheric conditions on account of the dilatation of the skin vessels produced by alcohol. Conditions producing profound shock and depression, especially where associated with severe traumatic injuries such as perforating wounds of the thorax and abdomen, severe lacerations, burns, or hæmorrhage, form another group of cases, and during the war every big push provided us with countless instances. In civil life all internal and spontaneous, as distinguished from external and traumatic, causes of collapse and shock may be attended with algidity, such as the passage of biliary or renal calculi, strangulation or obstruction of the intestines, or rupture of an abdominal viscus.

A sudden and profuse loss of blood is attended by a fall of temperature, well exemplified when the bleeding occurs as in typhoid during the course of a fever in which the temperature is above the normal. A similar fall in this disease attends intestinal perforation. In such circumstances the algidity is as a rule of brief duration and, where the patient survives, the thermometer, after a few hours, often exceeds its previous reading. Sudden and profuse diarrhœa or copious vomiting such as is seen in the summer diarrhœa of children may be followed by a great depression in temperature. The same phenomenon also occurs in Asiatic cholera in which, however, the internal temperature is often much elevated when the surface reading is markedly depressed. To the sudden fall of temperature at the onset of cerebral hæmorrhage we have already referred in a previous lecture. Charcot emphasised the depression of temperature which often ushered in the onset of pericarditis in elderly people, and Byrom Bramwell has made the same observation at the commencement of an attack of peritonitis. Other examples may be quoted such as asphyxia, acute yellow atrophy of the liver, and during the course of uræmia. Lastly may be mentioned the pre-agonistic fall of Wunderlich in which at the fatal termination of a febrile disease along with a falling temperature there is a rise in the frequency of the pulse and sometimes of the respirations, the pulse becoming thready, often irregular, and at last imperceptible. Quite exceptionally the pulse frequency lessens in the collapse which precedes death.

In cases of algidity speaking generally it may be said the greater the fall the more serious its significance, but the character of the associated symptoms and physical signs and the conditions in which the fall occurs must always be taken into account in forming a prognosis. Provided that the patient survives the period of depression the rise which succeeds may be of considerable duration. Instances may be cited in cases of apoplexy and in pulmonary tuberculosis where, after the fall of temperature attendant upon a profuse hæmoptysis, the subsequent rise may be of lengthy duration, being in many cases due to an inspiration pneumonia set up by the extravasated blood.

Chronic general depression of temperature is seen in myxœdema, chronic uræmia, catarrhal jaundice, and in some melancholic forms of insanity. In cancer of the stomach the temperature is not infrequently 1°–2° below normal, the depression being due to inanition rather than to the pathological character of the lesion. In many cases of chronic cardiac disease associated with cyanosis a subnormal temperature is seen. This is notably the case in morbus cœruleus. I would especially draw attention to certain cases of infective endocarditis. It is remarkable that in this disease clinical manifestations of mechanical disturbance of the circulation are so curiously lacking, the presenting features of the disease being predominantly those of the septicæmic component. I learnt a personal lesson many years ago.

There was admitted into the Middlesex Hospital a man presenting extensive œdema of the legs. He had been ill for many weeks. A systolic murmur was audible over the mitral area and the liver and spleen were enlarged. He gradually grew worse and died at the end of a ten days' sojourn. During this time the temperature had been subnormal. I had regarded him as a case of mitral regurgitation with congestive failure. Post-mortem examination revealed the existence on the mitral valve of those exuberant, friable vegetations characteristic of infective endocarditis. For the first time I realised that where congestive failure supervenes before death in infective endocarditis apyrexia may prevail. I had omitted to appraise the significance of the constant presence of blood in the urine and the degree of enlargement of the spleen.

Pyrexial Treatment of Disease

Little more than passing reference can be made to this subject. Treatment of general paralysis of the insane by Julius Wagner von Jauregg in 1917 has led to a great change in the treatment and prognosis of this disease. Since 1922 this treatment has been carried out systematically in many mental hospitals in England. Many other methods of inducing pyrexia have been employed, among which may be mentioned the subcutaneous injection of sodium nucleinate, hetol, and boiled milk, the intravenous injection of vaccines of *Bacillus typhosus* and of streptococci and staphylococci, the intramuscular injection of sulphur suspended in olive oil, and the inoculation with the organisms of rat-bite fever and of relapsing fever.

The best results have been obtained with *malaria*. The cause of the beneficial action of malaria is still uncertain. The generally accepted view is that the resulting pyrexia is the principal therapeutic factor. Another suggestion is that the antibodies formed by the patient against the malarial parasite are also effective against the spirochætes and that increased permeability of the capillary walls allows antibodies already present in the blood stream to penetrate to the spaces around the nerve-cells and reach spirochætes previously inaccessible. Histological examination of cases that have died after treatment fails to show the presence of spirochætes in the brain.

Therapeutically, malaria may be inoculated by the bite of an infected mosquito and in England such mosquitoes can be obtained from the Ministry of Health. In mental hospitals there are usually enough patients under treatment to permit of transmission to be kept up from case to case. The donor's blood is withdrawn, preferably during the decline of the pyrexia, and from 1 to 5 c.cm. are injected into the patient, usually by the subcutaneous route. If injected intravenously the incubation period is shortened. The incubation period is extremely variable, ranging from a few days to several weeks. The patient is usually allowed to have a series of ten malarial paroxysms and the infection can be terminated at any time by the exhibition of quinine.

Malarial therapy is unsuitable for debilitated patients and those showing evidence of cardiovascular disease. Should cardiac failure supervene the infection must be terminated. The best results are obtained in early cases. Juvenile paretics do not respond. The principal change in favourable cases is in the mental condition. No change occurs in the reaction of the pupils or in other reflexes. There is usually a reduction in the number of cells and in the globulin content of the cerebro-spinal fluid. The Wassermann reaction becomes less strongly positive and in exceptional cases becomes negative. It is said that 20 to 30 per cent. recover sufficiently to take up some form of work.

The use of Coley's fluid in the treatment of sarcoma may be instanced as another example of the pyrexial treatment of disease. The mixed toxins of the

Streptococcus erysipelatis and *Bacillus prodigiosus*, beginning with small doses and increasing until a rise of temperature is produced, are injected, if possible into the tumour. The injections are repeated daily or on alternate days for at least a month. If after this time there are signs of improvement the treatment is continued for a year. In this country the treatment seems very largely to have fallen into disuse.

Before concluding this section reference may be made to the improvement which is occasionally seen when for any cause fever arises during the course of a chronic illness.

Quite recently I have had under my care in hospital a girl suffering from subacute nephritis. She showed extensive œdema of the legs and ascites. The urine was loaded with albumin, a little blood was present on two or three occasions, and the blood cholesterin was high. For several months she had gradually been losing ground and the abdomen had been tapped on three occasions. An attack of acute tonsillitis attended by fairly high pyrexia lasting for the greater part of a week supervened. As the fever declined an enormous diuresis set in, and within another week the œdema of the legs had disappeared. The urine now contained little more than a trace of albumin. A surgeon who had seen her and had suggested a modified Le Riche's operation on the renal artery felt that he had been outwitted and she left the hospital, well, a fortnight later.

In this connexion I should also like to refer to a case of Graves's disease seen during the early part of the war.

The patient, a woman of about 30 years of age, living in Croydon, was attending the out-patient department of the Middlesex Hospital. As she was suffering from severe pyorrhœa, three or four teeth were extracted on the assumption that the infection might be responsible for the hyperthyroidism, but no improvement occurred. Seeing that she was pregnant and travelling facilities at that time were not easy, she said that she should cease coming up to the hospital till after her baby was born.

I saw nothing of her for six months, when she again paid a visit to the hospital. She had gained in weight and, except that the eyes were slightly prominent, the symptoms and signs of Graves's disease had disappeared. When I asked her what had been happening, she said that she was better and had come up because she had pain and swelling over the breast bone—she had in fact an infective arthritis of the right sternoclavicular joint. She stated that a week after the birth of her baby, which had occurred four months previously, she developed severe tonsillitis with high fever, that she was very ill for a fortnight and that her doctor had been greatly concerned about her. The temperature then fell and to her surprise the swelling in her neck went down and all her tremulousness and palpitation subsided.

The only suggestion that I can offer in explanation of this remarkable improvement is that the patient had been harbouring an infection in her tonsils from which absorption had long been taking place and that this in turn had given rise to Graves's disease. As the result of acute tonsillitis protective substances had been formed in such abundance as not only to overcome the acute tonsillar infection but also to completely eradicate the infective focus in the tonsils which was responsible for the long-standing hyperactivity of the thyroid gland.

Diagnosis

Sometimes a study of the temperature chart will give an important clue to the diagnosis of a case. For instance, a double diurnal rise is sometimes seen throughout a case of kala-azar. Relapsing fever presents a five or six days' period of high fever followed after a sudden fall by a five or six days' period during which the temperature remains fairly close to the normal line, and this in turn is followed by an abrupt rise to 104° or 105° for a further five or six days' period and so on. The temperature charts of tertian and quartan malaria may also be instanced. Unfortunately, while a fever is in progress we cannot examine the chart of the period still in front of us, or typhoid might be added to the list of diseases yielding a distinctive picture, with its staircase rise, its ten days' period of continued fever followed by a remittent and then an intermittent stage.

In cases of pulmonary tuberculosis a study of the temperature chart will help to determine the type of disease with which we are dealing. Thus acute caseating tuberculosis will show much wider excursions between the morning and evening temperature, and the general level is likely to be higher, than in cases of fibrocaseous tuberculosis, and the chart may be said to have prognostic as well as diagnostic implications. Although occurring in other diseases an inverse type of temperature may be expected in cases of miliary tuberculosis.

In attempting to ascertain the cause of fever, one naturally seeks to correlate the febrile condition with such other symptoms as are present and with such physical signs as are elicited by a careful examination of the patient. Sometimes one finds that crepitations over a small area in the lung have been overlooked or such have been late in making their appearance. In other cases it may be râles are discovered but one feels that their presence is insufficient to account for the general condition of the patient in question, their presence being simply an incidental complication of some more serious underlying condition. It is not always remembered that simple bronchitis is unlikely to give rise to pyrexia higher than 100·5° or 101°, and that in cases where the temperature exceeds this point it is likely either that there is a complicating broncho-pneumonia or that the bronchitis is secondary to some specific underlying infection such as typhoid fever.

Where the fever has been of short duration the possibility of the case being one of the acute specific fevers in which the rash has not yet appeared must be taken into consideration. In this respect perhaps the greatest difficulty may arise in the case of German measles, where in exceptional cases fever may exist for seven days before the eruption makes its appearance. During this time there is sometimes a complaint of stiff neck, and examination may show the existence of enlarged occipital, cervical, or axillary glands. In a case presenting these features it may be difficult to dismiss the possibility of glandular fever, and the more so as the mononucleosis characteristic of this disease may not be established till the third week of the illness in the case of an adult.

Another febrile disease in which difficulty in diagnosis may arise is erythema nodosum. It occasionally happens that fever persists for ten or twelve days without any adequate explanation for its presence until the typical nodules make their appearance. In herpes zoster, again, the eruption may be preceded by fever and malaise of a few days' duration and it may be impossible to make a conjectural diagnosis at this time unless initial pain is also present.

Pyrexia may undoubtedly occur in the absence of specific infection in cases where the heat-regulating mechanism has been rendered unstable by drug addiction such as morphia or alcohol or by a recent long-continued febrile illness. Pyrexia sometimes persists for several weeks after the original infection has come to an end. This may be exemplified by a reference to measles where a continuance of fever can sometimes be ascribed to inflammatory changes occurring in bronchial glands which have become infected as a result of the absorption of toxic substances from the inflamed bronchi. Radiological examination in these cases reveals the presence of enlarged glands. While glands are in this condition the child should be kept under medical supervision and special care should be taken to prevent exposure to any possible source of tuberculous infection. Another condition which sometimes gives rise to difficulty in diagnosis is subacute rheumatism in children. The onset is frequently insidious and symptoms at first may be equivocal.

I saw a case recently in which slight fever of three weeks' duration was associated with tenderness over the mastoid process and the question arose whether mastoiditis was the cause of the continued pyrexia. The hands were clammy, the pulse frequent, and on auscultation the first sound of the heart was short and of poor quality, while the cardiac rhythm was tic-tac in character. Ten grains of sodium salicylate were given every four hours but as three days later the tenderness over the mastoid was still present and the pyrexia, though running at a lower level, still continued, it was thought risky to delay operation. Nothing was found on exposure of the mastoid cells and, on increasing the dose of salicylates, the fever came to an end. It is clear that larger initial doses of the drug would have saved the child from unnecessary surgical intervention.

Occasionally children become febrile after the ingestion of certain foods: the so-called carbohydrate fever may be mentioned as a well-known example. A child harbouring round worms sometimes suffers from a low fever which may be baffling unless the possibility be borne in mind. I remember taking a midnight journey to Worcestershire to see a child who had been running a high temperature for a few days and who had been a complete puzzle to her doctor. Half an hour before my arrival pus had poured from the auditory meatus and unexpectedly established the diagnosis which had been sought in vain! Occasionally it appears to be quite impossible to determine the cause of severe pyrexia in children and it is to this type of case that Dr. Frederick Taylor gave the name of innominate fever. Metabolic disorders are sometimes responsible for pyrexia; thus fever may occur with Graves's disease and with gout in the absence of any obvious infection. Persistent pyrexia showing considerable oscillations sometimes occurs in association with cirrhosis of the liver, a fact which is sometimes adduced in favour of cirrhosis being properly regarded as a form of hepatitis.

The need for a complete examination in all cases of cryptogenic fever is well exemplified by the case of a little girl who ran a high temperature without any cause having been discovered. One day the nurse was asked to give an enema and reported that a curious condition of the vulva was present. On examination this was found to be due to cancrum vulvæ although there had been no complaint of pain. Energetic treatment was carried out, and I am glad to say the patient recovered.

Persistence of fever after abdominal operations sometimes gives rise to much anxiety. I do not refer to cases in which a wrong diagnosis has been acted upon and appendicectomy performed, for example in cases of colon bacilluria or in typhoid fever. A case of the sort I have in mind recently came under my notice.

An acutely inflamed appendix had been removed, but to the surgeon's disappointment the fever persisted and the presence of increasing abdominal distension associated with diarrhœa suggested the possibility of the case being one of typhoid fever. I suggested that a leucocyte count would be helpful, and it was found that there was a leucocytosis of 28,000 with a relative increase of polymorphonuclear cells. It was agreed that the surgeon should reopen the abdomen. When this was done a chain of acutely inflamed retroperitoneal lymphatic glands was discovered running along the iliac vessels.

I made reference to cases of abdominal distension associated with retroperitoneal lesions in the Lumleian lectures in 1932. Distension in these cases appears to be due to stimulation of the abdominal sympathetic system.

In another case which I saw last year a hæmatoma formed on the fourth day at the site of incision after an operation for a right inguinal hernia and slight fever was present. The hæmatoma was evacuated but the pyrexia became more marked. On the tenth day after the operation the patient had an attack of dyspnœa accompanied by acute pain in the chest and hæmoptysis. Examination of the chest revealed the existence of a pulmonary infarct. The femoral regions were examined for evidence of venous thrombosis but none was forthcoming. On examination of the back I found there was tenderness and œdema with pitting of the lumbar regions, more marked on the right side but present to a less degree on the left. The case was one in which thrombosis had tracked up from the site of the hæmatoma to the lumbar veins. After a stormy convalescence during which pulmonary infarction occurred on three occasions in all the patient recovered.

Abdominal distension with fever is sometimes seen in cases of malignant ovarian tumours with scattered metastases in the peritoneum. In such an instance, which I saw recently, it was difficult to decide whether the case was of this nature or whether it was one of tuberculous peritonitis of the ascitic variety. Where vaginal examination fails to elucidate the condition, laparotomy may be the only certain means of making the diagnosis. Sometimes a carcinoma of the colon is attended by pyrexia. In one case under my care in hospital in which symptoms of partial obstruction were associated with pyrexia and leucocytosis an annular carcinoma had ulcerated through the posterior wall of the colon and had led to the formation of a small abscess in the retrocolic tissues. The difficulty of distinguishing between such a case and diverticulitis unless X ray evidence is forthcoming is obvious. Of all malignant growths perhaps hypernephromata are most constantly associated with pyrexia.

Hodgkin's disease, gumma, and undulant fever are other conditions which must be borne in mind in cases of cryptogenic fever. I have of set design devoted so much time to stressing the importance of correlating pyrexia with clinical findings that I can do scant justice to the immense help which laboratory investigations afford in circumstances like these where the cause is in doubt. I feel that perspective is likely to be lost unless laboratory investigation is entered upon with circumspection and due regard to the end we have in view. To quote Drs. G. Bourne and K. Stone :—

> "The pathological laboratory should be used as a place which will return specific answers to specific questions, rather than as a temple to which the harried physician turns entreating arms in the extremity of his need. The man who when baffled demands a blood culture, a complete blood count, and every other test that he can think of is as likely as not to receive answers to his questions that will only serve to lead him deeper into the mire of doubt." (The Principles of Clinical Pathology in Practice, London, 1929.)

Not only so, but we must bring our judgment to bear on such results as these investigations may bring to light. Among the most useful adjuncts to the diagnosis of cryptogenic fever one would mention blood culture. Clinical pathologists have a way of delaying their reports, and in a case of food poisoning which I saw some time ago with Dr. Seymour Maynard and Dr. C. R. Box the patient was not only dead but embalmed before a report was received saying that *B. aertrycke* had been obtained from the blood ! But all facetiousness apart, in a case in which there may have been a lurking suspicion of tubercle it may be very reassuring to learn that *Brucella abortus* or *melitensis* has been cultured from a case which has shown little constitutional disturbance beyond fever and profuse sweating. A blood count may afford great assistance, and cognisance should be taken of the red cells as well as the white. Thus in a case of glandular fever the white cell count may suggest acute leukæmia but the absence of change in the red cells in the former will be of great significance. A leucocytosis with a relative increase in the polymorphonuclear cells will serve to distinguish pyogenic infections in general from the enteric group of fevers and other conditions in which leucopenia prevails. In the febrile blood diseases a blood count becomes essential for diagnosis. Similarly in agranulocytosis and monocytic angina the correct designation will very largely depend on the blood picture. In aplastic anæmia the red count will be low, whereas in agranulocytosis the red count is likely to be normal or nearly so. Examination of cerebro-spinal fluid, sputum, urine, and fæces may all provide their quota in a puzzling case. Biochemical and radiological examination may lead to further elucidation.

Climate

A few considerations on the adaptability of the body to climate may not be inappropriate to our subject. We have seen that if the body temperature is to be raised this can be accomplished in two ways, either by preventing heat loss or by speeding up the rate of heat production. Similarly, the body temperature can be lowered by increasing heat loss at the surface of the body or by slowing down the production of heat within. In health we can control heat production to a certain extent. When it is very hot appetite fails and the diminished intake of food will provide less fuel to be oxidised, and we have seen already in accordance with Van't Hoff's law that the chemical processes of the body are less active if its temperature is allowed to fall below a certain optimum. Moreover, when it is hot we do not feel like taking violent exercise, and since exercise generates heat, in this way also, we can limit heat production. On the other hand, when it is cold we eat more and take more exercise, and the more active we can make the heat-generating processes the more active does secondary heat production become.

Most animals with a constant body temperature are provided with a thick coat of hair or feathers which they can use to adjust the amount of heat leaving the surface. The robin, while sitting quiet on a cold winter's day, has his feathers all puffed out, and by this means is able to entangle a great deal of air, which is a comparatively poor conductor of heat, between his feathers. This layer of air, warmed by the heat of his body and intervening between his body and the colder air around, affords an efficient protection against the loss of heat. On a warm day the feathers are held tightly against the skin so that heat may escape more easily. We can produce a like result by clothes; on a hot day we wear as little as possible so that air can reach the skin and carry away heat by convection, while on a cold day we wear more clothes so as to imprison several layers of air between our body and the outer world, and we button up our coat so as to prevent these layers of air from losing heat by convection. From what has been said about the entanglement of air it becomes clear that two garments are more efficient than one of double thickness. Fur entangles a great deal of air and so is particularly suited to cold weather. But the most important thing of all in great cold is for clothing to be windproof. Eskimos wear only one garment. It is made of sealskin with the fur inside. It is tied tightly round the wrists and legs and at the neck and is windproof. Arctic explorers nowadays provide themselves with special windproof overalls which are lighter than fur clothes. Similarly oil is sometimes smeared over the body by farers on the North Sea on wintry nights to prevent the dissipation of heat.

Man, by the invention of clothing and by learning how to kindle fire, has made himself master of his climatic environment. Climate influences man in many subtle ways. I am indebted to Ellsworth Huntington's "Civilisation and Climate" for the following interesting facts.

> He states that both physical and mental activity are more pronounced in the spring and autumn than in midsummer and in midwinter. The most important climatic factors in order of decreasing importance are: (1) the mean temperature month by month; (2) the amount of change in the weather from one day to another; (3) the relative humidity. Changes of temperature, provided they are not excessive, are more stimulating than uniformity. In temperate climates a fall is more stimulating than a rise, and people are less efficient on fine days with a clear sky than on cloudy days or after a storm. It is comforting to know that the greatest efficiency in physical and mental activity is found with a mean temperature lying between 50° and 60° F.; it falls rapidly as the mean temperature rises above 65° F. It thus becomes possible to establish what constitutes an ideal climate—ideal from the point of view of human efficiency.
>
> Meteorological data show that climatic conditions approaching this ideal occur in western Europe and that the climate of England comes nearest to the ideal, and much the same may be said for that of Japan, New Zealand, and the south-eastern part of Australia. In the western hemisphere southern Canada, the east and central portions of the United States, and those portions of the Pacific coast stretching from British Columbia to California fall within the same category. While admitting the cogency of other factors, Huntington concludes: "No nation has risen to the highest grade of civilisation except in regions where the climatic stimulus is great."

Cramer claims that the thyroid-adrenal apparatus supplies the connecting link between climate and civilisation. Among other things he finds that a change from a warm to a cool environment is a much more powerful stimulus to the adrenal gland than a continuously cool environment. He maintains that the thyroid and adrenal glands are not merely regulators of metabolism but that their functional state affects man's physical activities and "colours his mentality." He regards the cool, variable climates in which human activity attains its greatest development as the constant source of stimulation of these endocrine organs. Not only then have hormones played their part in the history of the human race but in the more restricted sphere of everyday life Cramer would apply the same explanation to the relations between climate and health. We usually regard a bracing climate as one which leads to increased metabolic changes in the body, and a relaxing climate as one which makes fewer demands on man's metabolic activities. Cramer asks the question why resistance against infections such as tuberculosis is increased by a suitable, cool, dry climate, and by measures such as open-air treatment, hydrotherapy, and the like. He criticises the answer usually given that these conditions increase metabolism by pointing out that increased metabolism in itself does not explain the beneficial effect, for increased metabolism can be induced by other measures such as vigorous muscular exercise, which is likely to be harmful. According to his view those measures are beneficial which stimulate the thyro-adrenal apparatus without exhausting it and thus strengthen one of the normal reactions of defence of the organism against infection. "Conversely a warm moist monotonous climate weakens resistance against infections, not because it reduces metabolism but on account of the continued absence of a stimulus to the thyro-adrenal apparatus and the sympathetic."

Concluding Considerations

We have seen that metabolism is responsible for heat production; that a centre in the hypothalamus is concerned with the regulation of body temperature; that the centre is so constituted as to be sensitive to the temperature of the blood passing through it. If this temperature is raised the various means for increasing heat loss and decreasing its production are brought into play. If the temperature is lowered those for decreasing heat loss and for increased heat production become operative. We have also seen that the thyroid and adrenal glands acting through the sympathetic nervous system influence metabolism and together form a "humoral apparatus" (Cramer) concerned in heat regulation of the body; that the heat centre may be regarded as a group of nerve-cells representing the central connexions of the sympathetic. When we consider that during muscular exercise heat production may be increased from 200 to 300 per cent. without the temperature rising, whereas in fevers heat production may only be increased from 20 to 30 per cent. and yet pyrexia results, it is obvious that in cases of fever some *lack of adjustment* must occur. In infective conditions pyrexia must be regarded as the resultant of two forces: the toxic action of the invading organism on the one hand and the resistance of the infected person on the other. Such a conception is borne out when the temperature chart is studied in conjunction with the curve of the opsonic index. Stated in broad terms it may be said that the elevations on the temperature chart correspond to depressions of the opsonic curve and vice versa, that is, that the temperature chart bears an inverse relationship to the opsonic activity.

Since aseptic suppuration is accompanied by fever some investigators ascribe the fever and chills which occur in cases of suppuration to the absorption of autolytic products rather than to the direct action of poisons produced by the invading organisms. The rise of temperature which occurs when a patient begins getting up too soon after a pyrexial illness is to be ascribed to the increased cardiac action (consequent upon the increased exertion) washing out inflammatory products from the affected area into the general circulation.

The occurrence of pulmonary infections after anæsthesia is perhaps favoured by the thyro-adrenal exhaustion which follows the exhibition of general anæsthetics.

No mention has been made of hysterical fever as so little is definitely known of the processes concerned in its production, but that such occurs quite apart from fraud is generally admitted. In conclusion I cannot do better than to quote the concluding sentences of Cramer's "Fever, Heat Regulation, Climate and the Thyroid-Adrenal Apparatus," a book to which I have frequently referred during the course of these lectures.

"The study of the physiological basis of the effect of climate on man shows us man fashioning his own development by struggling to free himself from his climatic environment. We have seen that man in his natural state is unfitted to exist in any but a tropical climate. But this is the very climate which places a limitation on his mental development. The invention of clothing and, even more, of fire freed him from his thermal environment and enabled him to establish himself in climatic conditions where his mental and physical energy could find their highest development. We may have forgotten what the invention of fire meant to mankind. Primitive man expressed its deep significance in the Promethean myth that fire was a secret stolen from the gods to render man like unto them."

INJECTION OF THE GASSERIAN GANGLION

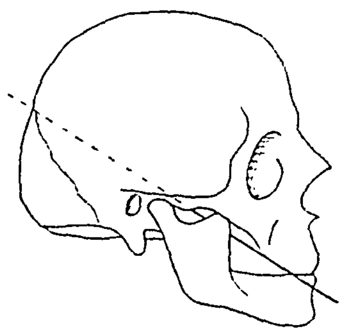
By H. S. Souttar, C.B.E., M.Ch. Oxon., F.R.C.S. Eng.

SURGEON TO THE LONDON HOSPITAL

Injection of the Gasserian ganglion for the relief of pain is one of the most valuable of surgical procedures. Quite apart from trigeminal neuralgia itself, the region supplied by the trigeminal nerve is a common site for the development of carcinoma in various forms, which may in its later stages give rise to pain of a very severe type which even morphia may fail to control. If properly carried out, injection of the ganglion may in all these cases give permanent relief, but a very precise technique is essential to success. It has frequently been stated that the uncertainty of the injection and the risks involved render it unsuitable for general use, and some surgeons would advise in preference such a considerable operation as is involved in division of the sensory root. In a long series of cases, however, I have met with such uniform success that I am convinced of the value and safety of the procedure.

The method first described by F. Hartel[1] is in my view far superior to the transverse methods described by F. Ostwalt and Schlösser.[2] Although the skin is entered at a point somewhat more distant from the foramen ovale, this increase in the distance of the objective is fully compensated by the fact that the plane of the foramen is at right angles to the needle, and the foramen itself is therefore as open as possible, whilst the anatomical structures adjacent to the path of the needle greatly facilitate its accurate insertion. Moreover, after entering the skull the needle now lies in the plane of the ganglion and the certainty of the injection being limited to the ganglion is therefore assured.

FIG. 1



A fine needle 10 cm. in length is inserted into the cheek at a distance of 1 in. external to the angle of the mouth, and it is directed upwards and inwards towards the lambda (Fig. 1), the point on the skull where the lambdoid and sagittal sutures meet. Passing at first through the substance of the cheek, the needle enters the internal pterygoid muscle on the inner side of the coronoid process. Leaving this, it enters the external pterygoid and comes to rest at the root of the external pterygoid plate. The point of the needle now rests just in front of the foramen ovale and on the base of the skull (Fig. 2). The needle is now partly withdrawn and directed slightly posteriorly to its former line, when the point should pass through the foramen ovale into the ganglion itself.

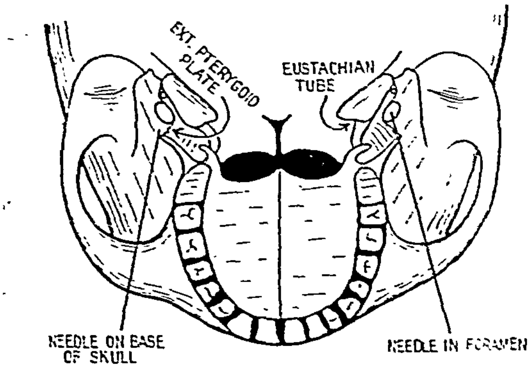
---

[1] Arch. f. Klin. Chir., 1912, c., 193.

[2] See H. Braun: Die örtliche Betäubung. Leipzig. 1925. p. 279.

In a normal individual the point of entry of the needle should be a little higher, but as most of the cases with which one has to deal are edentulous the point we have given is usually the best. In most cases it will be found that the foramen ovale lies precisely on a line between this point and the lambda, and it is therefore wise, in the first instance, to direct the needle slightly in front of this line in order that the base of the skull may be identified. Unless this precaution is taken one may easily enter the skull without touching the bone, and it is then impossible to establish the depth of the point of the needle with any certainty. The lambda is my own landmark, and is far simpler than those described by Hartel. It is easily felt as a depression on practicaly every skull, and if the index-finger of the left hand is placed on this point it will be found a very easy matter to direct the needle towards it. 1 c.cm. of 60 per cent. alcohol containing 2 per cent. of beta eucaine is now injected very slowly, when an immediate total paralysis of the fifth nerve should result, as is at once proved by the abolition of the corneal reflex. The time of the injection may with advantage be extended over as much as two minutes, the slowness of the injection increasing the certainty of the result. The eyelids are now gently drawn together by a fine silkworm suture, and in a conscious patient the painless insertion of this is in itself evidence of a successful injection. The suture is left in place for five days, the eye being carefully washed out twice a day with weak boric lotion, and if this precaution is taken it will be found that all risk of corneal ulcer is avoided.

FIG. 2



If the injection is carried out as described it is without danger, and the results are in many cases permanent. Certain contingencies must, however, be avoided. If the needle is passed too far it will enter the posterior fossa of the skull, and the injection of alcohol may paralyse the sixth, seventh, and eighth nerves, and may even injure the medulla. Such a catastrophe may, however, be avoided by noting the escape of cerebro-spinal fluid from the needle, and if this happens the alcohol must on no account be injected until the needle has been sufficiently withdrawn. If the ganglion itself is not entered the result will not be permanent, since the alcohol only reaches the nerve trunks, which can regenerate. If the needle is pointed too far backwards it may enter the Eustachian tube and alcohol may be injected into the middle ear, producing great pain.

In almost every case there will be a complete paralysis of the muscles of mastication on that side, but in many cases this is temporary, for with regeneration of the motor roots, the nucleus of which is of course not affected, the muscles may regain their power. In the rare cases where a bilateral injection is ultimately required this point is of great importance, since a bilateral paralysis of the muscles of the jaw would be an impossible condition.

I prefer to carry out the operation without general anæsthesia as the coöperation of the patient is a considerable help. The preliminary injection of a little 1 per cent. novocain along the track of injection saves the patient from any considerable pain, but as in many cases one is dealing with a patient exhausted by suffering I usually give half an hour beforehand gr. 1/6 of morphia and gr. 1/150 of scopolamine. If it is preferred there is no objection to a light general anæsthesia, but it must not be sufficient to abolish the corneal reflex, for otherwise the chief indication of the success of the operation is lost.

The operation demands considerable manipulative dexterity and should only be attempted after practice on the cadaver.

IRON IN THE TREATMENT OF SPLENIC ANÆMIA

By L. S. P. Davidson, B.A. Camb., M.D., F.R.C.P. Edin.

REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF ABERDEEN

In its commonest form splenic anæmia may be defined as a chronic disease, characterised by splenomegaly and hypochromic anæmia, with leucopenia, no enlargement of lymphatic glands, a tendency to gastro-intestinal hæmorrhages, and, in the late stages, a liability to cirrhosis of the liver. Histological examination of the spleen reveals pathological changes which are characteristic of this form of the disease group, which corresponds most strictly to "Banti's disease."[1]

The treatment almost universally recommended is splenectomy, preceded, when necessary, by blood transfusion. A study of many of the best-known text-books of medicine shows that iron therapy is believed to be of little or no value. In some books its inefficacy is indicated by absence of any mention of the metal, while in others it is positively stated to be valueless. At the joint meeting of the sections of medicine and surgery of the centenary meeting of the British Medical Association in London (1931), it was stated that the failure to respond to treatment with iron was a valuable point in the differential diagnosis between splenic anæmia and the nutritional anæmia of women, in which achlorhydria is frequently present and some degree of splenomegaly is not uncommon.

My experience of the excellent results which may not infrequently be obtained by iron therapy in splenic anæmia led me to protest against this therapeutic test being accepted as of differential diagnostic value. From what has been said above, it is evident that the view appears to be widely held that iron is of little or no value in the treatment of splenic anæmia. In order to demonstrate that this is not necessarily the case, reports of cases treated with iron are appended below, and illustrate the valuable results which may be obtained. These cases were selected from a larger series which have been under my charge during the past two or three years, because any doubt regarding the correctness of clinical diagnosis was subsequently satisfied by histological examination of the spleen.

CASE RECORDS

CASE 1.—Female, aged 22, domestic servant, admitted to Royal Infirmary, Aberdeen, on Sept. 7th, 1933, complaining of breathlessness and pain in the chest on effort. There was no family history of anæmia, jaundice, or hæmatemesis. The patient had had rheumatic fever in 1932, otherwise no illness of importance. Since the age of 12, when menstruation had started, the patient has always been somewhat pale and breathless on effort. Her periods were irregular and sometimes excessive. At the age of 15 she had had a severe uterine hæmorrhage which necessitated hospitalisation for two weeks. In June, 1932, she was confined and suffered from puerperal sepsis. In July, 1932, she had a sore-throat and pyrexia, which was followed by pain and swelling in her knees, ankles, and fingers. A diagnosis of rheumatic fever was made. The patient was in bed four weeks. In July, 1933, she had a severe epistaxis, but there was no history of hæmoptysis, hæmatemesis, or hæmaturia. Her doctor said that anæmia and enlargement of the spleen had been present for about seven years.

Her nutrition was good but pallor was marked. There was no jaundice or enlargement of lymphatic glands. Temperature was normal, pulse-rate 72, and blood pressure 146/82. The apex-beat of the heart was within the nipple line in the fifth interspace, and there were systolic murmurs at all areas. The spleen was greatly enlarged to below the umbilicus, firm and slightly tender to touch. The liver dullness was slightly decreased; the red cell fragility test was normal. Hess's capillary test was negative. Test-meal showed histamine-fast achylia, no retention of charcoal, and no blood or lactic acid. Blood count on Sept. 11th, 1933, showed: 3,120,000 red cells; 40 per cent. of hæmoglobin; a colour-index of 0·65; 1600 white cells; reticulocytes, 1·4 per cent.; platelets, 275,000; icterus index, 7; van den Bergh reaction positive indirect; and Wassermann reaction negative.

A diagnosis of splenic anæmia was made, and treatment with iron was instituted as a pre-operative measure. Ferrous sulphate exsiccatus, grs. 3, in tablet form, was given thrice daily. A steady improvement in the blood count and clinical condition occurred, and in six weeks the blood count was: red blood-cells, 4,910,000; hæmoglobin, 83 per cent.; colour-index, 0·84; white blood-cells, 2200; reticulocytes, 1 per cent.; platelets, 140,000. The spleen was slightly reduced in size but still reached to the umbilicus. On Oct. 30th splenectomy was successfully carried out by Prof. Learmonth. The spleen weighed 1070 g. On Nov. 9th, after a sore-throat, the patient developed rheumatic fever with numerous swollen and painful joints. She returned to my ward for medical treatment. Examination revealed a pericardial rub and great cardiac dilatation. The apex-beat was felt in the anterior axillary line. Pericardial effusion developed. The patient had a high, swinging temperature, and for three weeks was so critically ill that her life was despaired of. Eventually the condition settled down and the patient was removed to a convalescent home. She returned to the infirmary on Feb. 16th, 1934, greatly improved. The apex-beat had now returned to the nipple line Despite the serious operation and the toxic effects of rheumatic fever, iron administration had maintained her blood level at R.B.C., 4,100,000; Hb., 85 per cent. The patient is now extremely well.

CASE 2.—Female, aged 42, admitted to Royal Infirmary on March 1st, 1932, complaining of general weakness and breathlessness on effort. Her father was said to have been anæmic. Four sisters were alive, all said to be anæmic. Apart from sore-throat and influenza on several occasions, there was nothing of importance in the history. The patient had been anæmic since girlhood, and had never been fit for much exercise or hard work. The weakness had been increasing during the past three years. Menstruation had been regular but somewhat excessive. Two weeks previously she had had a large uterine hæmorrhage, lasting three weeks. Four days before admission she had a small hæmatemesis, and on the night of admission she vomited about one pint of bright blood.

Her nutrition was satisfactory, but pallor was marked. There was no cyanosis, jaundice, or enlargement of lymphatic glands. The tongue was glazed and atrophic, and there were fissures at the angles of the mouth. The nails were slightly flattened and brittle. Temperature was normal, pulse-rate 90, blood pressure 126/58, and the apex-beat at the fifth interspace four and a half inches from the midline. Systolic murmurs were heard at all areas. The spleen was palpable three fingers-breadth below the costal margin. The liver was not enlarged.

Mr. G. S. Davidson reported: "I could find no enlargement of the uterus or any polypus or other local condition to account for the hæmorrhage." Test-meal showed histamine-fast achylia. The red cell fragility test was normal. A blood count on March 7th showed R.B.C., 2,220,000; Hb., 30 per cent.; C.I., 0·68; W.B.C., 6400; reticulocytes, 3 per cent.; icterus index, 7·5; van den Bergh reaction positive indirect; and Wassermann reaction negative.

The patient was given grs. 90 of iron and ammonium citrate daily, and in one month the blood count was R.B.C., 5,560,000; Hb., 84 per cent.: W.B.C., 2800. Blood examination of two of the patient's sisters was made. In one no anæmia was found, while in the other the blood count was: R.B.C., 4,220,000; Hb., 48 per cent.; C.I., 0·57; W.B.C., 4070. A test-meal was given and histamine-fast achylia was found. No enlargement of the spleen was present and iron therapy was successful.

On Nov. 22nd the patient was readmitted to hospital in a collapsed state. Three days previously she had vomited about half a pint of blood. On examination the spleen was found to be enlarged three fingers-breadth below the costal margin. The liver dullness was slightly diminished. The blood count was: R.B.C., 3,690,000; Hb., 66 per cent.;. C.I., 0·9; W.B.C., 11,000; reticulocytes, 1 per cent. The patient continued to take iron, and deep X rays were given to the spleen in order to reduce its size, as a pre-operative measure. She was discharged on Dec. 16th to the convalescent home, and readmitted to the infirmary on Feb. 11th, 1933. She said that a week after her course of deep X rays her abdomen became greatly distended, but gradually became reduced in size again. The spleen was found to reach the umbilicus, and the liver dullness was diminished by two fingers-breadth. A lævulose tolerance test showed no diminution of liver function. The icterus index was 7·5, and the van den Bergh reaction positive indirect. The blood count was: R.B.C., 4,400,000; Hb., 93 per cent.; W.B.C., 2400. On Feb. 20th splenectomy was carried out by Prof. Learmonth. The spleen weighed 422 g. Convalescence was uneventful. The patient continued to take a maintenance dose of iron and reported regularly at the blood clinic. Her blood has been maintained consistently around R.B.C., 5,000,000; and Hb., 100 per cent.

CASE 3.—A married women, aged 41, admitted to the Royal Infirmary on Oct. 26th, 1932, complaining of weakness and breathlessness. There was no family history of anæmia, jaundice, or hæmatemesis. Personal history was satisfactory. Three years ago the patient began to feel tired and breathless on effort, and less fit for her housework. These symptoms have become progressively worse. During the past year she noticed that she had become paler, and that her ankles were swollen at night. Her periods had been regular but recently had become more scanty. There was no history of dyspepsia or gastro-intestinal hæmorrhages.

Nutrition was satisfactory, but the skin pale and somewhat lemon-coloured, and the tongue pale and atrophic. The temperature was normal, the heart-rate 72 at rest, and the blood pressure 132/74. The apex-beat was half an inch within the nipple line in the fifth interspace. Systolic murmurs were present at all areas. There was no enlargement of lymphatic glands anywhere. The spleen was enlarged three fingers-breadth and the liver two fingers-breadth below the costal margin. A lævulose-tolerance test showed no diminution of liver function. The icterus index was 5. Erhlich's aldehyde reaction to urobilinogen was negative. Test-meal showed achlorhydria. The Wassermann reaction test was negative. A blood examination on Oct. 27th showed: R.B.C., 2,630,000; Hb., 20 per cent.; C.I., 0·38; W.B.C., 2400; reticulocytes, 1·7 per cent.

The patient was given grs. 9 of ferrous chloride in tablet form daily, as a pre-operative measure. In four weeks the blood count had risen to R.B.C., 3,940,000; Hb., 65 per cent. The patient continued to take iron and reported at intervals, and on Jan. 4th, 1933, the count was R.B.C., 4,200,000; Hb., 83 per cent. Blood platelets numbered 693,000. On March 4th the blood count was R.B.C., 4,690,000; Hb., 85 per cent. It was decided that the time for operation had arrived, and accordingly *on March 9th splenectomy* was performed. The spleen weighed 430 g. Unfortunately the patient died two days later from acute pulmonary œdema.

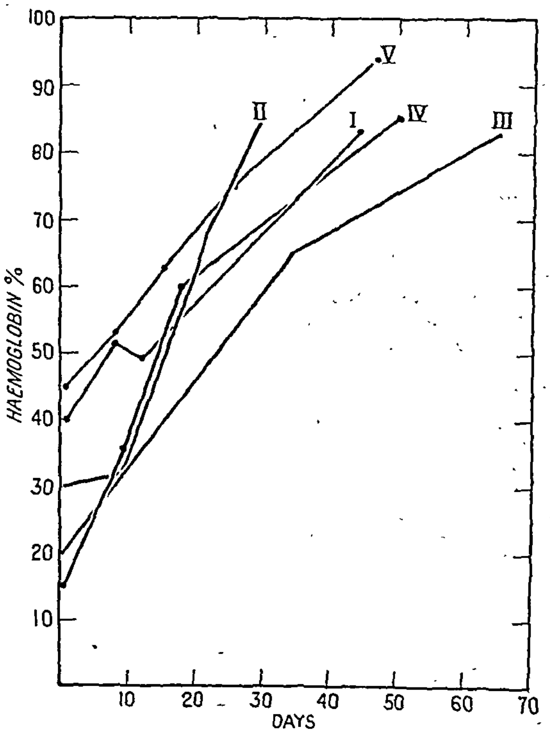
CASE 4.—Male, aged 8, admitted to the Royal Infirmary on Sept. 5th, 1933, complaining of pallor and weakness and vomiting of blood. The family history was satisfactory; there was no history of anæmia, jaundice, or tendency to bleeding. The previous history was also satisfactory. Until recently the boy's general health was stated by his doctor to have been good, although he was always somewhat pale. Five weeks before being admitted to hospital he developed a swelling in the left parotid region, which was not sufficiently large or painful to prevent his swallowing. A diagnosis of mumps was made by his doctor. He had no fever and stayed in bed only for a few days. During this time he was stated to have vomited some dark, tarry material, believed to be blood. Shortly after he got up he vomited a basinful of blood, red and partly clotted. Within the next 24 hours two further hæmatemeses occurred.

His nutrition was poor, with intense pallor, but no jaundice. His temperature was 100°, his pulse-rate 110, and his blood pressure 102/54. The apex-beat was 2¾ in. from the mid-sternal line in the fifth interspace. Systolic murmurs were heard at all areas. There was no enlargement of lymphatic glands anywhere except in the left cervical region, in the area draining the tonsil. The liver was just palpable, and the spleen extended three fingers-breadth below the costal margin. The red cell fragility test was normal, the icterus index 2·5, and the Wassermann reaction negative. A blood count on Sept. 5th showed: R.B.C., 1,400,000; Hb., 15 per cent.; C.I., 0·54; W.B.C., 3800, and very numerous platelets. He was treated with ferrous sulphate, grs. 6 daily, in tablet form. On Sept. 13th the count was: R.B.C., 2,660,000; Hb., 33 per cent.; C.I., 0·62; reticulocytes, 19·5 per cent. On Sept. 22nd the red cells numbered 3,500,000; Hb., 60 per cent. He returned home and continued to take the ferrous sulphate tablets. He was readmitted on Oct. 24th, when the blood count was: R.B.C., 4,780,000; Hb., 85 per cent.; W.B.C., 4000; reticulocytes, 1 per cent., and platelets, 160,000. Splenectomy was performed by Mr. F. K. Smith on Nov. 3rd, the spleen weighing 195 g. The operation was followed by transfusion of half a pint of blood. On Nov. 5th the patient developed a severe hæmoglobinuria, his hæmoglobin falling to 68 per cent. Otherwise convalescence was uninterrupted, and on the day the patient returned home (Nov. 16th) his blood count was: R.B.C., 4,290,000; Hb., 75 per cent.; W.B.C., 12,600. His doctor writes to say that he is back at school and in perfect health.

CASE 5.—Male, aged 32, admitted to Royal Infirmary on Dec. 28th, 1933, complaining of weakness and breathlessness on effort. There was no family history of anæmia, jaundice, or tendency to hæmorrhages. In childhood the patient had measles and whooping-cough, but not scarlet fever, diphtheria, or rheumatic fever. In 1921, at the age of 20, he had jaundice. It was not a severe attack, lasted only a few days, and was not accompanied by vomiting; he did not feel seriously ill. In 1926 his appendix was removed. Four months later he felt weak and ill. In September, 1927, he had a severe gastric hæmorrhage which caused him to faint. He was admitted to hospital on Dec. 27th, 1927, complaining of general weakness. A clear history of hæmatemesis and melæna four months before admittance was obtained. Blood count: R.B.C., 4,600,000; Hb., 85 per cent.; W.B.C., 5400. Examination of the abdomen showed a diminution of liver dullness, while the spleen was palpable. No ascites or enlarged veins were present. A diagnosis of Banti's disease was made, and on Nov. 8th splenectomy was performed by Mr. F. K. Smith. The spleen was enlarged and firm, with many adhesions posteriorly. The liver was hard and nodular. The pathologist reported: "The histological changes present are such as would correspond with Banti's disease." The patient kept well for some months but was readmitted to hospital in November, 1928, suffering from weakness and anæmia following a severe hæmatemesis. Between 1928 and 1933 he had at least five big hæmorrhages from the stomach.

Special Investigations in 1928.—Icterus index, 3·3. Lævulose-tolerance test: the blood-sugar rose from 100 to 146 mg. in one hour, denoting impairment of liver function. Radiogram of stomach and duodenum normal. Test-meal: normal acidity. Wassermann reaction negative.

The patient was first seen by me on Dec. 28th, 1933, when he was admitted under my charge complaining of weakness and breathlessness. The last hæmatemesis had occurred four months previously. Nutrition was satisfactory but pallor extreme. There was no jaundice or enlargement of lymphatic glands, but slight atrophic glossitis of the tongue. The temperature was normal; the pulse-rate 78, and the blood pressure 120/65. The apex-beat was within the nipple line in the fifth interspace. The liver dullness was markedly reduced. There were no enlarged veins and no free fluid in the abdomen. The lævulose-tolerance test was normal (despite the fact that cirrhosis of the liver had been known to be present for seven years). Bromsulphalein test showed definite impairment of liver function. The blood-urea was 23 mg. per 100 c.cm., the icterus index 6, and the Wassermann reaction negative. Blood examination on Dec. 30th showed: R.B.C., 3,150,000; Hb., 45 per cent.; reticulocytes, 1·6 per cent.; W.B.C., 7200. The patient was given grs. 90 of iron and ammonium citrate daily, and in six weeks his count was: R.B.C., 5,200,000; Hb., 94 per cent. ;W.B.C., 6000. The patient has recently reported at the blood clinic, looking and feeling in the best of health.



Graph illustrating the hæmoglobin percentage increase in five cases of splenic anæmia treated with iron.

PATHOLOGICAL EXAMINATION

The spleens were firm in consistence and grossly enlarged. No thrombosis of the splenic veins was found. Sections of the spleens removed from Cases 1, 2, 3, and 4 were examined by Dr. Duncan, pathologist to Aberdeen Royal Infirmary, and myself, and a diagnosis of splenic anæmia was made. The sections were subsequently examined by Dr. J. McMichael, University College Hospital, London, who has made a special study of diseases of the spleen, and who reports as follows: "Histological appearances in the spleens of Cases 1, 2, 3, and 4 correspond to those found in hepatolienal fibrosis. All the spleens showed periarterial hæmorrhage with organisation of the hæmorrhages leading to periarterial fibrosis. The venous sinuses showed definite dilatation, sometimes with moderate increase of collagen in their walls. (By hepatolienal fibrosis is meant that type of 'splenic anæmia' which is *frequently associated with hepatic cirrhosis*; but the pathological features are also found in the absence of gross cirrhosis—so-called 'pre-cirrhotic splenomegaly' or 'Banti's disease in the first stage')."

DISCUSSION

Several conclusions can be drawn from a study of the cases reported above and from the *Figure*. Iron therapy may be equally valuable in the splenic anæmia of (*a*) children or adults, (*b*) males or females, (*c*) as a pre-operative or post-operative measure. Obviously the response to iron treatment cannot be held to be a satisfactory test in the differential diagnosis of the various types of hypochromic anæmia accompanied by splenomegaly. The diagnosis of splenic anæmia, particularly in the early stages before gastric hæmorrhage or cirrhosis of the liver has occurred, is not always easy. The differential diagnosis depends essentially on a process of elimination. The following diseases, in which anæmia and splenomegaly occur, must receive serious consideration:

(1) Acute and chronic infectious diseases, with splenomegaly—e.g., infective endocarditis, malaria, and syphilis.

(2) Pernicious anæmia and the leukæmias, whose diagnosis depends on the presence of the characteristic qualitative changes in the red- and white-cell picture.

(3) The hæmolytic anæmias, such as acholuric jaundice, in which a raised reticulocyte level is present, with a stationary or falling blood level, the fragility of the red cells being usually, but not invariably, increased, and in which an increased serum bilirubin level and indirect van den Bergh reaction will be found. It must be remembered, however, that in the later stages of splenic anæmia a hepatitis may accompany the liver cirrhosis, in which case an increased icterus index and indirect van den Bergh reaction may be found (Cases 1 and 2).

(4) Idiopathic thrombocytopenic purpura. The platelet count in splenic anæmia is usually not decreased.

(5) The nutritional anæmia of women of the child-bearing age, in which a slight or moderate degree of splenomegaly is not infrequently found. As this is the commonest form of anæmia met with in this country, and one in which complete cure results from treatment with iron, it is very desirable that an accurate diagnosis should be made and that the patient should not be submitted to the serious risk of splenectomy.

Leucopenia is undoubtedly an important finding in splenic anæmia but is not always present. Moreover, a low white count is found in cases of nutritional anæmia: in a consecutive series of 100 severe cases 60 per cent. had a white cell count of 6000 or less. In both diseases achlorhydria may or may not be present. Four out of the last eight cases of splenic anæmia under my care had free hydrochloric acid in the gastric juice while the remainder were achlorhydric. Seventy per cent. of the above series of nutritional hypochromic anæmia were achlorhydric. The hypochromic anæmia in each condition is due to iron deficiency, since response to treatment with iron occurs without any alteration in the diet. Investigations carried out in Aberdeen in regard to the ætiology of the *nutritional anæmia* so frequently found in women clearly reveal that the cause of this iron deficiency was dependent on one or a combination of the following factors: (1) deficient intake of iron (high carbohydrate, low protein diet); (2) increased demands for iron (pregnancy and hæmorrhage); (3) decreased absorption of iron (achlorhydria). The same factors frequently play an important part in the production of the anæmia of splenic anæmia. The degree of splenomegaly in the simple nutritional anæmia is, generally speaking, less than in splenic anæmia, and treatment with iron results in the complete disappearance of the enlargement. In splenic anæmia treatment may result in some reduction in size, but I have never seen a spleen return to its normal size once it was definitely palpable.

From what has been said it is obvious that in early cases of splenic anæmia with slight splenomegaly, before hæmatemesis or liver cirrhosis has occurred, the diagnosis must remain in doubt. Accordingly it is advisable to institute iron therapy and watch the case over several months before operative treatment is seriously considered. Failure to do this has resulted in the unnecessary removal of the spleen in cases of simple nutritional anæmia. A gradual enlargement of the spleen and persistence of the leucopenia, despite iron treatment, favour the diagnosis of splenic anæmia.

Space does not permit me to discuss in detail the arguments for and against splenectomy as a therapeutic measure in splenic anæmia. Suffice it to say that there is no evidence that the anæmia is due to blood destruction, and therefore splenectomy cannot be advised for the reasons for which it is carried out in acholuric jaundice; nor is there satisfactory proof that the spleen harbours some infective agent, or that it has some toxic or inhibitory effect on blood formation. The most logical explanation for the beneficial effects claimed for splenectomy appear to rest on anatomical and mechanical foundations. Tying off the splenic artery and veins may be of value in relieving portal congestion and reducing the chances of hæmorrhages from the dilated gastric and œsophageal veins. Unfortunately, statistics show that 50 per cent. of patients with splenic anæmia who have had hæmorrhages before operation continue having them subsequently.

The real claim of the therapeutic value of splenectomy rests on the clinical observation and belief that operation is the best method available for improving the blood condition and prolonging the patient's life. Before this view could be held to be substantiated it would be necessary to compare a series of cases subjected to operation with a series adequately treated with iron and then followed up for many years. Unfortunately, evidence based on such a controlled experiment is wanting. The fact that individual cases have survived operation for periods of five, ten, or twenty years may be of little significance, since splenic anæmia is recognised to be a very slowly progressing disease, and every physician has had patients under his charge who have survived for ten years or longer without any surgical treatment.

It is difficult to understand why iron therapy is believed to be of so little value in splenic anæmia, but the two most probable explanations are (1) the exhibition of inadequate amounts of iron (it is only within the past few years that physicians have learnt once again the value of massive doses of iron) and (2) the estimation of the effects of iron in the treatment of cases of splenic anæmia during the terminal stages of the disease, when gross disturbance of the metabolic functions of the body are present and the bone-marrow is poisoned by toxic products.

In conclusion it may be said that whether one believes that operation is or is not indicated in splenic anæmia, treatment with effective doses of iron (iron and ammonium citrate, grs. 90 daily, Blaud's pills, grs. 45 daily, ferrous sulphate, chloride or carbonate in tablet form, grs. 9 daily) should be tried for at least six to eight weeks before iron therapy is held to have failed. Even in the late stage of the disease some benefit may be obtained. In cases which have not reached the stage of obvious liver cirrhosis, the blood level can always be raised and dramatic results are not infrequently produced, with such improvement in the general clinical state that the surgical risk and the liability to post-operative complications are markedly reduced. There can be little doubt that Case 1, who developed rheumatic fever and pericarditis two weeks subsequent to splenectomy, might have died if successful pre-operative treatment with iron had not been undertaken. Transfusion of blood, as a pre-operative or post-operative procedure, will be required much less frequently if adequate time is given to efficient iron treatment. Transfusion should be considered an emergency measure for raising the oxygen-carrying capacity of the blood, quickly and temporarily. Far from being a direct bone-marrow stimulant, it is the reverse, since by relieving the bone-marrow of its physiological stimulation to response (anoxæmia) it depresses function. The rise in the hæmoglobin level which results from increased activity of the patient's own formative tissues is far more valuable and permanent than the temporary rise which can be obtained by artificial means. After operation, iron treatment should be continued until a normal hæmoglobin value, if possible, has been obtained, and a small maintenance dose (ferrous sulphate grs. 3–6 daily, in tablet form) should be given. Iron is also of the greatest value in the treatment of the post-hæmorrhagic anæmia which follows hæmatemesis, whether this complication has occurred before or after operation.

DELAYED CHLOROFORM POISONING

By T. F. Todd, M.B. Lond., F.R.C.S. Eng., M.C.O.G.
RESIDENT SURGICAL OFFICER, ROYAL INFIRMARY, PRESTON

The existence of delayed chloroform poisoning seems largely accepted without question by the medical profession. As a student one is taught that such a condition may follow chloroform anæsthesia and cause death in about a week. In some quarters there is considerable opposition to the use of chloroform as an anæsthetic on any account; yet practitioners of 20 or 30 years' experience affirm that they have used it in thousands of cases without any detrimental effect as far as they could judge. Whichever view is held, there is agreement that delayed chloroform poisoning is extremely rare. The case recorded below has several unusual features.

Mrs. A., aged 25, was admitted to the maternity department for disproportion. She had had a dilatation and curettage 14 months previously for so-called endometritis. She had had no other trouble, and this was her first pregnancy. It was progressing normally, but the patient was uncertain about her dates. She was attending an antenatal clinic outside, and was referred to the maternity department because of apparent disproportion.

On examination the patient was seen to be in good general health, with a pregnancy about full term. The uterus was considerably larger than the normal full-term uterus and twin pregnancy was suspected. Only one fœtus could be distinguished on clinical examination and radiography showed a normal vertex presentation with the head engaged. The distension was presumed to be due to excess of liquor. The blood pressure and urine were normal. Induction of labour was decided on in view of the patient's mechanical distress and her uncertainty about her dates. A stomach-tube was introduced into the lower uterine segment the day after admission, under chloroform and ether anæsthesia. The induction of anæsthesia was with a mixture containing one part of chloroform and two parts of ether, and the maintenance was with pure ether. The whole procedure was short and the anæsthetist estimated that not more than 4 drachms of chloroform were used.

On coming round from the anæsthetic the patient vomited once, but she was then quite fit until the following day when she vomited several times. Labour had not commenced 40 hours after the induction, so quinine grs. 5 was given intramuscularly (in view of the emesis). Twelve hours later the tube was removed and the membranes were ruptured. Morphia, gr. ¼, had been given on both nights so far, and the patient's condition was satisfactory except for the anxiety the vomiting was causing. This progressed, however, and could not be checked. After the rupture of the membranes labour did commence but advanced very slowly, the cervix being only at half a crown dilatation at the end of 24 hours. The patient drowsed fitfully during the third day. The next morning, approximately four days from the time of the induction, she became comatose. The coma became quite deep very soon, and no response could be obtained to stimulation. For the first time the urine contained a trace of albumin, and ketones were also present. The pulse-rate became much more rapid and the pulse feeble, and two pints of gum saline with 200 c.cm. of 50 per cent. glucose were given intravenously. This was followed by continuous intravenous infusion of 10 per cent. glucose in saline. After three hours the patient gradually came out of her coma and could just respond to questions by movements of her head. Her general condition remained very poor and, in spite of the continued intravenous therapy, she died just over 100 hours from the time the anæsthetic was administered. There was no suggestion of jaundice during life, but after death the skin appeared slightly icteric.

Post-mortem examination showed a normal full-term pregnancy with labour advanced so that the cervix was just over half dilated. The fœtus was commencing to peel. There was no abnormality in the pelvis. There was some œdema of the base of both lungs. There was obvious cloudy swelling of the kidneys, but no evident necrosis or hæmorrhages. The liver was of normal size, but showed considerable wrinkling of the capsules and marked focal fatty change. Macroscopically the liver resembled what one would expect in a case of delayed chloroform poisoning, and microscopical examination of sections confirmed this view. There was generalised fatty degeneration and occasional microscopic hæmorrhages. The bulk of the liver cells were necrotic, the only cells relatively unaffected forming a small peripheral zone of the lobule, and even these showed cloudy swelling. The picture was that of an extensive central necrosis. The sections of the kidney showed a very marked generalised cloudy swelling, but nothing else was definite.

An alternative diagnosis from the microscopical picture alone would be necrosis due to intense sepsis, as in septicæmias or some varieties of general peritonitis. Neither of these possibilities was present and the diagnosis of chloroform necrosis is, I think, secure.

DISCUSSION

The features of most interest in this case were the occurrence of poisoning after an exceptionally small amount of chloroform, the absence of any convulsions or jaundice, and the temporary recovery from coma after massive intravenous glucose therapy. It will be remembered that the patient had had a similar general anæsthetic 14 months previously for a dilatation and curettage. She had had no post-operative symptoms on that occasion. Even had chloroform poisoning been threatening then but recovered from, there is no reason to presume any permanent damage.[1]

I have the impression that there was probably a marked idiosyncratic factor, in view of the rarity of chloroform poisoning even in cases where prolonged anæsthesia had been maintained with pure chloroform. D. N. Paton quotes the experiments of Whipple and Sperring on dogs, where they showed a wide variation in individual susceptibility, and stated that chloroform anæsthesia maintained for 35 minutes can cause fatal poisoning with almost complete liver necrosis. In the same paper he concludes that the experimental evidence points to the primary action of chloroform being due to its fixation by tissue cells, the degree of fixation depending upon the vascularity of the tissue and its lipoid content: and to its power of checking and finally stopping the processes of oxidation in them—thus ultimately killing them while accelerating the disintegrating necrobiotic processes which are the cause of late chloroform poisoning. The brain cells are most sensitive to anoxæmia; this fact, and the enormous blood-supply to the grey matter carrying the chloroform abundantly to the brain cells, explains the loss of consciousness. The remaining symptoms can be appreciated as due to the liver necrosis.

The most recent publication on the subject is a case report by Stander.[2] He remarks that as little as 2 oz. of chloroform used to induce surgical anæsthesia is sufficient to produce delayed poisoning. (In the case reported here certainly not more than four drachms were used.) He also comments on the fact that jaundice need not necessarily develop. He considers that the only place for chloroform anæsthesia in obstetrics is late in the second stage when it should be administered in whiffs with an abundant supply of air; even then it is not advised. Munro Kerr[3] remarks that it has taken several generations to stamp out the idea that chloroform is a safe anæsthetic in labour under all circumstances. While admitting its utility in domiciliary practice, he condemns its use in the presence of any variety of toxæmia or in prolonged labour. He advocates the substitution of local anæsthesia in carrying out an episiotomy or repairing a torn perineum. He insists that in all cases it is desirable to reduce as far as possible the amount of chloroform used.

The recent prominence given to the use of chloroform capsules during labour focuses attention once more on the possible idiosyncratic factor in chloroform poisoning. These capsules contain ♏20 of chloroform and it is not usual to use more than three. In other words, one drachm of chloroform is about the average. Rivett[4] states that capsules have been used in about 4000 cases without any fœtal or maternal death due to the chloroform. Certainly this statement should carry sufficient weight to exclude the existence of any marked idiosyncratic factor. The fact that a pregnant woman in a good condition of general health can die from acute liver necrosis four days after receiving less than 4 drachms of chloroform in mixed anæsthesia forces one to consider the existence of a definite pregnancy factor which can disorganise normal liver metabolism to such a degree that a small dose of poison can produce a general necrosis. It is known that fatty infiltration occurs in the central portion of the liver lobules in the later months of pregnancy, and this explains the occurrence of central zonal necrosis due to chloroform. Possibly the elucidation of the true ætiology of the toxæmias of pregnancy is more intimately associated with a fuller understanding of liver metabolism than has hitherto been realised.

I am indebted to Mr. K. M. Duncan, senior surgeon to the Royal Infirmary, Preston, for permission to publish this case.

COLLES'S FRACTURE

By Simon Holzman, M.B. Lond.

RESIDENT HOUSE SURGEON, ROYAL CRIPPLES HOSPITAL, BIRMINGHAM

Usual descriptions of the Colles fracture emphasise the break of the radius, generally oblique, and may add the injury to the ulnar styloid or its ligament. They lay no stress on the possibility of carpal displacement; yet of 26 cases treated at the Coventry and Warwickshire Hospital under my observation, two-thirds showed a complete break of the styloid process and this is an injury which immediately produces, or tends to produce, a radial displacement of the carpus relative to the separately displaced lower end of the radius. Fragmentation of the tip of the ulnar styloid process was seen in a few cases, and none of the 26 patients is likely to have escaped severe trauma of the internal lateral ligament.

The cases clearly demonstrated that deformity not infrequently develops after reduction—contrary to the accepted views, but in conformity with the experience of some of my colleagues. This may happen in at least two ways. For example, the radius may be maintained in position but owing to the fractured ulnar styloid the carpus slips radially (Case 1, Fig. 1); or the displacement of the radius may recur gradually after removal of the splint, as clearly illustrated in Case 2 (Fig. 2). In this case, at the third week, when the plaster was removed, there was no sign of radial deformity. No further support was given to the fracture but a gradual return, and then exaggeration, of the original deformity took place. Minor degrees of redisplacement were noted in other cases despite the fact that at the second week, when splintage had been discontinued, the wrist appeared normal in shape. Four of the cases were treated with a skeleton type of splint on the lines of a Delbet. The fractured radius was supported by a plaster cuff, steadied in position by a narrow ulnar strip held at the upper end of the forearm by a turn of Flexoplast (Case 1). About 40° of painless passive flexion and 40° of extension of the wrist were possible at the tenth day. The range of movement then only slowly increased and the final results were fair in two and poor in two. A radiogram of one of these (Case 1, Fig. 1 c) showed that the radius was maintained in position, but the ulnar styloid process was fractured and the carpus had slipped to produce a radial deformity of the wrist, with consequent weakness and delay in recovery.

These two important causes of failure to obtain a perfect result caused me to review my own and other methods of splinting and after-treatment. I am now using an unpadded plaster splint, which is based on the displacements occurring in this injury and the principles of the separate methods in use. The after-care was similarly evolved from these sources.

The splint I use consists of an encircling plaster covering a little more than the lower two-thirds of the forearm and extending to the metacarpal bases (Fig. 3). It is applied with the wrist in flexion and ulnar deviation. The wrist, still being kept in ulnar deviation, is then a little dorsiflexed. An anterior plaster strip is added. This extends to the distal palmar crease and more laterally to the thumb metacarpophalangeal joint. It is moulded to the palm of the hand and its borders.

Active movements can be readily carried out as the fingers are free, the wrist is in the position of function from the beginning, and an appreciable amount of extension is possible with much (and increasing) pronation and supination. The fractured end of the radius is held in position and the fractured ulnar styloid, or sprained ligament, is held relaxed. The splint is removed in three weeks and, as recurrence is possible even after this period, I then use an unpadded moulded plaster cock-up splint, which is worn at night only. Its use then counteracts the daytime tendency to displacement, prevents unconscious strain, and without exception allows greater ease of joint movement in the morning. It earns the gratitude of patients, who without it are in constant fear of being seriously injured when asleep.

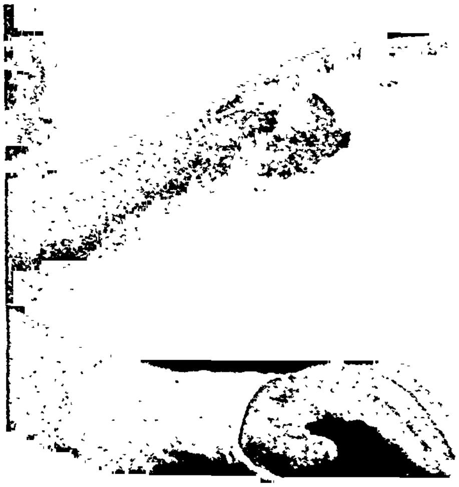

FIG. 3.—Photographs of the splint.

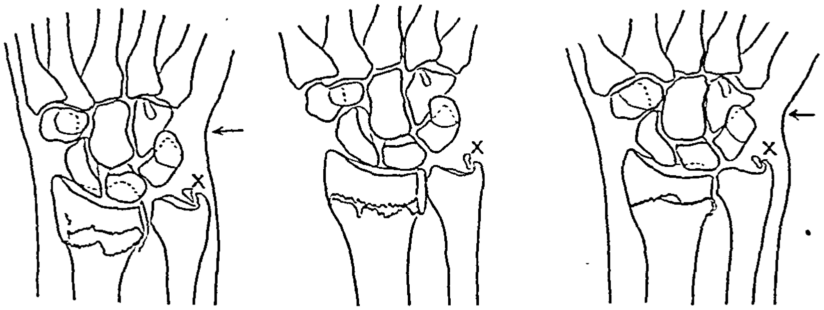
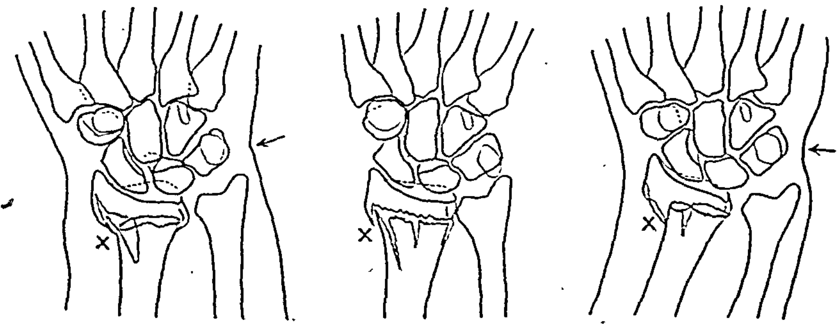
Careful after-treatment is an essential of success. It is the summation of gradually increasing active movement, which, if conscientiously carried out by the patient, hardly needs the aid of massage (Case 3). A useful list of exercises is enumerated in Böhler's book,[1] and I also use the following exercises in conjunction with those advocated by him: towel-wringing, for pronation and supination; squeezing of a Sorbo ball; walking fingers up the wall; turning of handles; and later the use of a mincing machine or mangle. For the first three weeks the hand is in the plaster splint described, and generally without a sling. The plaster splint must then be replaced by the anterior plaster shell, to be used at night for as long as the patient wants it. The treatment of the uncommon refractory case is supplemented by massage, ionisation, diathermy, radiant heat, or infra-red irradiation—in order of preference.

Direct contact with the cases has served, even more than the figures, to emphasise the advantages of the splints and after-treatment described. I was impressed by the quick recovery and negligible massage requirement, criteria which on further consideration were overshadowed by the uniform absence of any but the slightest deformity (despite the patients' high average age of 58), and a freedom of movement on discharge, usually almost equal to normal. I do not consider lack of deformity in this fracture purely an æsthetic consideration, important as this factor could easily be, but as the joint surfaces are again relatively normal, the not uncommon painful joint should be almost obviated and this, together with the freedom of movement, suggests that a continued excellent functional result is probable.



(a) Before reduction. (b) After reduction. (c) Five weeks later.

FIG. 1.—Drawings from radiograms in Case 1. The arrow indicates the visible deformity at the wrist; the cross shows the fracture producing the deformity.



(a) Before reduction. (b) After reduction. (c) Nine weeks later.

FIG. 2.—Radiograms from Case 2.

The following are illustrative cases :—

CASE 1 (Fig. 1).—Female aged 51. Treatment 11½ weeks. The fractured radius only was supported, the joint being left free for immediate active movement. The deformity was first noticed at the 36th day and radiography then showed that there was no lateral displacement of the radius, but that the clinical deformity was due to the carpus. Its ulnar attachment had become elongated, allowing it to tilt over to the radial side. The displacement progressed during treatment and was very much more conspicuous on discharge.

CASE 2 (Fig. 2).—Female aged 63. Treatment 9 weeks. The joint as well as the radius was supported for three weeks and the wrist then being almost normal in appearance no further support was given. Radial deformity became apparent and gradually increased until at discharge it had become very obvious. Lack of tendency to redisplace is considered a feature of this fracture but at least one of my colleague's cases was even more markedly affected in this way.

---

[1] Böhler, L.: Treatment of Fractures, Vienna, 1929.

CASE 3.—Female aged 51. Treatment 6 weeks. Hers is the most recent of the cases treated strictly in accord with the method described. The result is excellent. She has 80° of supination and 90° of pronation. The joint looks perfectly normal, there is no pain, and she is able to do work as hard as the washing of all her clothes.

The remaining cases treated in the same way were older and produced results almost as good as this one.

CLINICAL AND LABORATORY NOTES

ERYTHEMA NODOSUM

TREATED WITH ANTISTREPTOCOCCAL SERUM

By Gerald Slot, M.D., M.R.C.P. Lond., D.P.H.

SENIOR PHYSICIAN, ROYAL WATERLOO HOSPITAL, AND ROYAL HOSPITAL, RICHMOND; PÆDIATRICIAN, AND PHYSICIAN IN CHARGE OF RHEUMATIC SUPERVISORY CENTRE, LONDON COUNTY COUNCIL

THE cases here recorded suggest that antistreptococcal (scarlatinal) serum is a valuable means of treatment in erythema nodosum. Case 4 was the most striking, but in all the others there was rapid improvement, with less constitutional disturbance than would have been expected with previous methods of treatment. The trouble subsided in each case within 24 hours, and the only sign of reaction was in Case 3, where the patient had mild transient joint pain and pyrexia eight days after the last injection. The improvement obtained by the use of this serum seems to bear out the view that the cases were all streptococcal in origin, especially as in all of them there was sore-throat from one to four days before the appearance of the eruption. I realise that in Case 1 gold might have been blamed, especially as the eruption was profuse and widespread but, apart from the aurotherapy, the case does not seem different from the others; there was a preceding tonsillitis and the temperature subsided on the administration of serum.

CASE 1.—Married woman, aged 49. Admitted for arthritis and treatment by aurotherapy. On Feb. 7th 0·05 g. of Myocrysin was injected intramuscularly; she vomited twice on the following day. On Feb. 13th and 16th 0·1 and 0·2 g. respectively were given. On Feb. 17th she developed follicular tonsillitis; swabs showed micrococci and *Oidum albicans*. On Feb. 21st she developed an extensive erythema nodosum on the legs, forearms and buttocks and along the spine. She had a temperature during the last four days varying between 100° and 102°. On Feb. 26th 10 c.cm. of antiscarlatinal serum was given, and the temperature fell to normal within 12 hours; the rash faded simultaneously and by March 9th the erythema nodosum had cleared. It should be mentioned that in view of the possibility that gold was a factor in this case, she was also treated with Ametox, a preparation of sodium hyposulphite.

CASE 2.—A married woman, admitted on March 27th with erythema nodosum and hæmorrhagic nephritis. The urine and clinical picture were typically those of toxæmic kidney containing blood and albumin, but cultures were sterile. There was no history of sore-throats; the tonsils were small and slightly infected. Her temperature was 101°. She had had rheumatic fever some years before; the date is somewhat uncertain and she had had pains in her joints at times since. The erythema nodosum was typical; raised, red, tender patches extended from the knee to the ankle on the anterior surface of both legs. Besides the appropriate nephritic diet she was treated with 20 c.cm. of antiscarlatinal serum intramuscularly on March 28th. The temperature fell to normal on April 1st. It was noticeable that the rash gradually disappeared after the injection, and by April 2nd had disappeared completely. The nephritic condition cleared up and she was discharged completely well on April 21st.

CASE 3.—A married woman, aged 37. Fourteen days before admission she had tonsillitis with herpes labialis; this was followed by painful red swellings on the shins and thighs and pains in the joints, which were stiff but not appreciably swollen. On admission to hospital the joints were all normal, but there were several areas of erythema nodosum on both legs. Antiscarlatinal serum was given, and in two days the eruption had cleared up. On the eighth day she had a slight pyrexia and some joint pains, possibly due to a serum reaction; otherwise she rapidly improved, and in nine days the rash had completely disappeared. The heart and lungs were clinically normal and there was no suspicion of tuberculosis either in her history or on examination.

CASE 4.—A boy, 10 years old, was admitted under the care of my colleague, Dr. Cecil Bull, to whom I am grateful for permission to mention this case. This child had tonsillitis, which was followed four days later by extensive erythema nodosum on both legs, joint pains, malaise, and a temperature of 100°. The heart and lungs were clear. Ten c.cm. of antistreptococcal serum was given; the temperature dropped immediately to normal and the whole condition cleared up in four days.

The ætiology of erythema nodosum is still obscure. Full accounts and discussions of the various theories have been written recently by Collis [1] and by Pierre Fornara.[2] The three main views held are:—

(1) That it is a specific infection or an affection sui generis. This view has been advanced by writers from Trousseau onwards and has the support of Robert Hutchison, who in a personal communication quoted by Collis states that he believes it is a nodal fever. E. C. Rosenow claims to have found a specific organism which gains entry to the body through the tonsils and, although cases have been reported in the same family, this is extremely rare and the disease is not contagious.

(2) Many authorities believe that it is a manifestation of tuberculosis, and this view is widely held by the French and Swedish schools. Collis believes that the majority of cases fit into this group and has brought evidence that many give a positive reaction to one or other of the tuberculin skin tests and that in children the hilar glands are frequently enlarged. It is further stated that if no evidence of tuberculosis is found at the time of the eruption when followed up, many of these cases will be found to develop clinical evidence of disease at a later date.

(3) That it is a manifestation of rheumatism. This is supported by the fact that tonsillitis and joint pains may precede or accompany the eruption, and that it may be followed in a percentage of cases by cardiac lesions. These facts have led to the belief that erythema nodosum is but one of the variant manifestations in which rheumatism may attack the body. Its association, however, with active cardiac lesions is very uncommon, and its association with sore-throat and joint pains, while admittedly suggestive of a rheumatic origin, can only so far be regarded as a manifestation of the toxæmia with a primary source of infection in the throat.

(4) That it is a manifestation of toxæmia, not due to a specific organism but as a reaction to various types of toxin; hence it may be due to tuberculin in one case and to a streptococcal infection in another.

In London, at any rate, the majority of cases seem to be due to a streptococcal infection and not to tuberculosis, and the treatment and results described offer support of this view.

I would like to express my thanks to Dr. P. M. Deville, medical registrar to the Royal Waterloo Hospital, for much help in the compilation of this note.

ANEURYSM OF THE FEMORAL ARTERY

By F. D. Saner, F.R.C.S. Eng.
SURGEON TO THE ROYAL NORTHERN HOSPITAL, LONDON

Mrs. A. was referred to me by Dr. I. W. Laing on account of a painful tender swelling of the left thigh. On May 2nd she had developed tonsillitis followed by some enlargement of a gland in the neck. The temperature, which was unusually high, did not drop as the local condition improved, so she was admitted to hospital. After some ten days the temperature became normal, but being rather weak she was kept in hospital a further two to three weeks. The diagnosis was "influenza and tonsillitis." On discharge from hospital the gland in the neck had not entirely cleared and a few days after her return home a small abscess formed which was treated by her doctor and healed uneventfully. During the latter part of her stay in hospital and also at home there had been pain and aching in the left thigh; this being attributed by the patient to "rheumatism" was not mentioned until June 12th when the thigh began to swell. During the next two days the swelling rapidly increased in size, the pain was severe, and there was some rise of temperature, 100°–101° F. On the 15th admission was arranged to the private section of the Royal Northern Hospital.

The temperature on admission was 100·6° F., the pulse-rate 100. The patient, a spare woman, looked ill and complained of considerable pain in the left thigh, described as throbbing in character. The throat appeared normal, the neck was clear, and there was no evidence of any lesion in the chest or abdomen. On examination of the thigh a large rounded swelling (some 4 in. by 4 in.) was seen mainly on the inner aspect and towards the front of the junction of the middle and lower thirds. Except for engorgement of several big veins on the surface the skin was normal in appearance, it was not hot nor œdematous. The mass itself was dense, apparently confluent with the inner aspect of the bone, and very tender; on pressure there was thought to be deep fluctuation. There was no pulsation in the mass nor was it pulsatile, no thrill was felt; the temperature of the legs and feet appeared to be about the same, while the pulses at the ankles were thought to be equal; but, admittedly, sufficiently close attention was not paid to elicit any difference. Nor was a bruit listened for in the thigh.

Next morning the local condition was about the same; there was, however, a further slight rise in the temperature and pulse-rate, while through the night, in spite of sedatives, sleep had been considerably curtailed by pain. In radiograms taken of the thigh no abnormality could be detected of the bone or soft tissues. It was decided to advise that the swelling be explored. Under general anæsthesia an exploring needle was inserted in two or three places near its centre, but except for a little serum nothing could be extracted. A small incision was then made through the skin and muscle sheath when on separation of the muscle-fibres there was a rapid escape of blood clot followed by a gush of blood obviously from the main vessel. The wound was packed while the artery was exposed in Scarpa's triangle—pressure on which was found to control the hæmorrhage—and ligatured immediately below the origin of the deep branch. The original incision was left open.

Though during the next 48 hours the circulation in the leg was maintained, the foot and ankle remained cold and white from the time of the operation and gradually became discoloured. On the third day after the operation the discoloration was spreading up the back of the leg and since the pain in the thigh itself was undiminished and the general condition depreciating, amputation was advised and performed, but was survived only by a few hours. During the amputation as the muscles of the thigh were divided further blood clot was liberated together with some two or three drachms of pus.

The following is a description by Dr. Sholto Mackenzie of the post-mortem findings in the leg:—

About 1 in. distal to the point at which the femoral artery emerges from the adductor magnus there is a fusiform dilatation of the vessel wall some 2½ in. long and 1½ in. wide with a perforation on the anterior wall at its centre. This dilatation on opening proved to be an aneurysm in which the coats of the vessels were split, resembling in this respect a dissecting aneurysm. Immediately posterior and lateral to the aneurysm is an abscess cavity containing about 2 oz. of pus, but there is no obvious communication between the two. The vessel below the aneurysm was full of ante-mortem clot.

The provisional diagnosis before the exploration was that the condition was an inflammatory one—which proved correct to a point—but the absence of heat or œdema of the skin threw some doubts on the diagnosis. As an alternative there was the possibility of it being an aneurysmal swelling which, however, appeared to be excluded by the complete absence of pulsation or thrill; the presence of a combination of the two was not suspected and permission therefore for an amputation was not sought in the first instance.

It seems probable that during the original attack of tonsillitis a septic embolus lodged in the wall of the femoral artery producing an abscess in the vessel itself and its immediate surroundings.

TRYPAN-BLUE INTRAVENOUSLY IN POST-ENCEPHALITIC PARKINSONISM

By W. McCartan, M.D. Belf., D.P.H., D.P.M.
FIRST ASSISTANT MEDICAL OFFICER, WEST PARK MENTAL HOSPITAL, EPSOM

An annotation appeared in The Lancet of June 18th, 1932, summarising the work of Laignel-Lavastine and Jean Sterne [1] on the treatment of the parkinsonian sequelæ of epidemic encephalitis by trypan-blue. This publication was later reprinted [2] but has apparently received little attention in this country, and some observations on the use of the dye in similar cases may be of interest.

At West Park there are a number of patients suffering from post-encephalitic parkinsonism, this being one of the receiving hospitals for London. Most of the patients here have been on substantial doses of tincture of stramonium for some years and this was not withdrawn during the intravenous therapy, since Laignel-Lavastine and Sterne had continued to give scopolamine to their cases and since withholding stramonium rapidly reduces these unfortunates to a much more pitiable state.

A supply of the dye ("purified for physiological purposes") was obtained from British Drug Houses Ltd., and intravenous injections were commenced on three female patients, starting with very small doses and working up to 1 c.cm. Temperature, pulse, and blood pressure were carefully watched but no response of any sort was obtained. It was then felt that one might embark on a larger scale and 11 male patients had several series of injections.

In each case the first series was given in doses of 1 c.cm. at intervals of four days and was discontinued when there was definite evidence of a bluish tinge of the skin. This was noticed along the hair margin of the brow first and cleared up in about a week following the last injection of the series. In subsequent series one felt a little less cautious perhaps and, after an initial injection of 1 c.cm., continued the series in 2 c.cm. doses adhering to the four-day interval which the French workers recommend between each injection. With the 1 c.cm. doses the appearance of the bluish coloration of the skin was very insiduous and in the first patients treated 10 injections were given in the first series before one satisfied oneself that there was a definite tinting of the skin but in later cases 5 or 6 in the first series were the rule. Two months' rest was given between each series. Two patients had 23 injections in all, two had 22, one had 21, one had 20, three had 17, one had 16, and one had 14. These were given in three series except in the case of the patient who had 16 injections and whose injections were discontinued permanently at the end of the second series since his debilitated state did not encourage one to press a new remedy.

---

[1] Laignel-Lavastine, M., and Sterne, J.: Bull. et mém. Soc. méd. hôp. de Paris, 1932, xlviii., 689.

[2] Same authors: Jour. de méd. de Paris, 1933, liii., 14.

The results, apart from an initial feeling of improvement in a few cases in the early stages of the treatment (which was probably largely due to suggestion), were disappointing. None of the patients showed the least benefit. The fact that these results fall so far short of those of Laignel-Lavastine and Sterne may, of course, be explained on the grounds that the treatment was not continued for a sufficiently long period, but it is to be remembered that with these workers the second or third series usually opened up an improvement. Had a single patient at West Park shown any improvement the treatment would have been continued. But vital dyes have frequently been used experimentally to block the reticulo-endothelium and have been shown to seriously impair the production of antibodies,[3] so that the prolonged use of a cumulative substance with this property must surely be fraught with the risk of intercurrent infection.

On the rationale of the treatment Laignel-Lavastine and Sterne are silent. Trypan-blue is known to have a high toxicity for trypanosomes and it has been used in canine piroplasmosis (malignant jaundice). During the late war it was used in certain German military hospitals in the treatment of malaria. Its germicidal activities can, however, hardly be of much use for the relief of post-encephalitic parkinsonism.

Lubin Popoff, in a paper entitled "Resultats obtenus par le bleu de trypan en injections intraveneuses dans certain affections bulleuses,"[4] assumes that the beneficial action found by Laignel-Lavastine and Sterne is to be explained by blockage of the reticulo-endothelium. How that is likely to relieve the parkinsonian syndrome is a little difficult to understand.

Dr. N. Roberts, medical superintendent of West Park Mental Hospital, is to be thanked for permitting me to publish observations on these cases.

REVIEWS AND NOTICES OF BOOKS

The Principles of Heating and Ventilation

By H. M. VERNON, M.A., M.D. London: Edwin Arnold. 1934. Pp. 232. 14s.

THIS valuable book deals with the borderland between physics and physiology. The requirements of modern communities in the matter of warmth and fresh air are much more exacting, both in the home and in the office and workshop, than they were 50 years ago. The development of sources of warmth other than the open fire, and the fierce competition between them, on the one hand, and the British love of fresh air, even indoors, which complicates continental travel, on the other, have stimulated technical advances which have been adequately described. But the principles underlying heating and ventilation have recently been well studied, and Dr. Vernon's monograph is successful in welding into a connected whole the basic information scattered in various journals, including a good deal of original work done by himself.

The author first describes the various devices used by himself and others to supplement the mere determination of air temperature as an indication of the suitability of conditions in room, office, or factory for comfort and efficiency, passing on to consider various systems of heating and ventilation. Since under average conditions radiation accounts for about one-half, convection for one-third, and evaporation for one-fifth of the heat losses of the body, the value of instruments like Hill's kata-thermometer, Dufton's eupathoscope, and the author's globe thermometer, which enable with some precision the effect of any actual set of atmospheric conditions on the human body to be estimated and standards to be laid down, is evident. The heat losses through the walls and other surfaces of buildings are considerable; it is interesting to note that whilst a plain brick wall 9 in. thick will transmit 0·358 of a British thermal unit per hour for each square foot of surface, the difference of temperature being kept at 1° F., and a wall double the thickness transmits 0·218 B.T.U., the transmission of the thinner wall can be reduced to 0·103 by half an inch of plaster on cork-board set in half-inch cement. Concrete walls 12 in. thick transmit more heat than 9 in. brick, as also do stone walls. Stout paper covered with aluminium foil has been found to be an excellent thermal insulator for roof linings and similar purposes.

The costs of heating by various means are often in dispute. According to A. H. Barker, quoted by the author, although the cost for continuous heating by gas fires was more than twice that for coal fires in a seven-roomed house with a calculated heat loss of 87,000 B.T.U. per hour, when regard was paid to the actual times for which the fires were kept running over a period of six months, and the extra cost of cleaning and redecoration for coal-fired rooms, the advantage turned slightly in favour of gas. The various kinds of radiators, including those which are mainly convectors and air warmers as well as those which act mainly by radiation from surfaces heated by hot water or electricity, are described and their merits or demerits discussed. In a chapter on the necessity for ventilation, Dr. Vernon shows how ventilation and heating are inseparably connected. Without ventilation heating leads to discomfort, not because of the toxic effects of the products of respiration, but because the air becomes unbearably hot and humid. He has an interesting paragraph dealing with the effects of occupation on the ionisation of the air. We doubt, however, if he is right in speaking of (p. 142) "condensation nuclei such as particles of dust or smoke." Dust particles do not act as condensation nuclei, as air may be freed from Aitken nuclei while retaining its dust content. Equally adequate are the chapters on ventilation for dwellings, factories in which special industries are carried out, and places of amusement, and the discussion on air conditioning.

The book should be useful to all who have to advise on heating or ventilation as affecting the comfort and efficiency of human beings; it may be helpful also to experts whose knowledge is technical rather than fundamental. It is written in a very readable style and well illustrated.

Essentials of Infant Feeding and Pediatric Practice

By HENRY P. WRIGHT, B.A., M.D., Lecturer in the Department of Pediatrics, McGill University; Physician-in-Chief to the Montreal Children's Hospital. London: Humphrey Milford, Oxford University Press. 1934. Pp. 212. 12*s.* 6*d.*

IN the preface the author states that an attempt has been made to present the modern teaching of pædiatrics in a practical manner for the benefit of the trained nurse, the student of medicine, and the general practitioner. It is perhaps unfortunate that he did not direct his attention more particularly to any one of the three, or else considerably enlarge the scope of the book. As it stands, the sections devoted to disease in childhood are so sketchy as to be of little practical value in either the treatment or understanding of the condition described, or even (to take the basest view) in answering an examination question. Infant feeding, on the other hand, is dealt with more fully, and an excellent summary of the modern views and methods is given. Here again, however, the book fails owing to lack of a definite objective; neither nurse, student, nor practitioner is likely to want a table of values of the mineral ash composition of human and cow's milk given to three places of decimals, whilst even this section is insufficiently full to serve as a book of reference. For instance, the post-operative care and feeding of cases of pyloric stenosis is dealt with briefly and inadequately. It is regrettable that the very real merits of the book, which is clearly based on wide reading and careful assimilation of the best modern teaching of the subject, should be obscured in this way, and it is to be hoped that if a revision of the book is subsequently undertaken, the whole volume will either be devoted exclusively to infant feeding or else considerably enlarged.

Vital Cardiology

By BRUCE WILLIAMSON, M.D., M.R.C.P., Physician, Royal Northern Hospital, London. Edinburgh: E. and S. Livingstone. 1934. Pp. 344. 15*s.*

THE theory of medical practice to-day is based largely on hypothesis, and there is always a danger that hypotheses which are no longer in accordance with the facts may outlive their usefulness because they have been put forward in earlier days by some eminent authority. On the other hand, there is a tendency for new methods both in diagnosis and treatment to attract more attention than is their due, until eventually with lapse of time they find their true level. In this volume the author maintains that the orthodox methods of cardiology as practised to-day are fundamentally wrong, and that we must revert to simpler ideas, if we are to put the subject once more upon right lines. His thesis is that heart rate and heart force (by which he appears to mean stroke-volume) are the only two things which really matter and that all other considerations are of secondary importance. He endeavours to obtain support for this thesis from the teaching of Sir James Mackenzie; but he seems to forget that Mackenzie was in his prime more than a quarter of a century ago. During those 25 years knowledge has considerably advanced, and diagnostic methods such as electrocardiography and radiography of the heart, which were then in their infancy, have now made good and won for themselves a permanent place in clinical medicine. To shut one's eyes to these advances is to adopt an attitude of mind which ignores progress, an attitude which Mackenzie would have been the first to condemn.

Dr. Bruce Williamson's book contains much sound practical advice from the clinical aspect, but it also contains a great deal of arm-chair philosophy which is without scientific basis. Dr. Williamson holds rather unusual views on cardiology and has written this book in defence of these views, but it fails to carry conviction.

Volumetric Analysis

By H. P. STARCK, M.A. Cantab., Head of the Science Department, Technical College, Kingston-on-Thames. London: Baillière, Tindall and Cox. 1934. Pp. 228, with an appendix on Qualitative Analysis (pp. 31). 7*s.* 6*d.*

VOLUMETRIC analyses cannot be made unless the apparatus has been freed from grease and has been calibrated. Any good book on the subject must emphasise these preliminaries and describe how they are best carried out. Further, such a book should contain a clear and readable section on the theory and use of indicators. In these essentials Mr. Starck's book is not wanting. The book is noteworthy too in containing descriptions of a large number of analyses of pharmaceutical products for the benefit of students of pharmacy. But in congratulating the author on the soundness of his text, we would put in a gentle protest against some of his expressions. To "factorise" a solution (p. 30), meaning to determine its exact strength, may be pithy but it is not good English, and is there not loose thinking in the phrase "if the standard acid . . . has a factor" (p. 61)? By request the book contains an inset of good qualitative analysis tables.

Essentials of Histology

Thirteenth edition. By Sir E. SHARPEY-SCHAFER, F.R.S. Edited by H. M. CARLETON, M.A., B.Sc., D.Phil., Lecturer on Histology in the University of Oxford; Research Fellow of New College, Oxford. London: Longmans, Green and Co. 1934. Pp. 618. 15*s.*

THE first twelve editions of Schafer's Essentials of Histology have covered a period of close on fifty years, and for the great part of that time the work has been the standard text-book on the subject for medical students in this country. All these editions have been brought out under the editorship of the original author; the thirteenth, which now appears, has been edited by Dr. H. M. Carleton. The general form of the book has been maintained and most of the alterations are minor ones. The section on hæmopoiesis has been rewritten so as to include an account of the theory of Sabin on the development of blood-cells. The section on bone-formation has also been rearranged and set out in a simplified manner. A certain number of the older illustrations, such as those figuring obsolete microscopes, have been discarded, and several new microphotographs have been introduced. A new coloured drawing illustrating the structure of the anterior lobe of the pituitary gland might well be used to support the argument that good drawings are superior to microphotographs for teaching purposes. It is to be hoped that in future editions many more such drawings will be introduced, and that some of the microphotographs which still figure in the present edition will be replaced.

Practical Physiology of the Sense Organs

By R. J. Lythgoe, M.A., M.D., D.Sc., Reader in the Physiology of the Sense Organs in the University of London. London: Humphrey Milford, Oxford University Press. 1934. Pp. 30. *1s.*

The series of exercises described in this little book is extremely valuable. The experiments are designed as an introduction to the study of the special senses, and naturally more space is devoted to vision than to anything else. The student following this course becomes acquainted with the effect of drugs on the eye, the action of lenses, and the use of instruments. In addition, numerous experiments are made which demonstrate the underlying principles and illustrate the theories of visual perception. The most striking feature is the simplicity of the apparatus required; most of the exercises could be performed in the worst equipped of laboratories. This simplicity is no doubt due in part to the fact that the course has been tried out over a number of years and proved to be a practical proposition; chiefly, however, it is to be attributed to the insight which the author has into his subject and his skilful choice of easy but significant observations.

The Medico-Legal Necropsy

A Symposium held at the Twelfth Annual Convention of the American Society of Clinical Pathologists, June, 1933. Edited by Thomas B. Magath. London: Ballière, Tindall and Cox. 1934. Pp. 167. *11s. 6d.*

This collection of addresses delivered by seven leading American pathologists contains interesting material. Oscar T. Schultz discusses the medico-legal system of the United States of America, and lays particular stress upon the reasons why the coroner system should be abolished and its place taken by a State "medical examiner system." It is his view that "the obscure and political character of this office and the lack of clarity in the statutes defining its duties and authority combine to make the coroner's office an unsatisfactory agency in the administration of justice." Charles Norris, the chief medical examiner of New York City, deals with the general principles of holding medico-legal post-mortems and he reiterates a suggestion which he made several years ago, that in small counties a hospital pathologist and the health officer might assume the rôle of medico-legal experts. He recognises the difficulties of getting such a scheme adopted in his country where, he says, "the coroner's physicians are appointed largely through political influence." British authorities will be divided in the wisdom of the suggestions here made, but most will agree with his contention that "the primary qualification is that he (the person performing the post-mortem examination) must be thoroughly versed in the practical side of pathology; hence a long and varied autopsy experience." A. V. St. George describes the American method of performing post-mortem examinations, and the book contains also a discourse on the pathological anatomy of death by drowning, and a report by Harrison S. Martland, professor of forensic medicine in New York University, on the post-mortem appearances in deaths from shooting, stabbing, cutting, and asphyxia. The latter contains an account, with photographs, of certain findings which are said to be characteristic of gangsters who have been "taken for a ride" and "put on the spot."

The Identification of Firearms and Forensic Ballistics

By Major Gerald Burrard, D.S.O., R.F.A. (ret.). London: Herbert Jenkins Ltd. 1934. Pp. 220. *12s. 6d.*

Major Gerald Burrard, from his wide experience as expert witness in cases where medico-legal problems have been associated with firearm injuries, has become impressed with the prevalent ignorance of the elements of the construction and working of firearms. He has therefore set himself to explain clearly and concisely the fundamental principles of firearms and projectiles in so far as they are related to forensic problems. He describes first the various types of firearms and cartridges, the principles of ignition, combustion, and pressure, and the factors involved in ascertaining the range of a shot; and then deals with the methods of identification of firearms by microscopy of the fired bullets and cartridge case, supplying some excellent photographs and photomicrographs. Extracts from the evidence tendered in court in cases where the author was an expert witness serve to show the vital importance, in cases of this kind, that the medical witness should have a sound knowledge of the weapons involved and of the different lesions likely to be produced by them. "Expert" witnesses should also be skilled in the microscopical identification of the lesions. The essentials of forensic ballistics are here set out in a readable way and the book will fulfil a useful purpose if it helps to prevent avoidable misunderstandings in court and to establish common ground among those concerned in the investigation of injury or death due to firearms.

The Lyophilic Golloids

Their Theory and Practice. By Martin H. Fischer, Professor of Physiology in the University of Cincinnati; and Marian O. Hooker, Research Associate in Physiology in the University of Cincinnati. London: Baillière, Tindall and Cox. Pp. 246. *22s. 6d.*

Prof. Fischer's work on physical chemistry, particularly in relation to œdema, is so well known as to commend any publication of his to a wide circle. The present volume deals with researches carried out in his laboratory during the last 15 years and is divided into three parts. The first section is concerned with the general principles and behaviour of lyophilic colloids, a detailed study being given of a series of well-known systems—e.g., phenol/water, quinolin/water, and certain soap/ and gelatin/water systems. The second deals very briefly with the chemical application of these systems. The final section is concerned with the biological application of the two preceding sections and is the most interesting to the medical and physiological reader. No one who wants to understand the mechanism of œdema can afford to leave it unread.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 15, 1934

A NEW VIEW OF PSORIASIS

A NOTABLE contribution towards the solution of the problem of psoriasis, perhaps the greatest and most elusive in the domain of dermatology, appears to have been made by Prof. O. GRÜTZ, of Wuppertal-Elberfeld, in a lecture given to the Berliner medizinische Gesellschaft on June 6th last and published in the *Deutsche medizinische Wochenschrift*, July 13th, 1934, p. 1039. His hypothesis is based on the histological findings in a case of the disease in which diabetes, with hyperlipoidosis and hypercholesterinæmia were superadded. It was shown by special fat-staining methods that the lipoid substances which had been excreted into the skin, with the production of characteristic xanthoma nodules, were present in great abundance in the parakeratotic scales which are the clinical sign manual of psoriasis. This was no new discovery, for excess of cholesterin and lipoid substances had long since been recorded in psoriasis scales by UNNA, LINSER, and others. Its significance had, however, been ignored. GRÜTZ reinvestigated the point, went a step further, and in collaboration with a biochemical colleague Prof. BÜRGER, of Bonn, has now examined the lipoidal content of the blood of a large number of psoriatics. This had previously been done by PULEY and BRILL, but they appear to have contented themselves with only one or two examinations of each case and to have found no abnormality. A physician suspecting hyperglycæmia would hardly be satisfied with a single negative blood examination; the GRÜTZ-BÜRGER series of blood examinations appear to have been conducted on the lines of those which are now in use in the diagnosis and management of cases of diabetes before a routine has been definitely established.

In brief outline the procedure consists in giving 5 g. of cholesterin in 100 g. olive oil to the fasting subject, and then withdrawing 50 c.cm. of blood at 4, 8, and 24-hourly intervals for examination of the variations in the fat and lipoid of the untreated serum.[1] The alteration in psoriatics as compared with the normal is said to have averaged a 40 per cent. increase of total serum-fat content, together with a pronounced excess of cholesterin and phosphatide compounds. This figure is high enough to render recognition of the characteristic blood state a relatively simple matter, and should make correspondingly easy the task of the pathologists who will be investigating the justification of the claims put forward. If the results confirm BÜRGER's work we shall have to regard psoriasis as due to a disturbance in the metabolism of fats, and the pathogenesis of the disease will afford a close resemblance to that which now pertains for xanthoma. Right or wrong the hypothesis presents us with a key which appears to fit many of the subsidiary locks in the prison which has guarded the secret of psoriasis. On the side of its undoubted hereditary tendency it may be urged that just as diabetes—a carbohydrate dyscrasia—may be familial, so we may have a congenital inability to deal with the metabolism of fats. The effect of arsenic in psoriasis may be due to its influence on general metabolism, including that of fats—the excessive formation of which is sometimes stimulated by arsenical medication. No one would deny this possibility, for thyroid and other endocrine products have been generally accepted as having a favourable influence on the course of the disease in many instances. The benefit of local treatment with tar, chrysarobin, cignolin, and a host of other substances can similarly be explained as a local chemical effect—possibly of oxidation type—on the lipoidal and other fatty substances present in the lesions, while the recurrences after local treatment on this basis require no explanation at all. Nor would it be surprising that the effect of sunlight, ultraviolet light, X rays, and other physical methods should only be temporary.

The scheme of treatment suggested by Prof. GRÜTZ is presented in a very simple table. Fats, oils, cream, butter, cheese, and margarine are banned, and it should be the doctor's aim to reduce fat intake, which cannot be altogether excluded, to a maximum of 20 g. in the adult and 10 g. in children per day. Yolk of egg, in view of its cholesterin content, should also be excluded, although the white is allowed. Such a diet should offer little difficulty even in domestic circles, and calorie requirements are amply covered by carbohydrate and protein intake. There appears to be little danger of serious loss of weight even after months of fat deprivation, and no mention is made of nutritional effects due to the loss of vitamin D. It is quite likely that just as in most cases of hyperglycæmia there is an individual threshold, it would be possible to ascertain the fat and cholesterin tolerance by trial and experiment for each patient suffering from psoriasis, so that he would not necessarily have to endure a completely fat-free diet for the rest of his life. It is evident, so far as the work has gone, that dietary treatment does not and is not expected to cure psoriasis. But if it renders latent the inherent dyscrasia in the metabolism of fats, a patient conforming to the principles laid down by his doctor might reasonably expect to remain immune from attack. The periods of remission, followed by recurrences, which have hitherto been the disheartening fate of victims of this disease will make it impossible to assess the value of this new form of treatment for some years; the case records of Prof. GRÜTZ series are not given in his lecture, but are promised for early publication.

THE TEMPERATURE OF THE BODY

NOT long ago, in connexion with artificial pyrexia, we discussed briefly the principles underlying the maintenance and control of the body temperature.[1] Dr. C. E. LAKIN, in the Lettsomian lectures concluded on p. 586, reviews the subject in greater detail, and in considering the diverse lesions that may give rise to pyrexia indicates several gaps in our knowledge, especially of the part played by the ductless glands. ALBERT SALMON, of Florence, goes further and gives a comprehensive account [2] of his reasons for believing in the paramount importance of the inter-relations of the endocrine organs and autonomic nervous system, while W. CRAMER, in his well-known *monograph on fever and heat regulation*, lays the emphasis on the thyroid-adrenal apparatus, dismissing as a crudely vitalistic conception "the idea of a heat centre or of several centres, which are supposed to function like a thermostat and which in fever are supposed to be 'set' at a higher temperature." Dr. LAKIN gives due weight to differences of opinion on this point; and indeed it is important to retain a clear perception of the issues involved and to bear in mind that the subversive nature of such statements is more apparent than real.

By balancing heat loss against heat production the body is able to correct a rise or fall in temperature before it has gone too far, and this is unquestionably the principle of the thermostat. The real problem is the location and identification of the sensitive element; is this a restricted area in the brain, the sympathetic nervous system as a whole, or one or more of the ductless glands? It must be such that it is able to influence remote structures, for the reaction of the cells themselves is, when heated, to produce more heat, and when cooled to produce less: a vicious type of response which is the negation of temperature control. Some coördinating entity, which is able to balance off the activity of one set of tissues by varying that of another, is a logical necessity. Heat loss, depending on the sweat glands, the arrectores pilorum, and the calibre of the cutaneous blood-vessels, is almost entirely under the influence of the sympathetic and therefore of the thyroid and suprarenal medulla. Heat production, in so far as it depends on the metabolic rate, is subject to the same influences. But there is another aspect of the question. Most of the heat production in the body goes on in the muscles, and these are under voluntary and somatic reflex control; the more active they are, or the higher their degree of tonus, the more heat they produce. To a large extent, therefore, heat production is determined by external conditions, such as the temperature and humidity of the air, affecting tonus, and the expediency or otherwise of exercise. It is not denied that the sympathetic-endocrine factors *may operate somewhere in the chain*, but the starting-point is the state of the muscles. With these facts before us, we may be justified in postulating two convergent systems. The first, controlled by the sympathetic and ductless glands, arranges for a standard rate of metabolism, balanced by an equivalent rate of heat loss; the second gives rise to adventitious increases and decreases in heat production, and depends chiefly on the activity of the voluntary musculature. There is no similar duplication of the methods for heat loss, so that the one group of mechanisms must respond to a change, or threatened change, of temperature however produced. Theoretically the basic sympathetic-endocrine system could arrange for any standard rate of energy production on the part of the cells of the body, these being able to modify it by their degree of functional activity, and so long as heat loss was adequate the temperature would remain constant. There would be three courses open to the body when confronted, say, by a fall in external temperature. It might diminish its heat loss, it might increase by sympathetic activity or the outpouring of thyroid or suprarenal secretions the metabolic rate of all its cells, or it might increase the functional activity of voluntary muscle, which is sufficiently widely distributed through the body to lead to a fairly uniform increase in heat production. There seems no reason at present to give pre-eminence to any of these three methods, and probably all are operative.

In pathological disturbances of any of these three mechanisms, compensation could be brought about by adjustment of the other two, as in hyperthyroidism, and a normal temperature could thus be maintained. Where an abnormal temperature does occur, there must still be compensation once the temperature level is established; only the initial rise or fall is attributable to excess of production over loss or vice versa. Any permanent imbalance must result in a progressive and rapidly fatal rise or fall of temperature. We must therefore grant some importance to the conception of the "setting" of the thermostat, which though it does not explain, allows us to visualise the state of affairs in pyrexia or hypothermia. These conditions cannot be *explained merely in terms* of the amount of heat being dealt with by the body. The fact that they are so often associated with lesions of the suprarenal, thyroid, pituitary, and hypothalamus, points to these structures being intimately concerned with the thermostatic control *as well as with the manufacture and dissipation* of heat. The most plausible focus of this system is a group of cells in the tuber cinereum, which, through the autonomic nervous system, could control the other members. The evidence for this is admirably reviewed by Dr. LAKIN and Dr. SALMON *in the papers* to which we have referred.

[2] Presse méd., August 15th, 1934, p. 1292.

PUBLIC HEALTH AND POOR-LAW

More than sixty pages of the latest annual report of the Ministry of Health[1] are given up to a discussion of the results of the special surveys carried out by the officers of the Ministry since the passage of the Local Government Act, 1929. To what extent have county and county borough councils availed themselves of the power, which they have a large measure of freedom to use or to neglect, of coördinating their old and new public health and medical functions in one economical and efficient organisation for the public welfare? It was foreseen by those who had studied the Local Government Act with a background of knowledge of the poor-law system, that the removal of the more important medical services from its ambit by the method of "declarations" could have little immediate application, and the surveys confirm the prediction; but the reluctance of authorities to transfer institutions by the less drastic means of "appropriation" will disappoint progressive members of the public, as it has already disheartened some public health administrators. So far only 27 county borough councils and one county council outside London have appropriated one or more poor-law infirmaries in their area to be administered under the Public Health Acts. There are real difficulties. Many poor-law institutions are so constructed that it is difficult to dissect away their sick beds from the other manifold purposes of a non-medical character which they serve. Only 34 separately existing hospitals outside London were transferred to the councils at the passage of the Act, nine of which were in counties. Planning, therefore, and some rearrangement of the use of institutions and, above all, a progressive outlook were required. The report states that authorities rarely offered any reason for their inability to utilise the power of appropriation, but the Ministry have evidently a shrewd idea as to the main causes of this reluctance. These are the well-worn financial obstacles to appropriation. It has often been stated that the power of recovering costs from relatives under Section 16 of the Local Government Act is less wide in its application than that afforded by the poor-law, and that no power to charge costs to places of settlement is afforded outside of the poor-law. The validity of the former contention is questioned in the report and means are suggested of overcoming the second difficulty, but the essential point is emphasised that authorities who have taken the step have had no trouble in practice. It might have been added that an inspection of the accounts of the former boards of guardians would reveal that, in fact, negligible proportions of the sums of money which they collected were obtained on the strength of their special powers, and that the use of hospitals by non-residents is only significant in volume in relation to the inhabitants of adjoining districts, with whose authorities agreements can readily be made.

The real difficulty, as everyone knows who has watched the inside workings of local government, is the unwillingness of public assistance committees and their officers to yield up any of their functions. "It appears to the Minister unfortunate," the review mildly remarks, "if this issue is treated as one of domestic administration for a particular committee rather than as one of general council policy, and the Minister thinks that in some cases at any rate the question of appropriation requires to be considered from a somewhat broader point of view than hitherto." Besides appropriation of institutions, the other obvious and expeditious way of bringing about coördination of the transferred poor-law services with other public health activities is through the personal link of the medical officer of health. Indeed, so far as domiciliary medical assistance is concerned there is no other means unless "assignation" to the public health committee of the administration of this purely poor-law function of the public assistance committee is made, a procedure which the Ministry do not appear to consider worthy of mention. The review reminds us—and the survey reports made it clear to individual authorities—that, under the Public Assistance Order, 1930, the medical officer of health is the adviser of the public assistance committee in all medical and public health matters. It is a matter of common knowledge, and one causing the Ministry the greatest dissatisfaction, that medical officers of health in many areas have been quietly but firmly excluded from any part in poor-law administration. Although the Ministry do not mention it, it may properly be said here that in some, at least, of these areas the medical officer of health is partly to blame for lack of firmness and initiative in tackling the situation. The review does, however, draw attention to the vastly increased importance and responsibilities of the position of the medical officer of health, and discusses the qualities desirable in its holder, as well as the way in which his time and energies should be spent. Perhaps in some future report the Ministry will suggest means whereby the methods of selecting officers for this key position may be improved.

Even before the passage of the Local Government Act much of the clinical work of local authorities was carried out by coöperation with voluntary hospitals; of 26,773 beds approved for tuberculosis at Dec. 31st, 1933, 8140 were in voluntary institutions, and at the same time 112 voluntary associations provided 1928 maternity beds utilised by local authorities. The need for close and continuous coöperation between statutory and voluntary bodies has, however, been immeasurably increased by the acquisition of poor-law beds by the former. "It is," the review says, "one of the most definite impressions derived from the surveys that coöperation is essential and that its absence leads to inefficiency and wastage of resources." Here again the achievement falls far short of the desirable, and the main causes appear to be jealousy, suspicion, and fear of encroachment. Perhaps the recent success of the negotiations in London will act as a stimulus to those in the provinces who still hesitate. The status and relation of medical schools to both types of hospital managers is a matter to which the review does not refer but which requires early consideration. This report on the official surveys is a uniquely frank official document which ought to be read by everyone interested in the services and in hospital problems.

ANNOTATIONS

CINCOPHEN POISONING

"'This is the first known death from this particular drug after over half a million cachets have been sold,' said the Liverpool coroner (Dr. G. Cecil Mort). . . . The coroner explained that in recent years there was a group of drugs which had become popular under various trade names, but actually contained acid composed of constituents of quinine and carbolic acid. One group was called acidum phenylcinchoninicum, which had in some cases acted like a charm in chronic rheumatic disease. 'No doubt Crosby had an idiosyncrasy,' he added. . . . Dr. Frank William Crossley-Holland, of Dunstable, Beds., on behalf of the proprietors of the drug, said that it had been on the market five years, and that there was no record of any ill-effects. . . . The coroner added that a doctor friend of his took one grain of quinine. 'He was almost at death's door,' he continued. 'It was purely an idiosyncrasy.'" (From the report of an inquest in the *Manchester Guardian*, Sept. 4th, 1934.)

If that is a correct report of the remarks of the Liverpool coroner and of the medical witness, it calls for a reminder of the known toxicity of the drug in question. "Acidum phenylcinchoninicum" was the name given in the United States Pharmacopœia IX. to the substance which appears in the British Pharmacopœia and elsewhere as cincophen or quinophan, and which is widely sold as Atophan, Phenoquin, Agotan, &c. Chemically it is phenyl-quinoline-carboxylic acid, and has some affinity with salicylic acid (hydroxy-phenyl-carboxylic acid). It was introduced as a therapeutic agent in 1908 by Nicolaier and Dohrn, who suggested its use in gout because they found that it increased the excretion of uric acid. Since then it has been recommended not only in gout, but also for its analgesic properties in many chronic joint conditions and even in sciatica, for its antipyretic properties in acute rheumatism, for its antiseptic action in urinary infections, and on various grounds in other conditions as well. It sometimes produces minor toxic effects such as urticaria and other skin rashes, giddiness, headache, loss of appetite, nausea, vomiting, and albuminuria. These were early recognised, but it was not until 1923, 15 years after its introduction, that it was first accused—by C. C. Worster-Drought—of causing a toxic jaundice. Since then the published case reports of jaundice following its use have steadily multiplied, and there seems no doubt that the drug is responsible. Two years ago T. G. Reah [1] described in our columns 3 cases from the London Hospital and 32 collected from the literature; last year K. Larsen [2] tabulated 97 reported cases, and early this year the *Journal of the American Medical Association* [3] referred to 107. The mortality in these published cases is between 40 per cent. and 50 per cent., and where post-mortem examinations have been made the regular finding has been either hepatitis or subacute or acute atrophy of the liver. Those facts are in themselves sufficient comment on the statements made at the Liverpool inquest, and on the resulting headline "First Known Death from Drug: 500,000 Cachets Sold." It may be that no previous death had been attributed to the cachets prepared by this particular manufacturer, but the same cannot be said of the drug cincophen, which the cachets apparently contained.

The incident raises the wider question of the proper place of cincophen in medicine. Its extensive use over 25 years may be taken as presumptive evidence that it has an appreciable therapeutic effect. It produces, en masse, a therapeutic benefit—but at a cost; for it is known that about 50 persons have died of cincophen jaundice and there must be many other fatal cases unreported. In the last issue medical opinion must judge whether the benefit is worth the price. But before the issue is judged two inquiries must be made. First, is there any means whereby the giving of the drug may be made quite safe? Cincophen cannot be rendered safe by restricting its dose, for (see Carroll and Elliott [4]) jaundice has been reported after doses of widely varying magnitude and duration, even after so little as grs. 90 in a few days. Suspension of the drug on the first occurrence of warning symptoms (itching, skin eruptions, gastro-intestinal disturbance) might have saved some cases from jaundice, but in others there was no warning; small initial trial doses are of no help, for some patients have taken the drug for months before jaundice appeared. Once the liver has been damaged no known treatment can be relied on to save the patient's life. The second inquiry is: can any less dangerous treatment produce the same measure of benefit as the drug in question?. In the case of cincophen this is very pertinent. Its transient effect on uric acid excretion is well established, but whether it favourably influences the metabolic deviation underlying gout is open to question. As the *J.A.M.A.* once remarked,[5] "its striking effect on the elimination of uric acid captured the clinical imagination, which was at that time perhaps somewhat overconscious of uric acid." Sollmann is inclined to think that cincophen relieves pain and reduces fever in just the same way as salicylates do, and doubts the existence of any specific therapeutic effect beyond that. Less conservative opinion offers neocincophen (ethyl-methyl-phenyl-quinoline-carboxylic acid) as a safe substitute, and it appears that well attested cases of neocincophen jaundice are almost unknown (J. S. Davis[6]). In general, therefore, cincophen does not seem to have a peculiar therapeutic value that is as great or as certain as, for example, that of neosalvarsan in syphilis or that of quinine in malaria.

That being so, the onus is on the user of cincophen to prove, in the first place, that it is a more potent or more specific agent than salicylic acid and its harmless derivatives, and further that its virtues are so great as to be worth the death of a small but significant number of patients whose livers it damages beyond repair. Until that proof is forthcoming the drug should not be in general use, and its fatalities should not be condoned by pronouncing that blessed word idiosyncrasy.

A NEW CANCER GERM

DURING the last three years Dr. W. von Brehmer has maintained the thesis that cancer is due to a micro-organism and is always associated with a shift of the hydrogen-ion concentration of the blood towards the alkaline side, the critical value lying between 7·5 and 7·6. In a recent paper [1] he describes in detail the isolation and culture of the "Syphonospora polymorpha," and what he believes to be its relation to the genesis of cancer. This paper is followed by one from Prof. Victor Schilling, director of a university clinic in Berlin, who has repeated Brehmer's experiments, and by a brief communication from two bacteriologists, Dr. C. Börner and Dr. O. Janke.

The organism has been obtained from the blood of cancer patients and of animals bearing a malignant growth, and also from human and animal tumours. In the blood it is attached mainly to the outside of the red blood corpuscles, and it can be demonstrated in blood films by a Giemsa stain. By a "special subcutaneous injection," the nature of which is not revealed, this organism can be detached from the red blood corpuscles and appears then in large numbers free in the serum. The organism is a very pleomorphic aerobe and is stated to have an invisible phase in which it passes a membrane filter, to appear again, under suitable conditions, in the filtrate in a visible form. The life-history of the organism begins with a single spore, of a size varying between 0·1 and 0·6 μ. The spore may divide so that two or four spores come to be enclosed in the same membrane, or there may even be a division into numerous spores lying in a greatly distended membrane with a diameter of 5 μ or more, which eventually bursts and liberates the spores. The single and double spores have been found in the blood of apparently normal healthy persons, as well as in that of cancer patients. These forms are considered to be non-pathogenic, at least so far as cancer is concerned. They can exist at a pH varying from 6·5 to 7·2. Under suitable conditions, of which the most important is a pH of 7·4 to 7·6, the spores extend in one direction, so as to form tubules 0·5 to 2·8 μ long, and 0·2 to 0·8 μ broad, filled with spores. These are the pathogenic forms. The spores, when liberated into the blood, enter damaged cells. In the cytoplasm they again develop into the pathogenic forms which penetrate the nucleus and produce the malignant change. No histological evidence for these contentions is submitted. The crucial experiment, viz., the production of malignant new growths by the injection of pure cultures of the pathogenic forms, is stated to have given positive results, but no detailed evidence is given. In repeating these observations with Brehmer's assistance, Schilling succeeded in obtaining pure cultures of the tubular forms of the micro-organism from human and animal malignant tissue and from the blood of cancer patients and of tumour-bearing animals. He had, however, difficulty in convincing himself of the existence of these forms when the blood of cancer patients was examined directly. Moreover, his own experiments to demonstrate the production of malignant new growths by the injection of pure cultures have so far been negative. He leaves it, therefore, undecided whether the occurrence of this organism has any causal relationship to cancer.

It is difficult to reconcile Brehmer's conceptions with the known facts concerning cancer. The existence of an alkalosis in cancer is by no means an established fact; it has been denied by several competent observers using exact and direct methods with the necessary precautions. The clinical observation that it is possible to cure a patient (or an animal) completely by the removal of a malignant growth at its early stage, Lacassagne's work on the experimental production of mammary cancer in mice,[2] the impossibility of transmitting mammalian cancer except by the intervention of living cells, are only a few of the facts which do not fit in with the idea of a visible causative organism circulating in the blood and becoming pathogenic in an alkalotic condition of the blood. Brehmer's statements appear to have met with criticism in Germany. Until confirmatory evidence is available, claims of a successful treatment based on such a conception must be regarded with reserve.

PSYCHOLOGY AND SOCIAL PROBLEMS

THE recognition of the importance of psychology in sociology and in medicine has been a slow process. The reason for this is not difficult to understand: much of the traditional psychology is lacking in the precision and objectivity which science demands. Nevertheless, the operation of innate human tendencies in social life cannot be ignored. The problems of society, as Mr. Shepherd Dawson, D.Sc., points out in his presidential address to the psychology section of the British Association, are partly material and partly mental. The new methods by which the science of psychology is advancing are scarcely more acceptable to the medical mind than were the old philosophical hypotheses. The objective approach is now achieved by statistical inquiry; the work is laborious and the results are not spectacular. From the social point of view, the object of such investigations is to discover what is the innate capacity of groups of individuals and to ascertain what social environment is most suitable for them. Society must also be moulded to fit the desires and impulses of the individual. The inborn capacity expresses itself in various abilities which can be measured by mental tests; in course of time, it should be possible also to measure with accuracy temperament and special aptitude. The antithesis between the effects of heredity and environment is of great significance in social and psychological investigations. Numerous methods are available for examining the effects of environmental alterations upon mental ability; Dr. Dawson quotes an interesting example. In Glasgow some children were tested at the time of their removal from slum houses to a rehousing area, and again about 18 months later. At the second test they showed a just appreciable improvement, whereas a control group that did not move from their slums showed no such improvement. Dr. Dawson takes a hopeful view about the effects of attempts to improve mental ability by modifications in mode of life and education of individuals. He condemns the type of inquiry which purports to investigate problems of mental defect by throwing together mental disease, criminality, pauperism, and infantile mortality: such inquiries only investigate social inefficiency. Our knowledge of the mode of inheritance of mental characters is not yet precise enough to warrant the belief that social failure is due to heredity. The most promising method of attack, upon the social problems associated with mental defect, is so to adapt our social and educational environment that suitable occupations can be found for the large group of individuals who are unable to take full advantage of scholastic opportunities.

FOOD AND PHYSICAL FATIGUE

THOUGH everyone knows that the energy needed for work is derived from food, little has been done to ascertain whether the food converted into energy has been consumed recently or has first been stored in the body. Muscular work is supported by glycogen, much of which is carried by the blood from the storehouse of the liver; but carbohydrate food may also reach the blood direct from the stomach without being previously placed in store. Athletes engaged on long-sustained efforts have always recognised the value of taking during exercise some form of sugar, chocolate and dates being favourites. The practice is a sound one, although it has only recently received attention in scientific dietaries, and it has now been applied to industrial output which normally falls off in the last hour or so of the day. On the theory that this fall might in part at least be due to depletion of the glycogen in the blood, an experiment was conducted [1] in which a hot milk drink rich in maltose was consumed in the middle of the afternoon by girls occupied on light repetitive work. (Malt sugar is one of the first foods to leave the stomach and be converted into glycogen ready for the use of the muscles.) As a result of this extra nourishment output increased during the remainder of the shift by from 5·3 to 6·1 per cent.; the increase was greater where the process involved more muscular activity, and the work curve lost the shape indicative of fatigue. Probably for heavier work the improvement would have been even greater. This experiment suggests that advantage might be gained from careful consideration of the kind of food taken by operatives, both at home and (more particularly) at the works' canteen, and also of the time, in relation to work spells, at which it is taken.

POLIOMYELITIS VACCINE

IT was announced recently in the newspapers, both in this country and in America, that Dr. M. Brodie, working in the laboratories of the Department of Health of New York City, had produced a vaccine for prophylactic immunisation against poliomyelitis. So far as we are aware no description of this work has yet been published in any of the scientific journals, and the only details available are those given in the accounts that have appeared in the lay press and in a leading article published in the *Journal of the American Medical Association* (July 28th). The latter, being based on information furnished by Dr. W. H. Park, director of the New York City Laboratories, may be taken as representing the true state of affairs.

In the past many attempts have been made to devise a vaccine effective against poliomyelitis, but without any great success. As a matter of fact the same could be said of most virus diseases, for it is only during the last ten years that any material advance has been made in the immunisation of man against the virus infections to which he is susceptible. (Outstanding exceptions to this generalisation are, of course, prophylactic immunisation against smallpox and rabies.) The difficulty has been the preparation of a vaccine which would produce immunity and yet carry no risk, and the first real progress in this direction came from the use of formalin in the preparation of virus vaccines. About ten years ago this method was applied to the virus of foot-and-mouth disease, when it was shown that virus inactivated by low concentrations of formalin retained in large measures [illegible] and subsequent work with other vir[illegible] and yellow fever proved its general applicability. It must be remembered, however, that these formolised vaccines have never been found to confer a really good immunity, and in distemper prophylaxis the immunity produced by the inoculation of the vaccine is reinforced by a second inoculation of living virus. Without in any way wishing to detract from the value of Brodie's work, it may be pointed out that the preparation of his vaccine involves no new principle. It is a formolised vaccine and may have the same limitations as other formolised vaccines. This does not necessarily follow, of course; and further developments in his investigation will be awaited with great interest.

It has also been stated in the press that supplies of a "new English vaccine against infantile paralysis" have been sent to Denmark for use in a serious outbreak of poliomyelitis in which 700 cases are reported. This is not quite correct, for the "vaccine" is really a serum. It is prepared in the horse [1] and is intended for prophylactic use, and a considerable quantity has in fact been sent by the Lister Institute, Elstree, to the State Serum Institute at Copenhagen. It may be obtained, we understand, through Messrs. Allen and Hanburys Ltd.

AMBULANCES AND BOUNDARIES

THE ambulance authorities of the Croydon Corporation and the London County Council are to be congratulated on the common-sense arrangement by which patients are no longer to be trans-shipped on reaching the boundary between the two jurisdictions at Norbury Brook. Croydon patients injured within the L.C.C. area will be fetched home to Croydon by a Croydon ambulance without any shunting, and vice versa. It is stated that Croydon hopes soon to negotiate similar treaties with Purley, Caterham, Beckenham, Penge, and Mitcham. Eighteen months ago Mr. Doran, M.P., put a question to the Minister of Health as to this undesirable trans-shipment of sick and injured patients on the boundaries of local government areas and as to the possibility of legislation to enforce facilities for through services. The Ministerial reply [2] was more polite than definite. The matter remains one for local arrangement. No such hesitation to cross an English rubicon is shown by the voluntary workers of the Home Service Ambulance Committee operating under the joint authority of the British Red Cross Society and the Order of St. John of Jerusalem. But voluntary bodies are free from some of the legal restrictions which beset a local authority; their difficulty is not so much the fear of what a district auditor may say as the financial limitations inherent in their charitable work. Colonel Crookshank, M.P., endeavoured last June to incorporate in the latest Road Traffic Act a clause enabling a voluntary association for ambulance service to claim a fee of ten shillings for any patient transported for emergency treatment. His proposed amendment was rather heavily defeated. Comment was made last year [3] upon another aspect of the too rigid insistence on local government boundaries. A motorist had been fatally injured on the Kingston by-pass road and the Surbiton ambulance was summoned, but its driver took his vehicle home empty on finding that the injured man lay 70 yards outside the Surbiton area. It is not clear whether

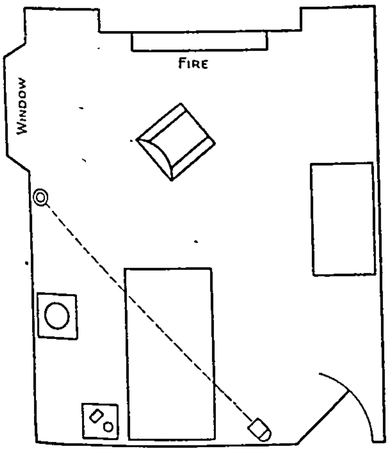
[3] Ibid., 1933, ii., 41.

Croydon's agreement with the L.C.C. will cover such cases as these. The public is apt to be impatient of these incidents, which recall the ancient squabbles between parishes or unions over the liability for paupers. Another not dissimilar difficulty has lately received attention. A child contracts scarlet fever and the local authority is asked to remove the patient to its isolation hospital. If the child turns out to be a mere visitor to the neighbourhood and to be really resident in some other authority's area, treatment has been refused. It was high time that the Ministry of Health took action to correct this anomaly, which was due to a vestigial survival of the old poor-law embedded in our public health legislation, and since July 1st every sanitary authority has the same obligation to deal with infectious disease whether the patient is a resident or a visitor. The recent reorganisation of English local government into fewer and larger areas is still imperfect unless the authorities make full use of their powers of reciprocal arrangement.

PHOTO-ELECTRIC TELL-TALES

THE use of a beam of light to operate a signalling device by means of a photo-electric or selenium cell is now some years old. In industry and traffic control, to name only two departments, it has been put to countless ingenious uses. In its essentials it consists of a "bridge" or light-sensitive switch, which allows a current to pass it when it is illuminated by a ray of light or, conversely, when a constant beam directed upon it is interrupted. If a ray of light is directed at the "bridge" a little above the track of a conveyor in a factory, each package that crosses the ray will record its passing on a counter. In the streets, a vehicle approaching the "bridge" and interrupting the beam, or shining its lights on the "bridge," can be made to work a signalling system. This device is employed in several districts near London, and a number of metropolitan boroughs have arranged for their electric street lighting to be turned off and on automatically when the daylight reaches a certain strength in the morning and when it diminishes at night or during a fog. The same principle is also used for turning lights on and off in factories and offices. A "bridge" placed near the lock of a door or safe can be trusted to sound an alarm when a burglar crosses the beam, or will light up a whole shop when the policeman shines his torch through the spyhole of the shutter. The device can be made to act quantitatively in order to give a precise measurement of the smoke concentration in an atmosphere—a valuable device for saving fuel and preventing pollution. The clinical applications of this invention, which under the name of the Raycraft projector can be obtained from the Radiovisor Parent Ltd., 28, Little Russell-street, London, W.C.1, do not seem to have been adequately appreciated. A hospital might save a considerable proportion of its lighting bill—as well as time and responsibility of staff, by controlling ward and passage lights in this way, and the emergency lighting of the theatre could be turned on without an instant's delay by this means if the primary system failed. For a moderate sum a bedroom can be so fitted up that the sleeper cannot approach door or window without awaking the nurse by an alarm bell; this has obvious value for mental patients and somnambulists. For the biochemist it has an interest in that it will give warning when a liquid reaches any given degree of turbidity



BEDROOM INSTALLATION OF APPARATUS

STANDARDS IN INDUSTRIAL HYGIENE

THE International Labour Office at Geneva has made an effort to define the basic requirements of hygiene in factories and offices, and the result is before us in a pamphlet[1] of 48 pages. A first glance prompts the inquiry whether a code is really necessary to define principles apparently so self-evident and to formulate them in language of such elementary simplicity. But a little reflection will make the reader realise that in both matter and form the work is very much to the point. The code is intended to apply to countries many of which are far behind England in hygienic standards; it is in fact based to a large degree on these standards. Our own practice lags behind ascertained knowledge and even behind the opportunities given by Factory and Public Health Acts. But this is only an additional argument in favour of the wide application of this code, since progress in the industrially advanced countries is bound up with the standards adopted by our competitors in foreign trade. As long as depressed conditions exist abroad our hands are tied from attempting much that is known to be desirable. The question of cost is inescapable. With regard to the language of the code, experience teaches that no language is too simple to convey basic facts. Much of the best work is never adopted in industry because the average manager fails to understand what it is all about. It is a pity therefore that the simple phraseology of the code is marred by Latin tags such as *a fortiori*, *per ascensum*, and *per descensum*. Comprehensive as it is the code is by no means complete. No mention is made of simple but effective means of combating skin conditions arising from irritant dusts or liquids. The effective earthing of electrical gear and the risks of explosion during the cleaning of ventilating ducts used in connexion with volatile solvents of cellulose might have been noted. The kata-thermometer receives but faint praise and the old bogy of chemical vitiation of the air lifts a timid head. These things can be rectified and do not mar an honest attempt to raise hygienic standards among those who do not know or who knowing sin against the light. Even the trite remark that "roofing should be such as to guarantee effective protection for the workers against the heat of sun and the inclemency of the weather" is not superfluous. The fact that our own Home Office welfare pamphlets cover the ground of this code both more fully and in a form more suitable for English readers should not lead us to undervalue any effort at international coöperation. In the industrial field we have many years start and we need to remember that peasant communities turning to industry tend to pass through a phase of hygienic depression similar to that experienced in this country 80 years ago. Anything that can limit this tendency must benefit the whole commonwealth of nations.

GLISSONIAN RICKETS

It has for long been a puzzling feature of the original descriptions of rickets that the disease should have been most prevalent in the rural areas, whereas nowadays it has a largely urban incidence. Other features which have given rise to difficulty are the extreme severity of the disease as observed by Glisson in the 17th century, and the epidemic proportions of its first appearance. These difficulties are solved by Dr. C. E. Kellett in a paper[1] describing the social factors which have operated to change Glissonian rickets into the comparatively mild malady with which we are to-day familiar. Dr. Kellett was moved to his task by his experience of two cases of rickets, so severe as to recall Glisson's description of the disease, admitted to Great Ormond-street Hospital. These cases, twin children of a Soho tailor, had been breast-fed for 18 months by their mother whose diet was found to be entirely lacking in vitamins Throughout lactation she had been helping the tailor at his work, so that the children were deprived of fresh air and sunshine. Dr. Kellett draws a striking parallel between the conditions under which the under-paid and ill-fed Soho tailor and his wife live and breed to-day, and the similar conditions which obtained in large areas of rural England at the height of the wool trade in the late 16th and early 17th centuries. The discrepancy between the steadily rising price of wheat and the diminishing wages of labourers reached a maximum in the years between 1620 and 1660, exactly the period in which severe rickets became epidemic. At this time the real value of wages had undergone great depreciation; these scanty wages were earned by preparing and spinning wool, and weaving it into cloth, the whole family working in their cottage throughout the daylight hours. Dr. Kellett gives reasons for thinking that the distribution of the severe rickets described by 17th century writers corresponds with the distribution of the wool industry, and that the diminution in its severity accompanied the decline in England's wool trade following the Thirty Years' War, and the impoverishment of her most important market. The occurrence of severe epidemic rickets was no mere coincidence but the direct result of the economic situation which arose in England in Glisson's time; it may still occur sporadically where a rachitogenic diet is combined with unremitting incarceration.

CEREBRAL BLOOD-FLOW IN EPILEPSY

The state of the cerebral vessels in epilepsy has long been a matter for speculation, illuminated by little direct evidence. Extremely interesting observations have recently been made in Boston, however, which provide important information on this point.[2] If the changes in temperature of a heated stylet, introduced through a hollow needle into a vessel, are recorded, it is found that the temperature of the stylet varies inversely as the blood-flow; the greater the amount of blood passing the instrument in a given time, the more heat is carried away from it, and vice versa. The stylet was devised and tested by Dr. F. A. Gibbs, and he and his co-workers have succeeded in introducing it into the internal jugular vein of several epileptic subjects, some in status epilepticus and some suffering from petit mal. The main result in all cases is quite clear—namely, that all disturbances of cerebral blood-flow occur after the seizure has started, and therefore play no part in its causation. In general the convulsions are accompanied by a rise in blood-flow, but often there is a sharp fall at first. The investigators state that any change in flow is registered immediately by the instrument; so it cannot be said that the decreased flow in these cases occurs actually before the seizure and is not recorded until after it has begun. "Light pressure on the neck over the jugular vein in which the recorder is located produces evidence of a decrease in flow within a fraction of a second. When the contralateral jugular vein is compressed there is evidence, within a fraction of a second, of an increase in flow." The published tracings bear out the claims of their authors, and in addition include respiratory records which suggest an accumulation of carbon dioxide during the attacks. The consequent vasodilatation, coupled with the rise of blood pressure which almost certainly occurs, is probably sufficient to account for the actual changes in blood-flow observed. Artificially produced cerebral anæmia fails to produce convulsions, and the oxygen content of the jugular blood gives no evidence of a chronic stasis of blood having preceded the spontaneous attacks. It is pointed out that only generalised vasoconstriction has been ruled out as a causal factor; a small focus of ischæmia would be unlikely to affect the jugular flow, and cannot be excluded on the basis of these experiments. Other reasons are advanced, however, which tend to discount this possibility.

THE EHRLICH MEDAL

The Paul Ehrlich gold medal was this year awarded to Dr. Walter Kikuth at a special medical meeting held, under the presidency of Prof. W. Kolle, on Sept. 7th, at Frankfort-on-Main. Dr. Kikuth, who is well known in England, has gained his laurels in the realm of chemotherapeutics. Born in Riga, he began his studies at Dorpat and completed them in Germany at the conclusion of the late war. After an assistantship in the Eppendorfer Krankenhaus in Hamburg, he took up tropical medicine in that city and subsequently worked in the Institute Oswaldo Cruz in Rio de Janiero. He then joined the staff at Elberfeld of the I.G. Farbenindustrie and was appointed successor to Dr. Roehl. Subsequently, in 1931, he became attached to the Medical Academy of Düsseldorf University. Dr. Kikuth has published important work on pulmonary carcinoma, and with Prof. Mayer has confirmed Noguchi's work on Oroya fever and verruca peruviana—studies which led him to embrace the whole of the bartonella group. It is however in immunology and chemotherapy as applied to malaria that his main achievements lie, culminating in the working out of the new synthetic drug Atebrin for the treatment of that disease.

It is reported that the Middlesex Hospital has bought from the Berners Estate the freehold of the rectangular island site of nearly three acres fronting on Mortimer-street on which it stands. The hospital holds its site on leases which expire in the year 2753, and pays an annual ground rent of £2750. When it was first built in 1745 it occupied two small houses off the Tottenham Court-road. In 1754 it acquired from Mr. Charles Berners land in what was then known as Marylebone Fields. This land was leased "for 999 years at a rent of 2s. for every foot in front of the said ground."

PROGNOSIS

A Series of Signed Articles contributed by invitation

XVIII.—PROGNOSIS IN SENILE CATARACT FOLLOWING OPERATION

It is only proposed to deal in this brief article with senile cataract and those of a similar character.

It may fairly be said that the normal sequel to the operative treatment of senile cataract and cataracts of a similar character is useful and effective vision. For this reason prognosis must be considered from a rather different point of view from that which would be adopted in conditions with a lower percentage of favourable results.

Before submitting himself to an operation for cataract a patient is naturally not entirely satisfied by the statement that 90 per cent. or 95 per cent. of operations have a satisfactory result. He will wish to know whether he is likely to be among the 90 favourable ones, or the ten of which the result may be less favourable. It is convenient to consider the conditions which may produce an unfavourable result under three headings: (1) those affecting the operative result; (2) those affecting the immediate visual result; and (3) those affecting the remote visual result.

Operative Result

There are certain conditions which in the past have had a disastrous effect upon the cataract operation. The most important of these is *septic infection*. Within quite modern times it has been the rule for 2 per cent. or even more otherwise satisfactory operations to terminate disastrously owing to this cause. It can be safely said that at the present time this complication is practically excluded by careful bacteriological examination before operation, and by suitable treatment in those cases where the culture reveals infection with dangerous organisms. Infection is almost invariably derived from the conjunctiva, not from the instruments used or the hands of the operator, and consequently attention paid to the conjunctival condition has provided almost complete freedom from this most dangerous complication.

Second to septic infection in its incidence but more destructive in its action owing to the implication of the other eye comes *sympathetic inflammation*. The causes of this complication are by now fairly well understood, though the actual ætiology is still a matter for discussion. Such knowledge as we have, though still not complete, has enabled this risk to be reduced to almost negligible proportions by studious attention to operative technique.

Expulsive *hæmorrhage* occurring at the time of operation invariably means destruction of the eye; fortunately it is a very rare complication. I have never experienced a case in my own series of operations, though I have seen two in a period covering over 22 years. Hæmorrhage occurring after the operation, though an annoying condition affecting and prolonging convalescence, is very rarely indeed serious in other respects. This is fortunate, since while intraocular hæmorrhage may occur as the result of undue activity on the part of the patient or of actual injury to the eye, it also occurs in a number of cases with no apparent cause on about the fifth or sixth day.

With modern methods the question of *maturity of the cataract* does not usually affect the time at which the operation can be performed, nor the success of the operation, and, consequently, the only question which is considered is the degree to which disablement by defective vision has progressed. A more serious condition is that of *hypermaturity*, since this may make the operation definitely more difficult. Even here, however, recognition of the condition with which one has to deal, knowledge of the difficulties which it may impose on the operator, and readiness to adapt the technique to meet these difficulties makes hypermaturity a circumstance which will affect but little the chances of success.

The existence of a *diabetic condition* in senile cataract, whether one regards it as incidental, as the cause of the cataract or, as is most probably correct, as a partial cause, does certainly affect both the operation and the subsequent course of the case. Complications from this cause may be very much reduced by careful medical treatment on modern lines before and after the operation. It should, however, always be pointed out to the patient, his doctor, or a responsible relative, that such a condition is quite likely to prolong convalescence and make the total period up to restoration of vision considerably greater. Furthermore, it is wise as a rule to make the operative procedure as simple as possible by omitting an iridectomy, if this can safely be done.

Immediate Visual Result

The immediate visual result of cataract extraction depends partly on the success of the actual operation and partly on the initial visual capacity of the eye. When the formation of the cataract has been observed from an early period the surgeon will have been able to note, while the cataract is still immature, the condition of the retina, and so will have good reason to believe that it is free from old inflammatory or degenerative changes. Such a belief does not of course amount to a certainty, because changes may have occurred since the cataract became too advanced for observation of the retina to be practicable.

In a considerable proportion of cases, however, the surgeon does not see the patient until the cataract is far advanced. In these he may be able to infer from the healthy condition of the better eye that the eye which is to be subjected to operation is likely to be normal apart from the cataract, but in these cases it is not possible to be so certain of the integrity of the retina. But there may be changes in the retina of the better eye, or the patient may have other disorders which increase the possibility of *retinal disease*. Such disorders include diabetes, especially when accompanied by increased blood pressure, arterio-sclerosis, or renal disease, or any of the three latter by itself. In such cases a careful estimate must be made from the duration and severity of the disease of the likelihood of affection of the retina. But even if it is affected, operation for cataract may still be advisable, since none of these conditions is likely to affect the vision as seriously as a mature cataract would do. But it must be remembered that the outlook for good vision following operation may be less favourable where the retina is diseased, and the medical attendant, though not necessarily the patient, should be warned of the possibility.

The most disappointing cases are those in which a perfect operative result is obtained, and then *macular degeneration* is found. This usually means that reading is quite impossible, though the vision is definitely improved. Gross retinal disease, such as detachment of the retina or very large patches of choroido-retinal degeneration, can usually be excluded by a careful examination of the light projection before operation, but there are no really satisfactory tests for the integrity of the macula. In some cases the presence of *vitreous opacity*, either as a result of previous inflammatory conditions or as an apparently primary degenerative change, may prevent the attainment of full vision, though the operation is completely successful in other respects. It is rare, however, for the vitreous opacity to be so gross as to prevent the attainment of vision that is reasonably useful for ordinary purposes, and even for reading, though the effect of floating opacity may be rather disturbing to the patient.

The operation mainly employed in this country is one of *extracapsular extraction*. In a certain proportion of cases after operation the capsule is so thin and unwrinkled that perfectly satisfactory vision is obtained within a few weeks of operation and without any further operative procedure. In most cases, however, the capsule is more or less opaque and the operation of *capsulotomy* must be performed, preferably within four or five weeks of the extraction, in order to give a satisfactory and permanent visual result. Some surgeons, in fact, prefer to do a capsulotomy in nearly all cases. Occasionally, where the capsule is thin, so that the vision is in the neighbourhood of 6/9, but the vitreous is cloudy, capsulotomy may have the effect of making vision slightly worse instead of better, owing to the projection of a knuckle of cloudy vitreous through the capsulotomy opening into the anterior chamber. Usually this cannot be foreseen. If, however, the vitreous is known to contain opacity it may be wise to avoid or at all events postpone capsulotomy. In cases where the needling of the capsule has resulted in a slight lowering of vision the sight often improves with lapse of time, though the process may take one or two years.

All patients submitting to cataract extraction should be warned that a slight second operation will probably be necessary a few weeks after the first, otherwise they may be disappointed at finding that the extraction has not completed the process.

Remote Visual Result

In the vast majority of cases of successful cataract extraction the good immediate visual result is maintained for the rest of the patient's life-time. Recently, since attention has been directed to the treatment of *retinal detachment* by modern operative methods, a number of cases have been reported in which detachment has occurred at varying periods after removal of cataract. This unfortunate sequel appears to be much more common after removal of juvenile cataract than after operation for the senile variety. It is probable that this is owing to the greater duration of life after operation and the consequent greater length of time available for the development of those changes which lead to detachment. It is certain that loss of vitreous during the operation is a serious factor in the production of this condition. At the present time the number of retinal detachments in aphakic eyes which have been cured by operation is small, but it seems probable that with increasing experience better results may be obtained. Occasionally *glaucoma* may threaten vision after cataract extraction. In some cases at least this is the result of a too extensive opening being made by capsulotomy. Hernia of the vitreous forward through the opening is almost invariable, and if the opening is large vitreous may almost fill the anterior chamber and a rise of pressure is definitely likely. It may be possible to check this rise of tension by medical or surgical methods, but the prognosis is correspondingly less good. Sometimes late inflammatory reaction may affect the visual result; in most cases this is due to an imperfect operation, either from faulty technique or from unavoidable difficulties encountered during the operation. In other cases it is due to general conditions which might cause inflammation in an intact eye. It is hardly necessary to say that as far as possible such conditions should be eliminated before operation is undertaken.

This list of possible complications sounds rather formidable; but many of them are avoidable, and the others are rare. The actual prognosis for visual acuity in ordinary senile cataract is extremely good.

MAURICE WHITING, M.B., F.R.C.S.,
Surgeon, Royal London Ophthalmic Hospital; Assistant Ophthalmic Surgeon, Middlesex Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Capts. L. Warren, O.B.E., to *Drake* for R.N.B., and E. MacEwan to *Queen Elizabeth* as Fleet M.O., on staff of C.-in-C., and as specialist in hygiene.

Surg. Lt.-Comdrs. E. C. Davis to *Victory* for Haslar Hospital and to *President*, additional, for promotion course; G. A. Miller to *Harrier*; J. J. Benson to *Dryad*; and T. F. Barlow to *Carlisle*.

The Gilbert Blane Medal for the year 1934 has been awarded to Surg. Lt.-Comdr. T. C. H. Neil.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. E. G. Thomas to *Effingham*

Proby. Surg. Sub-Lt. T. H. Pierce to *Victory* for Haslar Hospital.

ROYAL ARMY MEDICAL CORPS

The undermentioned Lts. to be Capts.: L. G. Irvine, and W. F. L. Fava.

Lt. (on prob.) H. V. D'A. Iles is restd. to the estabt.

Lt. (on prob.) J. Morgan resigns his commn.

SUPPLEMENTARY RESERVE OF OFFICERS

The undermentioned Lts. to be Capts.: D. T. Maclay, W. S. C. Copeman, J. N. Leitch, and C. D. Evans.

TERRITORIAL ARMY

Maj. R. W. Swayne, O.B.E., on ceasing to be empld. retires and retains his rank, with permission to wear the prescribed uniform.

Capt. E. J. Fitzgerald resigns his commn. on appt. to the Supp. Res. of Off.

ROYAL AIR FORCE

Group Capt. F. C. Cowtan to Princess Mary's R.A.F. Hospital, Halton, for duty as commanding officer.

RESERVE OF AIR FORCE OFFICERS

Flight Lt. (Honorary Squadron Leader) T. M. Walker ceases to be employed with the Regular Air Force, and relinquishes his commission on completion of service and is permitted to retain the honorary rank of Squadron Leader.

INDIAN MEDICAL SERVICE

Maj. F. Oppenheimer to be Lt.-Col.

COLONIAL MEDICAL SERVICE

The following appointments have been made: Dr. R. D. Fitzgerald becomes Director of Medical and Health Services, Straits Settlements, and Adviser for Medical and Health Services, Malay States; Dr. G. H. Garlick, Principal Medical Officer, Johore; Dr. J. D. Robertson, Medical Officer, Zanzibar; Dr. E. A. Seagar, Government Medical Officer, Turks and Caicos Islands; and Dr. H. O. Watkins-Pitchford, Medical Officer, Kenya.

SPECIAL ARTICLES

OBESITY IN CHILDHOOD

A STUDY OF FIFTY CASES

By R. W. B. Ellis, M.D. Camb., M.R.C.P. Lond.
IN-PATIENT MEDICAL REGISTRAR AND PATHOLOGIST, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON; AND

K. H. Tallerman, M.C., M.D. Camb., M.R.C.P. Lond.
ASSISTANT PHYSICIAN TO THE CHILDREN'S DEPARTMENT, THE LONDON HOSPITAL; PHYSICIAN TO THE PADDINGTON GREEN CHILDREN'S HOSPITAL

(*From the Children's Department, the London Hospital*)

Obesity is relatively common in childhood and early adolescence, but there is considerable uncertainty as to its significance—in both lay and medical minds. Not only are large numbers of otherwise healthy children empirically treated with thyroid extract, but it is extremely common to find fat children, especially boys, labelled as examples of Fröhlich's syndrome without any confirmatory evidence whatever. This is often done before the normal age of puberty has been reached, at a time when it is exceedingly difficult if not impossible to diagnose hypogenitalism, and when it is clearly out of the question to be guided by the non-existence of secondary sexual characters.

The following investigation was undertaken with particular reference to the occurrence of demonstrable pituitary disorder in 50 children between the ages of five and fourteen years, whose weight was found to be not less than 25 per cent. above the average for both their age and height. Most of them were brought to hospital, or referred by school medical officers, on account of obesity, but some were seen for secondary symptoms such as dyspnœa or pains in the knees. Information was obtained about race, family history (with reference to obesity), the approximate age of onset, the appetite and type of diet, general activity, and the occurrence of headache, vomiting, and visual and urinary disturbances (polyuria and polydipsia); inquiry was also made about any possible predisposing cause. The patients were examined with particular reference to the distribution of the obesity, the presence of striæ atrophicæ, genital development, secondary sexual characters, the condition of the fundi and visual fields, and the blood pressure. A stereoscopic X ray examination was made of the sella turcica; the urine was examined for albumin and sugar, and in 38 instances glucose-tolerance tests were carried out.

In those cases in which treatment was attempted, the patients were given a diet essentially of high protein and low carbohydrate content, with a total caloric value approximately that appropriate for age. Only in selected cases which were clearly failing to respond to this therapy was thyroid administered.

The Findings

SEX, RACE, AND AGE

Of our series of 50 cases 25 were boys and 25 girls. The race was recorded because it was thought that the diet used in the average Jewish household of hospital class might be found to be especially inducive of obesity. The figures, however (48 per cent. Jewish to 52 per cent. non-Jewish), do not differ materially from the proportionate out-patient attendance. The age of onset was as follows:—

Infancy	13	10–12 years	11
5–7 years	7	12–14 years	3
7–10 years	16		

In 11 instances in the last two groups the obesity was found to coincide with, or immediately precede (within six months), the appearance of the first evidences of puberty (pubic hair, mammary or genital development, menstruation). These cases have been regarded as primarily endogenous in origin.

It will be seen that the onset in the largest group was between the ages of seven and ten years, and with two possible exceptions (in which the condition followed scarlet fever and mumps respectively) these cases appeared to be primarily exogenous in type. All showed a tendency to over-eat, particularly of carbohydrate foods. One of the most striking examples was that of a girl whose mother had bought a sweet shop four months previously.

INFECTION

The rôle of infection in the causation of obesity is apt to be assumed on insufficient evidence, especially when the coincident factors such as good food, rest, and prolonged convalescence are taken into account. Obesity of sudden onset, sometimes accompanied by other symptoms such as polyuria and polydipsia, has, however, been recorded following specific fevers, chorea, &c., sufficiently often to suggest the possibility of a definite causal relationship in some instances.

In the present series the condition dated from scarlet fever in three cases and from mumps in one.

Case 1.—Female, weighed 163 lb., aged 12 years (average for height 113 lb.). Obesity followed scarlet fever at 6 years (within six weeks of onset of disease). Poor response to dietetic treatment. Some increased carbohydrate tolerance (maximum rise from 0·09 to 0·112 per cent. in one hour). Onset of menstruation at 11 years.

Case 2.—Male, weighed 114½ lb., aged 11 years (average for height and age 77 lb.). Obesity followed scarlet fever at 8 years (first noticed eight weeks after onset of disease). Responded well to diet. Sugar tolerance not increased (rise from 0·095 to 0·160 per cent. in half an hour). Onset of puberty aged 12½ years.

Case 3.—Male, weighed 128½ lb., aged 13 years (average for height and age 88½ lb.). Rapid onset (less than six weeks) following scarlet fever, aged 4 years. Diet refused. Sugar tolerance not investigated. Pubic hair present, aged 13 years.

Case 4.—Female, weighed 87½ lb., aged 10 years (average for height and age 65 lb.). Gradual onset of obesity following mumps at age of 7. Diet not attempted. No increase in sugar tolerance (rise from 0·086 to 0·132 per cent. in one hour).

In the first three cases the onset appeared to be relatively rapid, with a short latent period after the scarlet fever. In the fourth, in which the obesity was of more gradual onset, it was not possible to determine the latent period. Unfortunately, also, this child was lost sight of before the normal age of puberty had been reached, since the possibility of mumps affecting the ovarian function must be considered.

A fifth child, a boy, showed a rapid and excessive gain in weight after chorea at the age of nine, and he continued to gain weight after return home. In none of these cases, however, was there any confirmatory evidence of hypothalamic disturbance, and in the last (following chorea) one would hesitate to attach much importance to the history on account of the coincident limitation of exercise and increased home care. In no case in our series was there any history to suggest that the condition followed encephalitis lethargica.

FAMILY HISTORY

It was found that there were one or more members of the immediate family affected in 30 out of 50 cases. Of the parents, the mother, but not the father, was grossly overweight in 13 instances, the father, but not the mother, in 6, and both parents in 3. Siblings alone were affected in 8 cases. The most striking example of familial incidence occurred in a family consisting of two sisters (Fig. 1) and the two parents, who were both obese and were first-cousins.

CARBOHYDRATE TOLERANCE

On the basis of the criteria discussed below (age-incidence, family history, customary diet, &c.), the patients who could be so classified were divided into two groups, whose obesity was regarded as primarily of endogenous and primarily of exogenous origin respectively. Glucose-tolerance tests, using 1 g. glucose per kg. body-weight (to a maximum of 50 g. glucose), were carried out on 19 patients in each group after approximately 15 hours' fast, and blood-sugar values were obtained at half-hourly intervals up to 2½ hours. The following composite curves were obtained from the two groups by averaging the values obtained in each instance. The mean deviations from the mean (expressed in mg. per 100 c.cm.) were :—

	Endogenous group	Exogenous group.
Fasting	±11	± 9
½ hour	±23	±14
1 "	±23	±10
1½ hours	±19	±14
2 "	±14	±16
2½ "	±22	±15

It is clear from these figures that although the mean deviations from the mean are considerable (and show a wider range in the endogenous than in the exogenous group) the average values (Fig. 2) are consistently lower in the former than in the latter. Both composite curves are essentially within normal limits, but a comparison of the two suggests that there is a slightly greater carbohydrate tolerance in the endogenous than in the exogenous type of obesity. In the complete series, 5 cases showed a markedly increased tolerance as evidenced by a rise of blood-sugar of less than 10 mg. per 100 c.cm. after the loading dose of glucose. These cases were all in the endogenous group. In no instance was there glycosuria. This is consistent with the observations of Goldblatt, Forest Smith, and Gardiner-Hill,[1] who found that in exogenous obesity the tolerance to carbohydrate was normal or diminished, although oxidation was in general good, whereas cases of endogenous obesity under twenty years of age showed increased carbohydrate tolerance with excellent oxidation.

PHYSICAL CHARACTERS

The majority of patients in the present series were slightly above the average height for their age and sex, and were of florid complexion. There appeared to be singularly little limitation of activity resulting from even the severe degrees of obesity, though pains in the ankles and backs of the knees were complained of in 7 instances, and there was obvious pes planus and genu valgum deformity in 5. In 3 cases the deposition of fat was sufficient to cause the appearance of fine striæ atrophicæ on the shoulders, thighs, or chest. (These were not, however, at all comparable in size with the striæ seen in cases of gross endocrine dysfunction, such as pituitary basophilism.) The intelligence was within the normal in all except 5 children, who attended mentally defective schools. Two of the latter showed other congenital abnormalities—one a first-degree hypospadias and undescended left testicle (though the right developed normally at puberty), whilst the other boy showed bilateral congenital cataract, vitiligo, and a scattered distribution of white hair (the normal being brown). The basal metabolic rate was not estimated, but in no case did the physical appearance, activity, or pulse-rate suggest any gross degree of hypothyroidism.

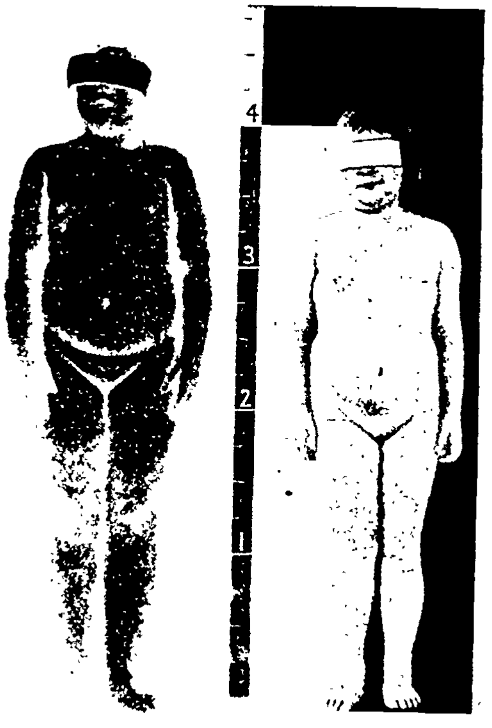

FIG. 1.—Familial obesity. Two sisters ; one aged 12, weighing 123 lb. (normal 81½ lb.), and one aged 10, weighing 89 lb. (normal 64 lb.). Both showed increased carbohydrate tolerance. The parents were first-cousins.

Blood-pressure estimations were carried out with the mercury sphygmomanometer in 40 cases in the out-patient department, after the patients had been at rest for at least half an hour and had lain supine for five to ten minutes. An average of three readings was taken in each case. The following results were obtained :—

Systolic Blood Pressure (mm. Hg).

	Cases.		Cases.
110 to 120	5	150 to 160	4
120 to 130	5	160 to 170	2
130 to 140	11	170 to 180	2
140 to 150	10	184	1

The last three values were recorded in three boys between 13 and 14 years of age, who weighed 224 lb., 179 lb.,' and 171 lb. respectively. The average value for the whole series was 143 mm.

While allowing for certain inevitable mechanical inaccuracies in taking blood-pressure readings on obese patients (e.g., the distance of the arm band from the artery), and the difficulty in standardising rest and emotional factors in the out-patient department, there does appear to be a definite tendency for obese children to have a raised blood pressure under conditions of everyday life. To judge from the relatively small number of these patients whom it was possible to admit to the ward for observation, however, the blood pressure falls rapidly toward the normal when the patient is in bed and completely at rest. The explanation of this may well be a mechanical one. The whole body is working at a mechanical disadvantage, and the actual amount of weight-lifting to be done is grossly in excess of that required of the normal child.

VISUAL FIELDS, SELLA TURCICA

In no instance was there any gross abnormality of the visual fields or of the sella turcica as shown by stereoscopic X ray examination. It was not possible to carry out an investigation of fluid intake and urinary output in more than 8 cases, but in none of these was there a condition of diabetes insipidus, and in none of the remainder was there a history of excessive thirst or polyuria or urinary abnormality.

Frequent *headaches* which were not directly attributable to errors of refraction were complained of in 7 instances, and one of these children suffered in addition from attacks of petit mal type. In no case was there associated vomiting, papillœdema, or other evidence of increased intracranial pressure. It is possible that the raised blood pressure (see above) found in the majority of these children may in some instances be related to the occurrence of headache, though it was not in fact found that the children with the highest blood pressures were those who complained of this symptom.

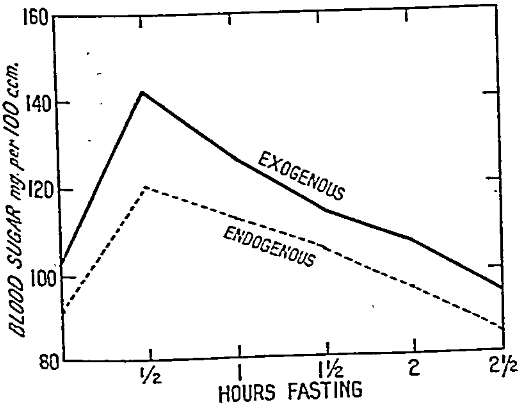

FIG. 2.—Composite carbohydrate-tolerance curves of endogenous and exogenous groups.

It can be said that as far as these investigations go, no evidence was found in any case in this series of tumour of the pituitary or suprapituitary region.

Discussion

In considering the ætiology of obesity, a more or less arbitrary classification into endocrine, endogenous, and exogenous types is often employed. This has a certain value if the limitations of the classification are recognised and the terms defined. By *endocrine obesity* we would describe those cases in which an excessive deposition of fat (as distinct from myxœdematous tissue) occurs as one symptom of a well-defined abnormality of one or more of the endocrine glands. Examples of this type are cases of the adrenogenital syndrome, in which hyperplasia or tumour of the cortex of the adrenal is associated with obesity, hirsutes, high blood pressure, and (in females) hirsutes and amenorrhœa; Cushing's[2] syndrome, a closely similar (if not identical) clinical type, in which a plethoric facies and a peculiar abdominal localisation of the obesity is associated with very large striæ atrophicæ and an adenoma of the basophil cells of the anterior pituitary; and the adiposogenital (Fröhlich's) syndrome, in which there typically occurs a girdle distribution of fat and hypogenitalism. When this last condition arises in childhood there is usually some degree of statural infantilism in addition. Many of the cases of Fröhlich's syndrome that have been described have been found to have been due to a tumour arising from Rathke's pouch, which presumably has damaged by compression both the anterior lobe of the pituitary and the neighbouring centres at the base of the brain. It is now generally held that the symptoms of sexual and statural infantilism are to be attributed to hypopituitarism, whilst the associated symptoms of obesity, diabetes insipidus, &c., which may occur are probably attributable to dysfunction of the hypothalamus (Cushing[3]). It is therefore only justifiable to speak of pituitary obesity (as exemplified by Fröhlich's and the Laurence-Moon-Biedl syndromes) when there actually are symptoms of pituitary dysfunction in addition to the obesity. Confirmatory evidence of a tumour, when such exists, may be found in constriction of the visual fields, papillœdema, or other evidence of raised intracranial pressure, whilst the sella turcica may be seen on X ray examination to be expanded or otherwise deformed. Craniopharyngiomas arising from Rathke's pouch may be situated either within or above the sella turcica (Cushing[3]).

Obesity due to hypothyroidism is characterised by a lowered basal metabolic rate, slow pulse, dry skin, and lethargy. Other examples of obesity associated with primary carcinoma of the thymus (Leyton, Turnbull, and Bratton[4]), tumours of the pineal body, and castration have been described.

The *endogenous* factor in obesity may be said to be the personal factor or peculiarity of individual metabolism which will cause a person to become stout on a diet on which another would remain stationary in weight. Strictly speaking, all types of endocrine obesity might be regarded as "endogenous," and, on the other hand, it may be urged that all endogenous cases are really due to endocrine dysfunction which our present methods of investigation are inadequate to recognise.

It does seem reasonable, however, at present to limit the term endocrine obesity to those cases where there is confirmatory evidence of involvement of one or more of the endocrine glands, and endogenous obesity to those in which there appear to be other factors involved in addition to excessive caloric intake and inactivity. Where the obesity is clearly determined by excessive appetite and food intake, with or without diminished activity, the term *exogenous* obesity is applicable.

It is obvious that such distinctions cannot be pressed too far, and the existence of a pure endogenous type has been questioned. Newburgh[5] has pointed out that not only is the actual food intake apt to be grossly under-estimated by the patient, but that the fluid content of the diet must also be taken into account, and that estimations of fluid intake and urinary output as usually carried out will give no indication of the amount of fluid retention. He regards obesity as essentially exogenous and associated with no specific metabolic abnormality.

Dunlop and Murray Lyon,[6] in a large series of cases of all ages, found only 8·2 per cent. which they regarded as definitely endogenous, 37·2 per cent. probably exogenous, and "the remaining 53·6 per cent." probably of mixed type.

If it is admitted that excessive obesity cannot occur in the absence of an adequate caloric and fluid intake in relation to the energy output, and that therefore there is to some extent an exogenous factor operative in every case, there nevertheless remains a considerable group of cases in which the occurrence of the obesity at a particular age-period, or a strong family history of the condition, suggests that there may be a primary endogenous factor at work as well. In children it is perhaps easier to determine this than in adults as in many instances the onset of the obesity can be more accurately dated, and there is no period corresponding to the menopause when possible endogenous factors are obscured by decreased activity and increased caloric intake. In considering the present series of cases, we have taken as evidence of an endogenous factor the onset of obesity in infancy or immediately preceding puberty, the existence of a convincing family history, and in certain instances the occurrence of an acute illness (see above) coinciding with or immediately preceding the obesity. It must, of course, be recognised that in some cases obesity dating from infancy simply represents overfeeding since this time, though in general it is found that the overweight infant (particularly when breast-fed) tends to gravitate rapidly toward the average during the toddler period. Similarly the occurrence of obesity in several members of a family may be attributable to the type of house diet and a mutual stimulus to over-eating rather than to a familial peculiarity. Whilst therefore any classification on these lines is admittedly tentative and the majority of so-called endogenous cases are really of mixed type, we have distinguished 19 cases in which the available evidence indicated an endogenous factor and 23 in which excessive appetite and diet alone accounted for the condition. The carbohydrate tolerance in these two groups has been discussed. The remaining cases could not be classified on the evidence available.

With regard to the endocrine type of obesity, it may be said that no case in this series showed any confirmatory evidence of pituitary dysfunction, and whilst hypothyroidism cannot be absolutely excluded in the absence of estimations of basal metabolic rate, it was in no case suggested either by the pulse-rate, physical appearance, or general activity.

The *distribution* of the obesity is a point of some importance, and one which is very often called in evidence of a pituitary factor in such cases. It is certainly true that the classical examples of Fröhlich's syndrome show a striking girdle distribution of fat on the trunk, with excessive deposition in the mammary region, hips, buttocks, lower abdomen, and pubis. The extremities are relatively little involved, and the hands and feet tend to be small and delicate. When such a distribution is very well marked, and particularly if it is associated with some degree of statural retardation, it undoubtedly has diagnostic significance. Examination of these 50 children, however, showed clearly that this general type of distribution of fat on the trunk may occur in *any* fat child, whether the obesity is primarily of endogenous or exogenous origin. Indeed, these sites of deposition appear to be the most frequent, the extremities seldom being affected to a corresponding extent in childhood. The resulting pseudo-feminine contours seen in boys, due to the wide hips, triangular pubis, and apparent mammary development had caused many of them to be regarded as examples of the adiposogenital syndrome; this is illustrated by Figs. 3 and 4. (There is, of course, no true mammary development, the nipples being actually retracted into the fatty tissue of the chest.) It may also be mentioned that the diagnosis of hypogenitalism before the normal age of puberty is extremely difficult in boys and impossible in girls. All those patients in the present series in whom it was suspected reached puberty normally. In fat boys the penis and testicles tend to be retracted into and overhung by the fat of the pubis. Even testes which during early childhood appear atrophic may subsequently develop normally. It was in fact found that every patient of the series who could be followed to the age of fourteen (31 in all) had by that time shown some evidence of the onset of puberty.

It has already been mentioned that the majority of these patients tended to be slightly above rather than below the average height for their age and sex, and in no case was there appreciable statural retardation. In 7 instances the height was that of an average child three to five years older, but as these measurements were all made about the period of puberty, when the normal variation is very considerable, it is probably unnecessary to postulate a condition of

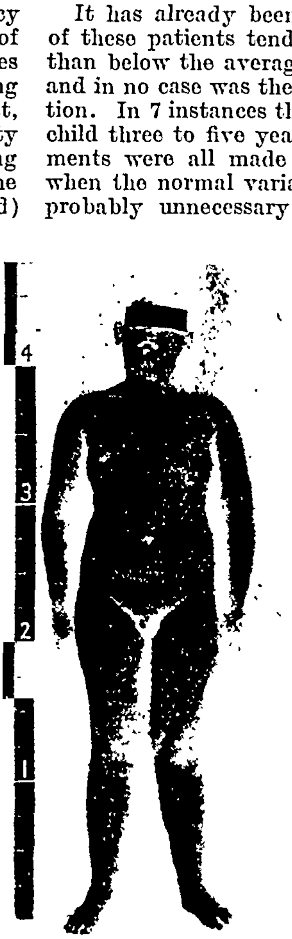

FIG. 3.—Boy, aged 10¾, weighing 108 lb. (normal for height 80 lb.). Pseudo-feminine appearance, due to deposition of fat on breasts, abdomen, and hips. Genu valgum and pes planus. Normal puberty at age of 14. Obesity of mixed type.

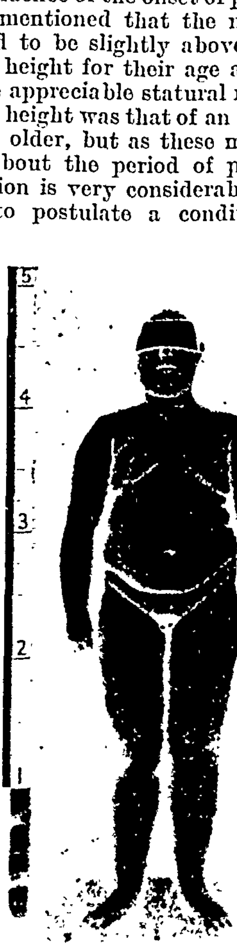

FIG. 4.—Boy, aged 11, weighing 145 lb. (normal for height 88 lb.). Apparent hypogenitalism due to retraction of genitalia beneath fat of pubis. Retraction of nipples. Normal puberty at age of 13. Obesity of exogenous type.

hyperpituitarism to account for them. (It is said that obesity of "hypopituitary" type may be preceded by hyperpituitarism). In none of these cases was the onset of puberty abnormally delayed, but in one Jewish girl it appeared unusually early (pubic hair being present and menstruation occurring at 9½ years of age). Here again, however, the early onset of puberty could certainly be paralleled in many normal children.

The following is an extreme example of the type of "florid" obesity (Fig. 4) to which the majority of these children conformed.

CASE 5.—The patient, a boy, had been overweight since infancy, but had increased rapidly in weight since 11 years of age. No family history of obesity. Appetite always excessive, with particular fondness for carbohydrate; always eating between meals. High colour, extremely active and cheerful, complaining only of pains in backs of knees. At 11½ he weighed 166 lb. (normal for age 77 lb.). When aged 13 (see photograph) he weighed 204 lb. (normal for age 88 lb., normal weight for height 110 lb.), and measured 5 ft. 4½ in. (normal 4 ft. 10 in.). Blood pressure 170/130. Blood-sugar showed a rise from 0·096 per cent. to 0·147 per cent. half an hour after the ingestion of glucose, and a fall to the fasting level in 1½ hours. At 14 years of age the boy weighed 224½ lb., and pubic hair had begun to appear. Genital development was subsequently normal. He showed fine striæ on breast, loins, abdominal wall, and axillæ. Discs, visual fields, and sella turcica normal.

The group as a whole illustrates the fallacy that may easily arise from treating cases of this type with one of the many pituitary or "bombshell" endocrine preparations at present on the market. Even supposing an active preparation is obtained, anterior pituitary extract can only be expected to influence growth and genital development. It is therefore only logical to employ it in those cases in which there actually exists some degree of statural or genital infantilism. Had it been used in the treatment of any of these cases which showed a girdle distribution of obesity with apparently small genitalia during later childhood, the occurrence of puberty at the normal time might easily have been regarded as due to the readjustment of the condition of supposed hypogenitalism. Actually it was seen that the onset of puberty occurred normally in the absence of endocrine therapy.

Treatment

Before instituting treatment one should decide whether it is really necessary in the particular case, and if it be embarked on, whether there is any prospect of the patient and parent carrying out the instructions conscientiously. This must be determined to a large extent by the severity of the symptoms. If there is appreciable interference with normal activity, dyspnœa on exertion, pains in the legs with or without deformity, or discomfort such as may occur from distension of the skin with fat or from pendulous abdomen or breasts; or if the child's physical appearance is such as to render her hypersensitive and wretched, it will be worth while attempting treatment. On the other hand, if the child is in good general health and in no way personally concerned with the condition, failure in any form of dietetic treatment is almost a foregone conclusion, and even if the patient can be persuaded to fall in with the vagaries of parent and physician, it is doubtful how much good will really have been achieved. Although it has not been possible to observe the present series of patients throughout adolescence, it is well known that the majority of overweight children tend to gravitate toward the normal after puberty has been reached, and diabetes (the bogy of the obese adult) does not appear to exercise the same selection in childhood. There is also some reason to believe that if too vigorous dietetic measures are employed, the obesity will only be remedied at the expense of growth. A similar objection applies to thyroid administration in cases which give no clear evidence of thyroid deficiency. Whilst with large doses it will probably be possible to make obese children lose weight, the interference with general health and nervous stability is likely to be disproportionately great.

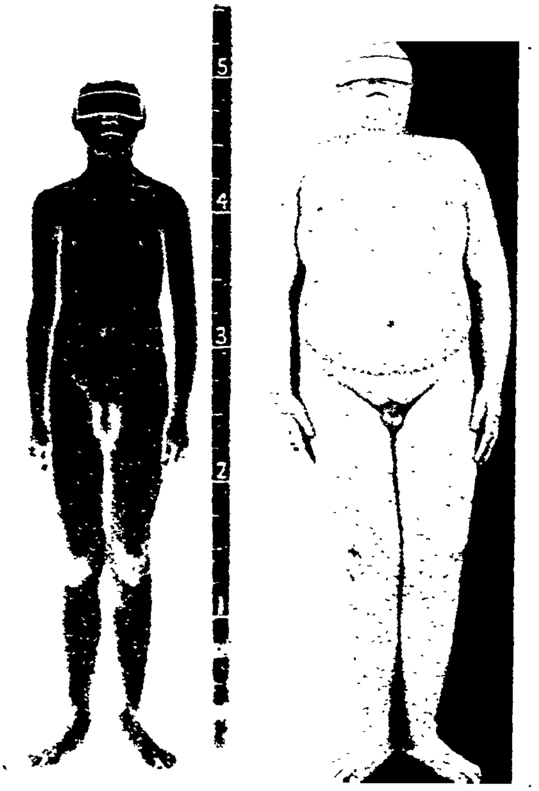

FIG. 5.—"Florid" obesity. Boy, aged 13 years, with contro of same age. Weight 204 lb. (normal for height 110 lb.). Height 64½ in. (average for age 58½ in.).

The limitations of dietetic treatment amongst patients of the poorer hospital class, such as those of our series, are very great. Not only is a high protein, low carbohydrate diet relatively expensive, but the preparation itself of a daily diet different from that of the rest of the household is often wholly impracticable. The most striking result obtained from dieting was in the case of a girl of nine years, weighing 100 lb., whose father was on an obesity diet and whose mother (the only other member of the household) adopted the same diet for convenience. The child gradually lost 25 lb. in the first six months, and then remained approximately stationary in weight for a further three months, although she grew normally and her general health improved. In the majority of cases, however, the most that can be expected is that the weight will remain stationary, or fall slightly, whilst normal growth continues, the child thus tending to "grow up to its weight." A careful inquiry should be made into the details of the daily diet, and suggestions given as to the limitation of specific items, particularly bread, sweets, potatoes, and fried foods, and the elimination of eating between meals. A general diet sheet of foods to eat and foods to avoid was given to each case in which any treatment was attempted (39), and a detailed weighed dietary to 8. Of the 21 patients who adhered at all strictly to the recommendations, the number who obtained any appreciable benefit from them (as judged by a stationary or falling weight) was 12. Since these cases were treated as out-patients and accurate supervision of the diet was impossible, no hard-and-fast conclusions can be drawn with regard to these results, but in general it may be said that those patients in whom there was operative an endogenous factor (puberty) tended on the whole to respond less well to diet than those in whom appetite and overeating were the principal factors. In these latter patients, substitution of green vegetables and salads for potatoes and bread was generally found to allay hunger and bring about a gradual decrease in appetite.

Thyroid treatment, starting with gr. ¼ b.d. and increasing gradually until an appreciable tachycardia occurred, was tried in 8 cases that had failed to respond to dietetic treatment, but in only one instance was there any convincing improvement. It seems probable that unless the drug is given to children in doses incompatible with normal health, any effects it may have on metabolism are counterbalanced by an increased consumption of food.

Summary and Conclusions

1. In 50 cases of obesity in childhood no evidence was found of statural or genital infantilism, nor of intracranial tumour in the pituitary region. None of these cases justified the description of "Fröhlich's syndrome" which had in most instances been applied.

2. A tendency to the girdle distribution of fat was seen in both endogenous and exogenous cases, and was in no instance associated with a delayed onset of puberty.

3. The majority of cases showed a considerably raised systolic blood pressure under conditions of everyday life.

4. Glucose-tolerance tests indicated an increased carbohydrate tolerance in a group of cases regarded as primarily endogenous in type (in view of family history, age of onset, &c.) as compared with cases primarily exogenous in type.

5. It is recommended that dietetic treatment should only be undertaken in cases in which the obesity gives rise to symptoms, and should never be sufficiently rigid to interfere with normal growth.

6. Treatment with thyroid or pituitary extracts is held to be contra-indicated in the absence of definite evidence of hypothyroidism or statural and genital infantilism respectively.

We wish to thank Dr. Maitland-Jones for permission to report cases under his care, and the members of the hospital staff who have assisted in the investigations.

A SPALDING NURSES' HOME.——A new nurses' home, which has been erected in the grounds of the Spalding Johnson Hospital at a cost of £2500, was recently opened by Mr. Ashley K. Mapley, the senior trustee of the hospital.

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF OBSTETRICS AND GYNÆCOLOGY

MR. S. GORDON LUKER (Bournemouth), a vice-president, took the chair at a meeting of this section at which a paper on the

Treatment of Chronic Cervicitis by the Diathermy Cutting Current

was read by Mr. J. C. AINSWORTH-DAVIS (London). For the past 18 months, he said, his attention had been more and more drawn to the fact that chronic cervicitis was responsible for certain diseases of the urinary tract whose ætiology had been imperfectly understood; this conclusion was supported by clinical observation, by experimental evidence, and especially by the results following operative treatment. Any urological out-patient department was overcrowded with women whose chief symptoms were dysuria, frequency of micturition, pain in the loins, and backache. Many were referred from the gynæcological department with a note "will the urologist please see and treat ?" In the majority of cases no abnormality could be found other than a mild trigonitis and an associated chronic urethritis. Changes might also be demonstrated in the upper part of the urinary tract. The urine was usually sterile, but may contain pus and *B. coli.* The significant thing in most of these women was the presence of some degree of chronic cervicitis. Winsbury-White had demonstrated the spread of infection from the uterine cervix to the urinary tract by means of Indian ink or tubercle bacilli injected into the cervices of rabbits.

The complete cure of this chronic cervicitis necessitated the removal of the lining membrane of the cervical canal and of the pars intermedia, together with all subjacent cervical glands. Non-surgical procedures gave unsatisfactory results. Complete amputation of the cervix would certainly remove the infected tissues but this operation was not to be recommended in young women anxious to bear children. Dilatation, followed by the cautery, failed to destroy the deep glands. The ideal method of complying with the essentials of treatment was to remove the glandular tissue completely by means of a wire loop activated by the diathermy cutting current. Mr. Ainsworth-Davis had been unable to use successfully Williams's coniser. He went on to describe in detail his own instrument and emphasised the necessity for the use of a non-inflammable antiseptic. As each strip was cut the bleeding stopped automatically. Saline douches were given 14 days after operation and continued until the cervix had healed, which took two months. The results had been excellent, both clinically and pathologically.

Mr. ALECK BOURNE (London) said he had used this method in a few cases and had found difficulty both in controlling the depth of tissue removed and in controlling severe hæmorrhage.

Mr. W. S. RICHARDSON (Bournemouth) had used the treatment described with great success, as also had Dr. MCCURRICK (Hove). Dr. DUGALD BAIRD (Glasgow) was unable to believe that a relationship between a chronic cervical infection and a chronic urinary infection was as common as Mr. Ainsworth-Davis had declared. In reply, Mr. AINSWORTH-DAVIS stated that experience decided the depth of the strip of tissue removed and slowness of incision, the hæmostasis. A supple scar was left and he did not believe the method led to difficulty in conception or ensuing childbirth.

Sequels of Pregnancy Pyelitis

Dr. DUGALD BAIRD read a paper on the after-results of pyelitis of pregnancy, with special reference to subsequent pregnancy. It was based on 208 cases of pyelitis of pregnancy studied over a period of 1–5 years. Of these patients 74 had had no subsequent pregnancy; 52 per cent. of these did not feel well and 47 per cent. still had infected urine. Some of the patients with urinary infection felt well and some with sterile urine did not feel well. The type of attack gave no indication of whether the infection would clear up or not. Urological examination showed that in many cases there was permanent damage to the kidney. Symptoms complained of were renal pain or pain along the course of the ureters, usually worse before the menstrual period, debility, and occasionally hæmaturia. There had been a subsequent pregnancy in 134 cases; 87 women had one pregnancy (46 of them with pyelitis recurring), and 32 had two succeeding pregnancies (14 with pyelitis in both). As a rule if the urine became sterile before the onset of a second pregnancy, pyelitis would not recur. If the urine remained infected, pyelitis would often recur, dependent on the stasis of urine in the ureters. The exacerbation was in almost all cases less severe than the original attack. In some cases the infection became less severe with successive pregnancies and disappeared spontaneously. In others the infection persisted, giving rise to stricture, hæmaturia, calculus, and uræmia. In a number of these women termination of pregnancy and subsequent nephrectomy were required.

The CHAIRMAN (Mr. Luker) thought that the cases of pyelitis of pregnancy that he had seen were becoming less severe and very rarely required a treatment so drastic as the termination of the pregnancy. Mr. CARNAC RIVETT disagreed. Before the war he had never seen a case. He thought the condition was increasing in frequency and severity. Treatment was not energetic enough, and failure to respond to medicinal measures should at once indicate the necessity for termination of pregnancy. Dr. ETHEL TOWNEND (Hull) also advised early termination of the pregnancy in such cases. Mr. R. A. R. WALLACE (Bishop's Stortford) said that he had not had one single case in 1000 confinements, except one that occurred in the puerperium. Dr. V. B. GREEN-ARMYTAGE (London) wondered whether the use of such drugs as Uroselectan was safe in a woman during an attack of acute pyelitis. Dr. BAIRD, in reply, laid stress on the importance of "forced fluids" in the treatment of these cases.

Chloroform in Midwifery

Mr. R. CHRISTIE BROWN (London) demonstrated a chloroform inhaler for use in normal midwifery. In the first instance it was designed in order to be useful to patients who were attended by midwives. He was of opinion, however, that to put any form of anæsthetic or analgesic into the hands of midwives at present might bring about a rise in the maternal mortality. Before this was done he believed that the following points would have to be considered. The analgesic must be inhaled. Chloroform should be used, for not only did it appear to be safer when used in midwifery but also its name was magic—a fact which was of importance considering that the pain was to a large extent mental. The chloroform must be administered by the patient herself and not by the midwife, thereby preventing any possibility of an overdose. The midwives must not be allowed to purchase the drug in bulk, and, lastly, the apparatus must be small in size and cheap in cost. The inhaler demonstrated was in design (see THE LANCET, 1933, i., 383) like that of the unspillable inkwell and was covered with a small linen bag. The air breathed passed over and not through the chloroform. At the City of London Maternity Hospital the inhaler had been used with considerable success in over 800 cases. When used by doctors a mask could be used which covered the patient's face, which mask could be fitted to the inhaler.

Mr. A. J. WRIGLEY (London) believed Mr. Christie Brown's chloroform inhaler to be a great advance on the chloroform capsules. Mr. CARNAC RIVETT could not understand why anæsthetics were regarded as so much more dangerous in the hands of midwives. He felt they could be entrusted to the midwives with perfect safety to the patients, provided the midwives were instructed in their use. Prof. J. S. ENGLISH (Singapore) compared the inhaler to one designed by Murphy.

Retroversion

The CHAIRMAN read a paper on retroversion of the uterus. Speaking of the wide divergence of opinion about the symptoms which resulted from this malposition, he suggested that confusion had resulted from grouping all cases together. He would classify cases of retroversion of the uterus into the following groups. First, those women who were single and had a congenital retroversion. Most of these patients were unconscious of the condition and of course no treatment was required. He believed that as they grew older increasing retroflexion might result in venous congestion and symptoms of backache, dysmenorrhœa, and pelvic discomfort. Secondly, married women who had a congenital retroversion might complain of dyspareunia or they might seek advice for sterility or, if they became pregnant, miscarriage might result. Treatment was required in these patients. Thirdly, retroversion was acquired after miscarriage or labour. In 200 consecutive confinements he had found that a month after delivery 13 per cent. of the primiparæ had retroversion and 3·5 per cent. of the multiparæ. Should this condition be left untreated backache, dysmenorrhœa, and leucorrhœa would result and the malposition would predispose to future prolapse.

In the treatment of the congenital cases manipulation, if necessary under anæsthesia, should first be tried. A Hodge pessary was left in position for three months, and if the uterus remained in good position nothing further was necessary. Failure to correct the retroversion in a married woman would probably indicate operation. Preventive treatment came first in the cases of acquired retroversion. The puerperal woman should assume a prone position for at least two hours daily. A post-natal examination should always be made at the end of a month and if necessary the malposition should be corrected and a Hodge pessary should be inserted for two months. Pessary treatment was chiefly required as a therapeutic test or as a temporary measure in puerperal retroversion. In Mr. Luker's opinion the indications for operation could be summarised as follows: when the retroversion was fixed or was complicated by adhesions or by chronic pelvic inflammation; when the retroversion was giving rise to symptoms that were increasing, such as backache, menorrhagia, dysmenorrhœa; when the retroversion caused symptoms which disappeared after correction and insertion of a pessary; when the retroversion caused sterility or miscarriage. The operation advised was a modified Gilliam's operation.

Mr. **Christie Brown** said that in post-natal examination of over 1000 women at the City of London Maternity Hospital he had found a retroverted uterus in only 49 cases. Miss **Alice Bloomfield** (London) described a follow-up of cases in which there had been some operation for correction of a retroverted uterus. The impression she had formed was that a permanent relief from symptoms could only be expected when some pathological condition accompanied the retroversion, and that the malposition, per se, seldom caused symptoms. Mr. A. E. **Chisholm** (Dundee) and Dr. **Hutton** (Orpington) disagreed with the last speaker and said they agreed with Mr. Luker that retroversion did account for definite symptoms that were cured by corrections.

Prolapse

Mr. A. C. **Palmer** read the last paper of the day, entitled the Prolapse Syndrome: its Treatment by Vaginal Hysterectomy, with Reconstruction of the Pelvic Diaphragm. By the term prolapse syndrome he implied that a condition of prolapse existed associated with excessive bleeding from the cavity of the uterus. In the early part of the century removal of the uterus by the vaginal route was almost abandoned in favour of the abdominal route. This change was due to the fact that gynæcologists were becoming surgeons rather than physicians and because in most cases abdominal hysterectomy was the method of choice. Mr. Palmer had had to operate on a number of fat patients possessed of an enlarged uterus, who complained of excessive bleeding and who had a varying degree of prolapse. Abdominal hysterectomy had been performed with great difficulty and had often been followed by a prolonged convalescence. Even then only half the condition had been treated and further operative procedure was demanded for the prolapse. This treatment had appeared very unsatisfactory and the question arose why a vaginal hysterectomy should not be combined with a reconstruction operation. It had been argued that removal of the cervix by hysterectomy lost for the surgeon a stable suture point. But this was surely fallacious because removal of the cervix was claimed to be an important part of the operation for the cure of prolapse. The above considerations had led him to combine the two operations and up to the present time 60 patients had been so treated. Common symptoms associated with the prolapse syndrome were a sense of diminished physical capacity, girdle ache, a sense of prolapse, frequency of micturition, menorrhagia, and excessive leucorrhœa. Before the operation was attempted it was necessary that the uterus and appendages should be mobile, and that the uterus should not be too large or the appendages grossly inflamed, the cervix should come down readily to the vulva and the vaginal outlet be relaxed. The operation consisted in an anterior colporrhaphy, vaginal hysterectomy, reconstruction of the hernia of the pouch of Douglas, posterior colporrhaphy, and perineorrhaphy. The operation, in Mr. Palmer's hands, took about an hour to perform. As a rule there was no appreciable shock. A vaginal discharge often appeared but cleared up readily on douching. Forty-four patients had been examined 12 months or more after operation and the anatomical result was excellent except in one case where there was a slight bulge of the posterior fornix, due to imperfect fixation. There was one death, which occurred in a mentally defective woman who removed her perineal stitches with her fingers; the wound became septic and she died from pulmonary embolism. The remaining 15 patients were seen three months after operation and the results appeared excellent.

A cinematograph film accompanied Mr. Palmer's verbal description.

SECTION OF PÆDIATRICS

After some introductory remarks by the chairman, Dr. F. J. **Poynton** (London), president of the section, Dr. W. G. **Wyllie** (London) opened a discussion on

Encephalitis

using the term to include inflammatory, toxi-degenerative, and vascular cerebral lesions. The subject, he said, was one of recent growth; prior to 1916 it was little known, but it had been developed as the outcome of the appearance of epidemic encephalitis at that time and of meningo-encephalitis in the last 12 years. The disorders which he reviewed fell into three main types: (1) encephalitis lethargica and polio-encephalitis; (2) complications of vaccinia and fevers; and (3) acute encephalomyelitis of spontaneous onset. Of these the first group stood out as distinct entities of known pathology, although polio-encephalitis was decidedly rare. Dr. Wyllie depicted briefly the clinical features of encephalitis lethargica, and drew attention to the decline in its incidence in recent years, and the rarity of acute attacks at the present date. He maintained that cerebral lesions were rarely caused by the polio-virus, and a diagnosis of sporadic polio-encephalitis was likely to be erroneous. The symptoms of this disorder were fever, vomiting, and convulsions of sudden onset; coma; residual hemiplegia, sometimes with mental defect and epilepsy. A syndrome such as this might result from other types of encephalitis, and its nature cannot be determined on clinical evidence. Cases of acute hemiplegia had been habitually attributed to polio-encephalitis since the publication of Strümpell's paper in 1884, though this author had not received unanimous support in regarding them as closely analogous to poliomyelitis.

Passing to the second group, Dr. Wyllie said that these nervous complications had long been recognised as rarities; since 1922 they had become more common and had received intensive study. Various syndromes were met with; a purely meningeal one, with or without convulsions, might arise in connexion with any fever. In addition to this he mentioned: (1) a combined cerebral and spinal type; (2) a mainly spinal type; (3) a cerebellar type; and (4) a focal cerebral hemiplegic type. The first two were most commonly found in association with vaccinia, small-pox, and measles. The third, or less often the second, followed chicken-pox. The fourth was the commonest complication of whooping-cough, scarlet fever, and mumps. Encephalopathies following rubella were rare, and varied in type. It was found that the nervous complications of vaccinia, measles, small-pox, chicken-pox, and rubella had certain features in common—an interval of about a week between the onset of the primary exanthem and the nervous symptoms, and the absence of any relation between their occurrence and the severity of the fever, or the size of the epidemic. Dr. Wyllie discussed the relative frequency of these complications and pointed out that the incidence of all of them was small. The mortality-rate was least (6 per cent.) in varicellar cases, about 10 per cent. in morbillic, and 30–40 per cent. in post-vaccinal. When recovery took place it was usually complete, though some form of paralysis, or disturbance of speech or behaviour might linger for a while. Some permanent incapacity occasionally remained, most often in cases following measles. Hemiplegia might occur at any stage in scarlet fever. In whooping-cough the symptoms were delayed until late in the paroxysmal stage. They took the form of convulsions (pertussis eclampsia), sometimes accompanied by hemiplegia, diplegia, idiocy, and blindness. Most cases, though not all, were fatal. Cerebral complications had followed mumps, but were very rare. They also occurred in other acute infections such as pneumonia, erysipelas, and otitic inflammation.

The secondary encephalopathies could be divided, Dr. Wyllie said, into two main types from the pathological point of view—"acute toxic encephalitis," and demyelinating encephalitis. The features of the first were congestion, œdema, vascular endothelial proliferation, and ganglion cell degeneration. It was almost certainly a reaction to bacterial toxins rather than the result of a microbic invasion. Toxic encephalitis occurred most typically in connexion with whooping-cough and acute infections such as pneumonia. Fairly distinctive changes had been found in fatal cases of pertussis eclampsia, and the endotoxin of pertussis could produce a rapidly fatal meningo-encephalitis in guinea-pigs. An exaggerated importance had been given in the past to vascular lesions as a cause of hemiplegia. Demyelinating encephalitis was characteristic of the encephalomyelitis following vaccinia, measles, small-pox, chicken-pox, and rubella. The origin of the reaction was unknown. In vaccination experimental research had failed to reproduce lesions analogous to the demyelinating encephalomyelitis seen in man.

Turning to spontaneous encephalomyelitis, Dr. Wyllie stated that it included several conditions which presented cerebral, spinal, and meningeal symptoms, combined or separately. One form showed the same demyelinating feature as did the cases following vaccinia and measles. Toxic encephalitis was also represented among them. Cases which had been described as "epidemic serous meningitis" were regarded as a meningeal type of this disorder. The cases described as acute tremor, acute ataxy, and acute hemiplegia were difficult to place; their causation and pathology were obscure, though they might be of toxic origin. The hemiplegias were usually permanent, and often accompanied by amentia and epilepsy. Dr. Wyllie had performed a post-mortem on one such case, and found thrombosis of one anterior cerebral artery.

The cerebro-spinal fluid was fairly uniform in these disorders; it might be normal, or show some rise of protein and cells. The persistence of normal chloride and glucose content was of assistance in excluding tuberculous meningitis. Lumbar puncture was of therapeutic as well as diagnostic value, and should be repeated daily in the acute stage.

Dr. **NEILL HOBHOUSE** (London) thought that in the past a disproportionate amount of attention had been given to the secondary as opposed to the spontaneous form of encephalomyelitis. From his own experience he thought that the secondary form was decidedly rare; the fatalities which it had caused had given rise to the impression that it was commoner than it really was. On the other hand, the spontaneous form was extremely common, but had as yet hardly gained general recognition, partly because the extent to which it simulates other diseases had led to many cases remaining undiagnosed. The symptomatology of the spontaneous form was very varied, and the disease must be recognised more by its course than by its symptoms. He looked upon it as a disease with acute or subacute onset, producing multiple lesions in the afferent, pyramidal, and cerebellar tracts, often breaking the reflex arc, but sparing the lower motor neurone. The course was characterised by shifting lesions, fresh ones developing as earlier ones cleared up, and by the fact that it left no residua behind. He had found that there were two diseases for which it was liable to be mistaken, tuberculous meningitis, and much more commonly poliomyelitis. The normal chloride content of the C.S.F. was the best guide in excluding the first of these. The differential diagnosis between it and mild poliomyelitis might be difficult, but in encephalomyelitis there was some active movement in the muscles, electrical reactions remained normal, and there was no true wasting. Sphincter disturbance was very rare in poliomyelitis, but was a pronounced feature of encephalomyelitis.

Dr. W. H. **BEST** (Bournemouth) raised the question whether any of the factors which predisposed to neurotropic virus infections could be controlled. Treatment was at present ineffective; it was necessary to fall back on general prophylactic measures, and important to determine which of them were likely to be successful. It was probable that the virus of encephalitis entered by the nasopharynx, and it might be neutralised by healthy nasal secretion. Efforts should be made to keep the air-passages as healthy as possible, and to ensure that dormitories were well ventilated and beds adequately spaced when the disease was prevalent. Sources of nervous exhaustion should be reduced to a minimum. He suggested that the virus of vaccinal encephalitis might gain entry through the vaccination lesion, and that the chance of this might be lessened by the application of antiseptic dressings, which diminished the local inflammatory reaction.

Dr. T. R. **HILL** (London) discussed the effects of chronic encephalitis lethargica in children. These appeared in the first instance as two distinct syndromes—parkinsonism and behaviour disorder. The latter was never found in conjunction with bilateral parkinsonism, but mixed and transitional types were seen as the mental disturbance became replaced by the physical one. Various types of dyspituitarism also occurred, and might be associated either with parkinsonism or with behaviour disorder. He looked upon the basis of the behaviour disorder as a primary exaggeration of emotional and instinctive functions, and stressed the fact that it was not accounted for by diminution in intelligence or inhibition. Different primary instincts showed exaggeration in individual cases. The reverse picture was seen in the mental state which accompanied parkinsonism. Here the condition was one of emotional inertia without dementia (bradyphrenia). He was reminded in this connexion of Head's belief in the existence of a basal (thalamic) area which he called the seat of "affective consciousness." Primary emotion was inseparable from primary impulse, and this area must also be associated with instinct. It seemed probable that its functions were disturbed by the encephalitic infection in such a way that they were exaggerated in behaviour disorder and diminished in parkinsonism; possibly a state of irritation from an active virus passing into one of paresis. In conclusion he asked whether certain constitutional mental disturbances in children might not be due to defective function of the same areas as are damaged in encephalitis.

The **President** said that some of his published cases of hemiplegia, to which Dr. Wyllie had referred, were due to congenital syphilis. His experience had coincided with Dr. Hill's in that he had seen post-encephalitic children changing from behaviour disorder to parkinsonism. The diseases which had just been described produced some of the most tragic cases which he had seen among children; he called to mind a healthy boy dying suddenly after vaccination, and a pitiful collection of parkinsonian children shown at a medical meeting. There seemed to him to be a close analogy between the lesions of encephalitis and of chorea, which was best explained as a meningo-encephalitis caused by the rheumatic virus. Tuberculosis, a disease which was often compared with rheumatism, had its counterpart in the lesions of the fatal tuberculous meningo-encephalitis.

Dr. G. M. **Findlay** (London) distinguished three types of virus: (1) a strictly neurotropic, (2) one which can be rendered neurotropic, and after a certain number of passages became fixed for nervous tissues—e.g., yellow fever—and (3) one which was never neurotropic. There was a group of diseases characterised by demyelinisation occurring after virus infections, but no *known* virus is capable of producing demyelinisation. A number of diseases pathogenic to animals had lately been shown to be capable of affecting man—e.g., louping ill; it was possible that some virus diseases not previously recognised had also done so.

Dr. A. A. **Moncrieff** (London) referred to cases of encephalomyelitis which were in a state of acute mania at the onset, and to others which began in status epilepticus. He agreed that there was complete recovery without residua. He had formed the impression that there was a non-rheumatic type of recurrent chorea, and it was possible that it was a form of encephalitis; its recurrent nature, however, did not suggest a virus infection.

Dr. H. **Chodak Gregory** (London) thought that the prognosis from the mental point of view in encephalomyelitis presented difficulties. She had seen deterioration both in behaviour and in intellect which seemed to have followed this disease.

Dr. J. **Graham Forbes** (London) said it was often difficult and sometimes impossible to distinguish tuberculous meningitis from encephalomyelitis by examination of the cerebro-spinal fluid.

Dr. B. E. **Schlesinger** (London) thought it unlikely that the virus entered through the site of vaccinia, since encephalomyelitis had followed intradermal vaccination. He suggested that a rigid insistence on vaccination was somewhat out of date, and deprecated exclusion of all unvaccinated children from convalescent homes. In view of the mortality statistics of recent years it would really be more practical to insist on diphtheria immunisation.

Dr. R. D. **Clarkson** (Larbert) described a dramatic case of recurrent chorea which subsequently developed parkinsonism. With regard to Dr. Hill's observations, he thought that many children with behaviour disorder continued their performances throughout the development of parkinsonism as long as their muscles would serve them. Some of these performances were very fantastic, and the primary instinct concerned was not easily determined.

HOUSING IN SCOTLAND

(FROM OUR EDINBURGH CORRESPONDENT)

A reaction towards the high tenement is now noticeable in Scotland, although students of the housing movements know that the tenement has been one of the great incubuses on Scottish housing development. But now it is being said that the numbers of houses needed in growing localities cannot be provided at 12 or 16 or 24 houses per acre without using more land and money than the cities can afford. That overcrowding exists is now recognised, but the suburban outbursts are not enough to relieve it and the expense is too great. The new tenements are to be built with lifts and other common-sense amenities, and they are to be let at rents suited to the mass of wage-earners. Surely the memories of builders and municipalities must have become shorter than usual. The main problem to-day is a reasonable and *low* enough rent. But the new type of tenement is not likely to bring that any nearer. Meanwhile it is encouraging to record that, in Scotland, about 180,000 houses have been built (by local authorities or subsidised private enterprise, and so forth) since 1919. If we include housing schemes under construction or already planned, the number would be considerably increased and the non-subsidised houses now run into many thousands. Naturally the tenement owners are becoming alarmed at the pilgrimage to the new suburbs, which is favoured by the increase of bus transport. In Edinburgh alone, small cottages or bungalows are appearing by the score all round the city. Every week sees a difference and there is no sign of failure in the activity of the speculative builders. Criticism of form and structure is common, but not as a rule well-grounded.

The cry for removal of slums goes on; but, in Scotland at least, the compound Act which requires removal of slum and simultaneous provision of houses is every day gaining in favour with the local authorities. They are now coming to believe in the new unit grant, which is no longer a flat rate per house, but a grant proportional to the number of persons rehoused. This has resulted in a steady increase in three- and four-roomed houses, which cost the local authority only slightly more than two-roomed houses.

Sir Hilton Young's new Bill, it has lately been announced, is to start from a new datum line—namely, the reduction of overcrowding. This, of course, is the aim of all the schemes. But it will be interesting to see whether it will be possible to achieve this with the money that is available. So far the new proposals—building societies—do not seem to be getting under weigh. At the time of the report of the Scottish Royal Commission in 1917 the only course possible was to put an obligation on the local authority to build. The new scheme will put an obligation on the local authority to build up to a required standard. The idea deserves success, but it will be neither cheap nor easy to carry it out. Incidentally there is a growing need for a middle-period census, which, I believe, is now possible under the statute.

In a recent lecture the Edinburgh Lord Dean of Guild recalled a remark made in his youth regarding the large number of tenements then being erected—"we are just re-building the slums in the suburbs." He sometimes heard the same remark to-day. But it was emphatically not true that we were to-day rebuilding the slums in the suburbs. Drab in appearance many of the new tenements might be, sadly lacking in the invaluable uplift that even a little bright colour would give them. But in the planning of the houses themselves, in sanitary requirements and equipment, in such little things as the keeping of tubs and sinks out of living rooms, in the provision of a small larder where foodstuffs might be kept in fit condition for human consumption, and particularly in the arrangement of the windows so as to catch the sun and ensure adequate ventilation they were incomparably superior, not only to the slums of the past, but to a very large number of the houses of yesterday occupied by the great mass of the people of Scotland—*Experto crede.*

MEDICINE AND THE LAW

A Televisionary Consultation

CAN any practitioner with a Harley-street address recall having been consulted by Mr. Henry John Trimnel, of Cardiff, as to the treatment of a diabetic patient named George William Haken? At the inquest on Haken last week Mr. Trimnel, a homœopathic herbalist, admitted that he had assured the patient's parents that he was obtaining a second opinion about the case from a Harley-street specialist. The parents told the coroner they thought this meant a physical communication by word of mouth or by letter. Mr. Trimnel explained that he conducted the consultation by prayer and meditation. Another esoteric feature of Mr. Trimnel's technique was his use of a "pathometer" for the purpose of homœopathic diagnosis. He described the instrument as built up on the plan of a short-wave wireless set. A specimen saliva paper was placed in the slot of the machine, Mr. Trimnel manipulated a dial and the instrument gave the answer. Not that it is necessary, according to Mr. Trimnel, for a homœopathic practitioner to make a correct diagnosis; diseases, he said, are often cured by homœopathy without the practitioner being aware of their existence.

Dr. G. F. Petty, assistant house physician at Cardiff Infirmary, gave evidence that Haken first consulted him for diabetes about five months ago. He did not see him again till August 1st, when he went to the patient's home in response to an urgent summons and found him in a state of diabetic coma. He was told by the parents that Haken had suffered from diabetes for about six years, and during the past four months had been treated by "Dr." Trimnel, who had cut down his insulin injections and during the last month had stopped them altogether. Dr. Petty resumed the insulin injections, but the patient died that day. The diet had contained sweet and starchy foods; the effect on a diabetic subject deprived of insulin would be to make him worse. Asked by the coroner if he approved of Trimnel's treatment, Dr. Petty said he did not; if the patient had received insulin treatment and a proper diet it was unlikely that he would have died when he did. Mr. S. Dixon, the Cardiff public analyst, said that three boxes of pills taken from Haken's home contained merely cane sugar; a bottle of medicine supplied to Haken by Trimnel contained a solution of alcohol. Dr. J. Gough, lecturer in pathology at the Welsh National School of Medicine, said that a post-mortem examination showed no trace of the diseases which Mr. Trimnel said his pathometer registered. Dr. Gough was questioned as to the report of the committee which, under the presidency of Lord Horder, investigated the "Abrams box" in 1924. The committee, he replied, described the method as scientifically unsound and ethically unjustified in the treatment and diagnosis of disease. It may be recalled that an instrument described as an improved form of "Abrams box" figured in the prosecution of Mr. C. C. Abbott last year. Reference to the report of the Horder committee was made in discussing that prosecution at the time (see THE LANCET, 1933, i., 766). Mr. Abbott, a "physio-medical practitioner" who used the instrument, was acquitted on a charge of negligence arising from the death of one of his patients. There was, of course, nothing unlawful in the use of the box if Mr. Abbott honestly believed in its virtue. In Mr. Trimnel's case the coroner's jury did not get as far as a verdict of criminal negligence.

The coroner was careful to make it plain that there was no suggestion of illegality in the practice of homœopathy or herbalism. The vital question for the jury, he very properly explained, was whether Trimnel discharged his duty and responsibility to Haken, irrespective of whether he was qualified or unqualified. The jury found that Haken's death was due to natural causes, that Trimnel had discharged his duty to him but had shown negligence, though not wilful negligence. The coroner pointed out that the verdict was inconsistent—a man could not be negligent and yet discharge his duty. The jury retired and finally returned the verdict that Trimnel was negligent but not wilfully so; "although such negligence as he showed accelerated death, it did not amount to gross negligence." Presumably they considered that Mr. Trimnel had an honest belief in his pathometer. As regards his televisionary communication with Harley-street, they censured his statement to the patient's parents as "most improper and"—a cryptic epithet—"uncalled for."

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 1ST, 1934

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2097; diphtheria, 1099; enteric fever, 30; acute pneumonia (primary or influenzal), 378; puerperal fever, 48; puerperal pyrexia, 92; cerebrospinal fever, 15; acute poliomyelitis, 18; acute polio-encephalitis, 3; encephalitis lethargica, 7; dysentery, 9; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 10th–11th was as follows: Small-pox, 0; scarlet fever, 1234; diphtheria, 1451; measles, 329; whooping-cough, 274; puerperal fever, 22 mothers (plus 9 babies); encephalitis lethargica, 270; poliomyelitis, 6; "other diseases," 249. At St. Margaret's Hospital there were 18 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 12 (0) from measles, 5 (1) from scarlet fever, 13 (2) from whooping-cough, 28 (7) from diphtheria, 44 (10) from diarrhœa and enteritis under two years, and 11 (2) from influenza. The figures in parentheses are those for London itself.

Sheffield reported the only death from enteric fever outside London. Fatal cases of diphtheria occurred at Liverpool 4, Leeds 3, Dagenham and Bootle each 2. Liverpool, Newcastle-on-Tyne, and Birmingham each reported 4 deaths from diarrhœa; no other great town more than 2.

The number of stillbirths notified during the week was 280 (corresponding to a rate of 45 per 1000 total births), including 41 in London.

CORRESPONDENCE

THE TEST-MEAL IN THE DIAGNOSIS OF GASTRIC DISEASE

To the Editor of THE LANCET

SIR,—Although Dr. Maclagan's most interesting paper (Sept. 1st, p. 471) provokes this letter it is not my purpose to offer any criticisms on the conclusions to which he has come; they are, indeed, pretty much what I should have expected. But as I think that a good many people may draw the conclusion that the histamine test is in general a more useful proceeding than the ordinary fractional meal, I would like to point out that this by no means follows even if we accept all Dr. Maclagan's conclusions.

In applying the results of laboratory investigations to clinical work we may proceed in two quite different ways. First, we may use them as penny-in-the-slot aids to diagnosis; this method, although frequently spoken of in slighting terms, is perfectly legitimate and is in daily use—e.g., in Wassermann tests. In earlier days it was used in dealing with the results of the Ewald meal in the diagnosis of gastric ulcer and carcinoma, though no one even then credited it with the degree of accuracy that is essential for the really successful application of this method. As experience accumulated it was largely discarded; but with the advent of the fractional meal it came into favour again and attempts were made to establish various types of curve as diagnostic of different gastric diseases. Again further knowledge has shown that these attempts were not justified.

This method demands that statistical analysis should show high accuracy, but it does not demand any knowledge of the pathological basis on which the test rests, and in some at least we have no such knowledge.

The other method of dealing with laboratory investigations proceeds on very different lines. Here we note the facts that the laboratory gives us just as we note the facts that our fingers and ears give us in percussing a chest, and we use them in exactly the same way, trying to fit them all into a comprehensible pathological picture and on that to base our conception of the disease. The successful application of this method demands an accurate knowledge of the pathological basis of the test.

Dr. Maclagan's observations are concerned entirely with the first method; it remains to be considered whether we cannot get more information by using the second. I think we can, but only if we interpret our curves in the light of all the available facts. A "peak" or a "plateau" curve, for example, may be produced in several different ways, just as an alteration in the percussion note in the chest may be the result of quite distinct lesions, and you can no more diagnose definite gastric disease by noting simply an alteration in the shape of the curve than you can diagnose the nature of the pulmonary disease by the mere presence of a dull patch. For our purpose here there can be no doubt that a fractional meal gives much more useful information than an estimation of the histamine secretion.

I am not going to discuss the merits of the various hypotheses that have been put forward to explain the mechanism of the fractional curve; I will only say that if fractional meals are to be interpreted in this way this mechanism is not, as many seem to think, merely a matter of academic interest but is of immediate clinical importance. Dr. Maclagan, as the result of a very careful statistical inquiry, has discarded duodenal regurgitation as a factor of no importance. I am glad that I do not find his argument conclusive, for by accepting the pylorus as an important controlling factor I do get considerable help from test-meals.

I am, Sir, yours faithfully,

G. W. GOODHART.

West Cromwell-road, S.W., Sept. 8th.

RADIOLOGY IN GENERAL PRACTICE

To the Editor of THE LANCET

SIR,—From your report last week (p. 565) of the B.M.A. discussion on Radiology as an Aid to the General Practitioner it seems that one speaker made the following statement without challenge: "The general practitioner who purchased an X ray outfit was likely to become a menace to his patients." Having found myself handicapped by the want of X ray facilities, I have for more than two years owned an X ray apparatus and used it in the ordinary routine of my practice; and still do not regard myself as other than a practitioner of general medicine. I do therefore challenge most heartily the statement quoted, and would rather suggest that before long X ray apparatus will be regarded as an indispensable part of the equipment of a conscientious practitioner. In my experience it is desirable to have an X ray film under view during the setting of any fracture. Much pain is avoided if radiography can be arranged to obviate delay in treatment; the result too is very much better after immediate reduction and setting than if the patient must spend time in travelling to and from a radiologist.

The following three instances, occurring in ordinary routine, may enforce my argument:—

An old lady of 86 was moved carefully into bed after a severe fall in her own home. The following morning a photograph, taken with the minimum of disturbance by a portable apparatus, showed a paratrochanteric fracture of the femur. This picture facilitated immediate treatment, and greatly assisted in the production of the perfect anatomical and functional result which was obtained.

A patient who was giving himself injections of insulin broke a hypodermic needle in his arm. An X ray photograph, with indicators at the point of entry, showed a considerable length of needle deeply placed. This was removed under local anæsthesia, having wet plates under view. The needle had already travelled since introduction and its removal presented difficulty, which would have been increased still further by delay.

A woman, seven months pregnant, was found clinically to have a persistent transverse lie of the fœtus. Having confirmed this by X ray examination, version was performed without moving her from the couch, and she saw a film showing the vertex presenting before returning home.

Is it not possible that the time has come for the recognition of the advantage to patients of routine radiography, as required in the practice of general medicine, without any sort of displacement of the consulting radiologist? Surely as a result his scope would expand. Certainly more would be expected of him.

I am, Sir, yours faithfully,

W. B. R. MONTEITH.

Bourne, Lincs, Sept. 8th.

THE EDINBURGH PREGNANCY DIAGNOSIS STATION

To the Editor of THE LANCET

SIR,—From a letter sent out as from the Pregnancy Diagnosis Station here to those medical practitioners whom it has served in the past it would appear that the station is closing down in Edinburgh and is reopening in London.

Actually this is not so. It is the case that, to my great regret, Dr. Wiesner, to whom is due all the credit for the inception and successful development of the station, is leaving this Institute and is moving to London where he intends to continue his diagnostic and advisory work. But during the past five years the station has become a necessity to many practitioners and accordingly will not be closed. At least it must continue to serve Edinburgh and the East of Scotland and to do this it must serve a much wider area, for its efficiency must be largely determined by its size and this must depend on the number of clients. To ensure efficient running, prompt reliable service, and low charges several thousands of tests must be made annually. Its income must be sufficient to provide skilled medical supervision, an efficient technical staff, smooth routine, and above all sufficient data, for only then can the records possess any considerable scientific value. I have to hope therefore that this laboratory will be used by practitioners from all parts of Great Britain.

If the facts were better understood there would of course be room for more diagnostic laboratories than at present exist. It is irritating to recognise that even yet so many practitioners either do not know that there is such a service in most of the larger cities or, knowing, take no advantage of its existence. It should not be necessary to keep repeating that the tests now used yield an accuracy of not less 97 per cent.; that pregnancy can be recognised as early as 10–14 days after conception; that the report on any given specimen can be despatched after 24 hours, 48 hours, or 5 days according to the particular test made, and that all that is required is 50 c.cm. of morning urine.

The interest of this work is not commercial, it is to be found in the unusual and the exceptional; for in these cases is the seed of knowledge which being disclosed will contribute largely to the endocrine therapy of the immediate future.

I am, Sir, yours faithfully,

F. A. E. CREW.

Institute of Animal Genetics, Edinburgh, Sept. 8th.

THE WORLD WE LIVE IN

To the Editor of THE LANCET

SIR,—Your leading article in to-day's issue on Sir James Jeans's address to the British Association ends with a paragraph that appears somewhat confused. You state that no naturalist could believe the proposition that man's control over nature has outstripped his moral control over himself. This proposition you derive from the presidential address at the York meeting of the Association in 1932 when Sir Alfred Ewing stated his belief that man was *ethically* unprepared for so great a bounty as had been conferred upon him by modern engineering science. He added that this bounty in the hands of knaves or fools might easily wreck our civilisation, but he ended the theme with a declaration that he could not think that man was destined to atrophy through cultivating one of his most God-like faculties—the creative ingenuity of the engineer.

To me Sir Alfred's address conveyed an impression wholly opposite to that which it seems to have created in your mind, Sir. His view can hardly be styled a "gloomy misconception" nor does it appear to be inconsistent with "the plain experiences of life." Science is being prostituted all over the world in the service of sectional interests and in order to forward motives hostile to human welfare. The "knaves or fools" have the whip-hand in many places and they constitute a very real danger to civilisation. How comes it that "no naturalist could believe that"?

If your concluding paragraph refers to some technical point in philosophy then I must ask you to allow me to withdraw this criticism; but if, on the other hand, it refers to the "plain experiences of life" then I feel sure you must have mis-read Sir Alfred Ewing or else hold a view of certain modern tendencies which appears to me wholly opposed to the weight of the evidence.

I am, Sir, yours faithfully,

LEONARD P. LOCKHART, M.D.

Beeston, Notts, Sept. 8th.

*** We take the opportunity of regretting the misprint of Yale for York as the locus of Sir (James) Alfred Ewing's address two years ago.—ED. L.

HYPEREMESIS GRAVIDARUM

To the Editor of THE LANCET

SIR,—In support of Dr. Hurst's view that there is an important functional element in the vomiting of pregnancy, it would perhaps be of interest to quote two cases.

1. A husband asked me to see his wife in the country. She had lost her first baby from hyperemesis gravidarum; she was pregnant for the second time and seemed likely to do the same as she was vomiting repeatedly. I saw her and explained things to her that evening and again next morning. Her vomiting ceased and she carried her child to term.

2. A patient of mine went abroad, being pregnant at the time. At three months she was vomiting practically everything and was subsisting (if I remember rightly) on sponge-cake. She was so ill that she returned to England. I saw her and explained to her the presence of an hysterical element in her vomiting, told her to get up and have a good square meal at the Berkeley with a cheery companion She went with her husband and her vomiting ceased.

I am, Sir, yours faithfully,

Park-square West, N.W., Sept. 5th. C. H. RIPMAN.

JOHN KNIGHT, SERJEANT SURGEON

To the Editor of THE LANCET

SIR,—In addition to the interesting account of Mr. Serjeant Surgeon Knight given in your annotation last week, the following extracts from the Calendar of State Papers quoted by Morgan Richards in his "Chronology of Medicine" may be useful to "E. M. C."

1661, July 11th. Grant to Richard Pile, of the office of first Principal Surgeon to the King and of first Serjeant Surgeon; and similar grants to John Knight and Hum. Painter, with annuities of £150 each.

1661, March (? 1662 historical year). Petition of John Knight, Serjeant Surgeon to the King. Having served his Majesty abroad was continued with others in their respective places on the Restoration, received the usual fee belonging to his office for embalming the Duke of

Gloucester, being the only profit that has fallen to him, but is now ordered to divide it with Richard Wiseman, Surgeon in Ordinary. Begs not to be made the only person who has had his fee taken from him. Grant to John Knight of the office of Principal Surgeon: fee £26. 6. 8 with the like pension of £150.

1662, September. Petition repeated in the same words as those used in March.

1662, Sept. 11th. Warrant to Mr. Knight to retain the whole usual fee which he received for embalming the late Duke of Gloster, which has been disputed for by some other of the King's Surgeons.

I am, Sir, yours faithfully,

Cavendish-place, W., Sept. 10th. CECIL WALL.

VACCINES IN PEPTIC ULCER.—Dr. J. N. Gale writes: "In my letter last week I inadvertently omitted the source of the vaccine used in the treatment of peptic ulcers. It is sold by Parke, Davis & Co., under the name of *Intestinal Streptococcus Vaccine*, and I used carbolised saline as a diluent."

OPENING OF THE MEDICAL SCHOOLS

IN connexion with the opening of the session at the London medical schools the following arrangements have been made:—

Charing Cross Hospital

The opening of the school will be celebrated at the inauguration of the centenary year. Details of the arrangements will be published later.

Guy's Hospital

On Tuesday, Oct. 2nd, at 2.45 P.M., the prizes will be distributed by Lord Nuffield. Mr. C. H. Fagge will deliver the inaugural address.

King's College Hospital

On Saturday, Sept. 29th, from noon to 6 P.M., and on Sunday morning, there will be lectures and demonstrations open to all practitioners. Post-graduate lectures will also be delivered in the lecture theatre of the medical school on Thursdays at 9 P.M. from Oct. 11th onwards. The annual dinner of past and present students will be held on Sept. 29th, at 8 P.M., at the Connaught Rooms, Great Queen-street, W.C., Dr. Wilfrid Attenborough presiding.

London Hospital

A post-graduate course for former students of the hospital will be held from Oct. 17th to 20th. The old students' dinner will be held on Thursday, Oct. 18th, at 7.30 P.M., at the Trocadero Restaurant, with Dr. James Thomas in the chair.

Middlesex Hospital

The hundredth winter session will be opened in the Queen's Hall, W., on Monday, Oct. 1st, at 3 P.M., when Dr. Henry MacCormac will deliver an introductory address, entitled Our Profession, and Sir Farquhar Buzzard will present the prizes. A post-graduate course for former students of the hospital will be held from Sept. 28th to Oct. 1st. On Oct. 1st the annual dinner will be held at the Savoy Hotel at 7.30 P.M.

Royal Free Hospital

On Monday, Oct. 1st, at 3 P.M., Dr. M. H. MacKeith, dean of the British Post-Graduate Medical School, will deliver an opening address on the Institutes of Medicine, and will afterwards distribute the prizes. Miss Elizabeth Bolton will be in the chair. The annual dinner will be rsday, *Dec. 6th, also at the Savoy.*

mew's Hospital

5th, an appeal banquet will be held at the ouse in connexion with the medical college funds for the purchase of the Charterhouse site.

St. George's Hospital

Sir Humphry Rolleston will preside at the prize distribution on Monday, Oct. 1st, at 3 P.M., when Prof. Langdon Brown will deliver an address entitled We Have Reason to Think. A post-graduate course for former students of the hospital is being held from Sept. 28th to Oct. 1st, and the annual dinner will take place on Saturday, Sept. 29th, at 7.45 P.M., at Claridge's Hotel, with Mr. W. Fedde Fedden in the chair.

St. Mary's Hospital

A week-end post-graduate course, open to all medical practitioners without fee, will be held from Sept. 28th to 30th. The annual dinner of past and present students will take place in the new medical school library on Saturday, Sept. 29th, at 7.30 P.M., when Dr. P. Montague Smith will be in the chair.

St. Thomas's Hospital

A post-graduate course for former students will be held *between Sept. 24th and 28th. Dr. W. L. Wainwright* will preside at the old students' dinner which will take place at the Dorchester Hotel, at 7.45 P.M., on Sept. 28th.

University College Hospital

On Monday, Oct. 1st, at 3.15 P.M., in the library of the medical school, Sir John Rose Bradford, F.R.S., will deliver the opening address. The annual demonstrations for old students will take place on Oct. 11th and 12th, *and the annual dinner will be held in the library of the* medical school on Oct. 12th, at 7.30 P.M., with Sir John Parsons, F.R.S., in the chair.

Westminster Hospital

On Monday, Oct. 1st, at 3.30 P.M., the winter session will open at the Central Hall, Westminster, when Sir John Simon will deliver the inaugural address. A short course for former students of the hospital will be given on Saturday and Sunday (Sept. 29th and 30th), and the annual dinner of past and present students will take place at the Trocadero Restaurant, on Saturday, Sept. 29th, at 7.45 P.M.

Royal Dental Hospital

Prizes will be distributed at the hospital on Friday, Oct. 5th, at 8 P.M., at a conversazione at which Prof. William Wright will preside. The annual clinical At Home will be held at the hospital on Nov. 24th, and the dinner of past and present students will take place on the same evening at the Trocadero Restaurant, at 7.30 P.M., when Mr. J. Thornton Carter will be in the chair.

Further details of post-graduate courses will appear in due course in our Medical Diary.

MEDICAL NEWS

University of Cambridge

Dr. A. B. Appleton is resigning his appointment as lecturer in anatomy on going to *St. Thomas's Hospital as professor of anatomy in the University of London.* Among university teaching officers who vacate their offices on Sept. 30th, on reaching the limit of tenure, are Mr. V. C. Pennell, F.R.C.S., and Dr. D. G. Reid, university demonstrators in anatomy.

University of London Medical Graduates Society

The next extra-metropolitan dinner will be held at Queen's College, Cambridge, on Friday, Sept. 28th, at 7.30 P.M. Members should apply for tickets to the hon. secretaries at 11, Chandos-street, London, W.1.

Central London Throat, Nose, and *Ear Hospital*

From Oct. 1st to 27th an intensive post-graduate course in laryngology, rhinology, and otology will be held at this hospital. On Dec. 1st and 2nd a general week-end course has been arranged, and from Dec. 3rd–8th there will be a course in methods of examination and diagnosis. The annual address will be given at 4 P.M. on *Friday,* Oct. 12th, by Mr. Douglas Harmer, consulting surgeon to the throat department at St. Bartholomew's Hospital, who will *speak on treatment of malignant disease in the* upper jaw.

ADDRESSES AND ORIGINAL ARTICLES

THE USE OF THE DIATHERMY KNIFE IN MALIGNANT DISEASE OF THE MOUTH, NOSE, AND PHARYNX

WITH AN ANALYSIS OF 109 CASES

BY NORMAN PATTERSON, M.B. Edin., F.R.C.S. Eng.
SURGEON TO THE THROAT, NOSE, AND EAR DEPARTMENT, LONDON HOSPITAL

THERE is nothing novel in the employment of heat for the destruction of tumours. The "fire drill" was used in Egypt for the cauterisation of fleshy tumours of the chest (vide Edwin Smith Surgical Papyrus, dated 1600 B.C. but probably compiled a thousand years earlier) (Breasted). Hippocrates (400 B.C.) states "The man who had a carcinoma in the throat cauterised was cured by us."

Celsus (A.D. 50) recommends cauterisation in the treatment of cancer "attacking the ulcers of the mouth." Galen (A.D. 131) also advised cauterisation as a remedy for such ulcers. Albucasis (936–1013) was a strong supporter of the cautery and describes its successful use in a large tumour of the mouth. It is interesting to note that he opposes applications of the cautery to the centre of the cancer as it causes ulceration, but he advises its employment in a circular manner round the growth. Guy de Chauliac, of Montpellier (1300–68), advocated the actual cautery in cancer of the lips. Marchettis, of Padua (1664), excised with the scalpel and cauterised a fleshy tumour of the floor of the mouth.

Wiseman, of London (1676), advocated the use of the button cautery for the arrest of hæmorrhage. He appears to have used the cautery to good effect in a female, aged 40, suffering from a cancer of the lower jaw, and in another case of the same disease affecting the upper jaw and palate. The latter patient was apparently cauterised almost daily till in five weeks a scar formed which did not break down during the succeeding seven years. Dr. Turner, of London, in 1722 mentions the use of the cautery, but advises palliative measures only for cases of cancer of the mouth. Benjamin Bell, of Edinburgh (1786), used twisted wire sutures in excising carcinoma of the cheek or tongue and the cautery for the arrest of hæmorrhage.

Development and Technique of Electrical Methods

In 1850 John Marshall removed various tumours with the aid of the electric cautery. Middledorpff in 1855 advocated the use of the electric cautery in such operations as removal of a cancer of the tongue where hæmorrhage was likely to be severe.

By diathermy is meant the passage through the body of a high-frequency current which generates heat in the tissues. Nikola Tesla, in 1891, first suggested its use in medicine.

In 1896 Oudin described a method of destroying benign tumours by sparks from a d'Arsonval generator, a method which became known as "fulguration." It was used by Rivière for the destruction of malignant tumours, and by F. H. Cook, of New York, from 1904 onwards, in conjunction with X rays, for a similar purpose. In 1906 de Keating-Hart, of Marseilles, referred to the use of diathermy in cancers. In England Philip Turner described 20 cases of carcinoma treated by fulguration and diathermy from 1909–12. These included 7 cases of carcinoma of the tongue and mouth. All died of metastatic growths, but there was only one local recurrence.

Nagelschmidt recommended the use of diathermy for arthritis in 1907, and in 1919 demonstrated its employment for the coagulation of tissues. He visited St. Bartholomew's Hospital on Oct. 21st, 1919, and treated three cases, one a post-nasal growth. Harmer and Cumberbatch adopted the method. In the meantime Czerny (1910) introduced a method which he called the "arc operation," the instrument being referred to by Howard Kelly as the "acusector." Another pioneer of diathermy was W. L. Clark, of Philadelphia, who began to employ it in 1909.

Surgical diathermy and endothermy are now extensively used in various parts of the body, mainly, but not entirely, in the treatment of malignant neoplasms. Lambert Lack used diathermy for the first time at the London Hospital for a case of carcinoma of the soft palate in 1913. At this time I had the privilege of being his assistant. So far as I can ascertain I was the first to employ diathermy in carrying out a set excision, and since then I have used this method whenever possible. One of its great advantages over the original procedure of piecemeal destruction of the tumour with a button electrode is that definite surgical removal is accomplished by cutting through the surrounding healthy tissues, the diseased area being left undisturbed. Another advantage—though it does not affect the result of the operation—is the obtaining of an excellent specimen for examination by the pathologist. The excision is always supplemented by a thorough application of the button electrode to the cavity left after the removal of the tumour.

The current used in diathermy is of very high frequency (500,000 to 1,000,000 per second); Wyeth, indeed, uses a frequency of 5,000,000 per second. When a good modern apparatus is available the electrode may take the form of a small knife or needle. A terminal of this form is the most suitable kind of electrode for cutting out the required amount of tissue. Sometimes it is useful to have the knife or needle set at an angle to the shaft. The same remark applies to the button used in treatment of the cavity. The amount of blood circulating in the immediate vicinity determines to some extent the depth to which heat generated around the electrode penetrates. The tissues can to some extent be devascularised by pressure, as with the button terminal, or by ligation of the main vessel or vessels supplying the part. Devascularisation by ligature has the further advantage that sloughing extends to a greater depth ensuring more complete destruction of the tumour and minimising the risk of hæmorrhage. In employing diathermy the fluids in the tissues should be raised to boiling point, but desiccation and sparking should not be allowed to occur. To counteract this the electrode can, by the application of a little more pressure, be advanced into a fresh area or buried more deeply. Reduction of current, scraping dead material from the electrode, or the application of normal saline to the wound may be necessary. No fresh application to the tissues should be made when the current is running, and the current should be stopped before removal of the instrument. Steam issuing from the field of operation interferes with vision; it can be blown or sucked away by employin a suitable apparatus.

Before operation the same attention should be to the teeth as if ordinary cutting instruments to be used. This means that in most cases all must be extracted from two to three weeks pr the employment of diathermy. In some cas thorough investigation of the patient by a physi is necessary before operation. It is always advisa to have a Wassermann reaction carried out, but t surgeon must not be influenced by a positive result if the clinical picture is one of carcinoma.

The anæsthetic employed must be non-inflammable.

The points to be attended to in using the excision method of diathermy are the following:

(1) When applying traction, as in removal of a portion of the tongue, it must be remembered that the growth and its surroundings are elongated, and this may lead to the removal of too much tissue in one direction and too little in another. This can be avoided by marking out with the diathermy electrode the exact area to be removed before the parts are subjected to tension.

(2) The section should be made when possible at a distance of from ½ to ¾ of an inch from the margin of the growth.

(3) The electrode should always be made to cut at right angles to the surface, and on no account be allowed to slope inwards towards the tumour.

(4) Care must be exercised in nearing the site of an artery such as the lingual; it can generally be isolated and ligatured or obliterated by the use of the diathermy button.

(5) Sometimes the growth is of the diffuse or infiltrating type with no surface ulceration, and its margin may be very difficult to define. In such a case transection with the diathermy knife may be the best means of ascertaining the exact extent of the tumour.

In most of the regions under consideration the tissues around and deep to the growth consist mainly of muscles, and, when cutting through these, the surgeon has no difficulty in recognising the tumour should he by mischance cut into it. On rare occasions when excision cannot be accomplished and it is decided to destroy the tumour piecemeal with the button electrode, it is best to commence the application around the growth and gradually work towards its centre. When coagulation has been carried to some depth the dead material can be removed with a spoon or forceps and the process repeated at a deeper level. Layer after layer can in this way be destroyed.

The main advantages of diathermy over ordinary cutting instruments are briefly these: avoidance of cell implantation; little or no hæmorrhage during the operation and therefore a clear field to work in; destruction of tissues beyond the actual site of section; and sterilisation of the wound. Access to the growth is more often possible by the normal channels, and this avoids the necessity for such procedures as splitting or removing portions of the mandible. It follows from this that the growth can generally be attacked from its surface of origin. A second or even a third operation may be undertaken for recurrences. Bone which has become invaded by growth or which is in dangerous proximity to the tumour can be destroyed.

After operation the mouth, pharynx, or nose should be frequently cleansed with some mild antiseptic lotion. The food must be soft and nourishing. Sometimes the patient will have to be fed for a time through a nasal tube. It is best not to interfere with sloughs until they are quite loose; they usually do not begin to separate till the seventh day or later. Bony sequestra may take months or even years to separate. Secondary hæmorrhage is rare if scrupulous attention be paid to the removal of sepsis from the mouth before operation and if the main vessel of supply be ligatured. Hæmorrhage is more liable to occur after the treatment of an extensive growth. Pressure will generally control hæmorrhage, but bleeding points may require ligature, or the main vessel supplying the part, if not previously tied, may have to be secured. It might possibly be necessary to ligate the external carotid on the opposite side. When this is required, either before or (rarely) after diathermy, I have on several occasions carried out the following procedure which obviates the disadvantages of the classical operation described in the text-books (Patterson, 1930):

> The skin incision is the same as that employed in the classical operation. The deep fascia is incised slightly posterior to the anterior border of the sternomastoid and carefully separated from the under surface of that muscle. The muscle is now retracted and the carotid sheath is exposed on its outer aspect. A longitudinal incision is now made through the fascia covering the internal jugular vein which is freed from its fascial covering for a distance of from 2 to 3 inches. As a rule there are no tributaries entering from behind, and it is a comparatively easy matter to retract the vein medially and at the same time slightly elevate it from the underlying arteries. The vagus nerve must not be disturbed, and care should be taken not to injure the hypoglossal nerve or its branches. In this way the external carotid is brought into view by approaching it from the outside instead of from the inside of the internal jugular. The technique of the actual ligature of the external carotid does not in any way differ from that usually employed. It is very important, of course, not to apply the ligature until the superior thyroid and lingual arteries have been clearly defined. Sometimes it is advisable to tie the ascending pharyngeal artery.

As a temporary measure, compression of the common carotid against Chassaignac's tubercle may be tried.

Growths of the larynx, with the possible exception of a small carcinoma affecting the tip of the epiglottis, are unsuitable for diathermy. Tumours affecting the piriform fossa or the retrocricoid region are quite unsuitable for this form of treatment. In applying diathermy to a carcinoma of the posterior pharyngeal wall care must be taken not to cause necrosis of the cervical vertebræ. Carcinoma of the nasopharynx is a very hopeless disease from the point of view of surgical treatment, but if a growth were diagnosed very early it might be worth treating it with diathermy.

A Series of Cases

The following observations are based on 109 consecutive cases of malignant disease treated with diathermy before 1929—that is, over five years ago. I have subdivided them into groups, which will be considered separately:

	Cases.
Tonsil, soft palate, and faucial pillars	51
Tongue and floor of mouth	31
Lower alveolus	3
Buccal mucosa of cheek	6
Hard palate, upper alveolus, and maxillary antrum	8
Miscellaneous (nose, post-nasal space, and posterior oropharyngeal wall)	10
Total	109

The Tonsil, Faucial Pillars, and Soft Palate

It is convenient to consider tumours of this region under the above heading although the tongue is frequently, and the alveolus occasionally, involved in the growth. In an advanced case all these regions may be invaded, and it is often quite impossible to ascertain the exact site of origin. A tumour arising near the centre of the tonsillar mucous membrane, on the uvula, or close to the middle line of the soft palate may, even when it has reached a considerable size, still be classified as a tonsillar or palatine growth.

Diagnosis as a rule presents little difficulty, but it is astonishing how often carcinoma is mistaken for syphilis—syphilis practically never for carcinoma. It must be remembered that malignant disease may start on the posterior aspect of the soft palate, or starting at the edge of the palate it may extend upwards, involving mainly the posterior surface of the velum. In such a case ordinary inspection, unaided by examination with the post-nasal mirror or by palpation, may give rise to an entirely erroneous impression as to the situation and extent of the tumour. A carcinoma arising in the anterior part of the tonsil or on the anterior faucial pillar is liable to extend to the neighbourhood of the tonsil capsule, and if ulceration occurs a deep vertical cleft is produced in this region sometimes before the surface or substance of the tonsil has been extensively invaded. In this type of case the prognosis is extremely unfavourable as the disease has in all likelihood invaded the fibrous and muscular structures of the pharyngeal wall. There is little doubt that a carcinoma may originate in the lining epithelium of one of the tonsillar crypts and for some time, possibly a long time, if the site of origin be deep in the crypt, give rise to no symptoms or signs. Such a tumour, according to its size and situation, may or may not reveal its presence to the palpating finger. Eventually, no doubt, it will cause a tumour or ulcer on the surface of the tonsil, but by the time this occurs the disease may be far advanced. Two cases of this sort have come to my notice.

The first was a woman who was sent to me by my colleague, Mr. Russell Howard, with a large mass on the right side of the neck. I failed to discover any primary focus for what was obviously a malignant condition of the cervical glands. Some weeks later I again examined the patient. A small irregular area situated on the surface of the right tonsil was noticed which, however, did not present the typical appearance of a carcinoma. I removed the suspicious tissue and under the microscope it proved to be a carcinoma.

This was the first case of carcinoma of the tonsil I had seen in a woman. Since then I have met with only two others.

A few years ago a man was sent to me with what appeared to be a very large malignant mass on the right side of the neck. On inspection no primary growth was observed, but remembering the patient to whom I have just referred, I carefully palpated the tonsils and found on the right side a tiny area showing increased resistance. I removed the tonsil by dissection. Dr. P. N. Panton and I examined the specimen together, and it was with considerable difficulty that we located in the substance of the tonsil a small nodule which was harder than the surrounding tissue. This proved on section to be a carcinoma.

If a tumour of such small proportions, not larger than a split pea, can give rise to a large mass in the neck, in this case as large as a tangerine orange, it seems quite probable that a very considerable metastasis in the cervical glands may be secondary to a tumour of such diminutive size that it may entirely elude detection. Possibly in cases where malignant cervical glands are diagnosed, and no primary tumour can be found it would be wise to enucleate the tonsil on the corresponding side and submit it to the pathologist. I think it quite likely that not a few cases of early cancer of the tonsil have been overlooked. The disease is certainly uncommon. Baker records that of 500 cases of cancer occurring in the practice of Sir James Paget from 1843–61, 2 occurred in the tonsil, 30 in the tongue, and 9 in the gums and palate.

Cancer of the tonsil shows a greater tendency to grow upwards into the palate or downwards so as to invade the tongue than to extend forwards or backwards. As is the case with intrinsic cancer of the larynx, retrocricoid pharynx, bowel, and other regions, it tends to develop in a ring-like fashion. However, in the situation under consideration, a tumour starting laterally has seldom passed far beyond the middle line before the death of the patient. It must be remembered that a growth which on superficial examination appears to be purely tonsillar may be found on palpation to be largely situated in the tongue probably having originated in that organ. In some cases the growth spreads to the upper or lower jaws, involving the mucous membrane of the alveolus, the ascending ramus, or even the cheek.

TREATMENT AND ITS RESULTS

Until recently cancer of the tonsil and fauces has proved almost hopeless even when treated by the most heroic operations. With modern methods, which include diathermy and radiation, results have been much more encouraging. Possibly at the present time in suitable cases a combination of these two methods is best. As in other regions, the presence or absence of glandular metastases forms a most important factor when considering the prognosis (see Table).

During the second half of the nineteenth century numerous attempts at the removal of tonsillar tumours were made. In 1859 Houel saw Nélaton operate on a carcinoma limited to the tonsil. In the same year Maissonneuve described several cases of carcinoma of the tonsil where caustics were applied to cause sloughing of the tumour. This method, called "cauterisation en flèches," did not create a favourable impression. Demarquay in 1862 exposed the great vessels by an incision in the neck, and while these were retracted by an assistant he removed a carcinoma of the tonsil with an écraseur and treated a recurrence a month later with the cautery. In 1865 Langenbeck removed a carcinoma of the tonsil through an external incision; the patient recovered from the operation. In 1869 Cheever, of Boston, independently treated a case of carcinoma of the tonsil by the same route, with success. Erichsen in the same year removed portions of an encephaloid cancer with the écraseur.

Newman in 1892 found 144 recorded cases of malignant disease of the tonsils, and knew of a patient operated on by Macewen who was well twelve years later. Jacobsen in 1901 described 95 cases from the literature. Of these cases, 29 of which were treated by buccal excision and 24 by the external route, 7 survived for more than two years. He was able to report a case, microscopically confirmed, free from recurrence eleven years after removal of the tumour by a galvano-cautery loop. Five other successful cases had previously been collected by Watson Cheyne. Mathews in 1912, who could report no success himself, published 25 cases treated by other surgeons with 3 living for three years, 2 being very early cases treated by the cautery. Berven, of Stockholm (1931), surveys the work of continental surgeons. Out of 116 cases operated on only three lived for three years, one of these living for seven years.

I record here a series of 51 consecutive cases, all treated by diathermy over five years ago. Of these 10 were not microscopically confirmed, 1 was a malignant endothelioma; the remaining 40 were all squamous-celled carcinomata.

The failure to make a microscopic examination in some cases was either due to the destruction of the tumours by diathermy prior to the routine use of the excision method, a biopsy beforehand being considered inadvisable, or to an oversight. It may be observed that not a single case in my whole series diagnosed clinically as cancer, removed by diathermy excision, and subsequently examined microscopically proved to be non-malignant. So characteristic indeed is a carcinoma in the region under consideration that for purely diagnostic purposes it is seldom necessary to make a preliminary biopsy. If a biopsy is considered necessary a small portion of the tumour should be removed by the endothermy knife. The pathological examination can often be left till after operation, but of course it should not be omitted, and it must always, when a specimen is available, include a report on the glands. Many cases treated by surgeons in the past and quite a number which have recently undergone treatment with rays are unaccompanied by any pathological report, but in the case of the primary growth the margin of error when the observer is a clinician of experience is probably negligible.

The results in my series are as follows:

RESULTS

Of 51 consecutive cases treated over five years ago, 11 lived over five years=22 per cent. (Of 41 cases microscopically confirmed, 9 lived over five years=22 per cent.)

Of the successful cases 7 patients are still alive after periods of 13 yrs. 4 mos., 10 yrs. 9 mos., 9 yrs. 2 mos., 8 yrs. 11 mos., 8 yrs. 10 mos., 7 yrs. 11 mos., and 6 yrs. 10 mos. Four have died after 14 yrs., 8 yrs. 5 mos., 10 yrs., and 5 yrs. 6 mos., and one after 13 years from a recurrence.

In addition to the 51 cases recorded, in 4 advanced cases death followed block dissection of glands and in 2 cases extraction of teeth, before the intended diathermy operation. In 4 cases the glands were explored and found to be inoperable. In the other 51 cases the state of the glands was:—

	Total treated.	Lived 5 years.	Per cent.
Gland carcinomatous.	23	3	13
Glands not involved..	28	9	32

Three patients who had secondary deposits in glands are still alive and well after 10 yrs. 9 mos., 8 yrs. 10 mos., and 7 yrs. 11 mos.

It is difficult to compare my results with those published by other workers, but it is to be hoped that these notes will be an aid to those who wish to assess the prognosis after diathermy. Douglas Harmer, Gordon-Taylor, Dan McKenzie, Gwynne Williams, and W. L. Clark, of Philadelphia, have reported favourably on diathermy, but none of these surgeons has described any number of tonsillar cases treated by this method. Colledge and Peacock, reviewing the work at St. George's Hospital for 1921–30, mention only a few cases, one of which lived for two years.

In recent years radiological methods have been employed. The best published results from radiation seem to be those obtained at Stockholm by Berven (1930), using a new technique, including the use of the radium bomb, but a further lapse of time is required before it can be shown if these will be as permanent as in the case of patients treated by diathermy. The most striking results from radiation have been obtained in cases of so-called lympho-epithelioma, but no tumour of this type occurred in this series of tonsillar growths, although I have met with examples in the nasopharynx and more recently in the tonsillar region.

(To be concluded)

BEQUEST TO HOSPITAL.—Dr. John Frederick Jennings, of John-street, Berkeley-square, W., who died on July 5th (and whose obituary appeared in THE LANCET of July 14th), left estate of the gross value of £47,660, with net personalty £45,790. Subject to a legacy of £500 to his wife, he left the whole of the property in trust for her for life, and then to St. Bartholomew's Hospital for the endowment of beds or the foundation of scholarships for medical students.

ARTERIAL HYPERTENSION *

By O. L. V. DE WESSELOW, D.M. Oxon., F.R.C.P. Lond.

DIRECTOR OF THE CLINICAL MEDICAL UNIT AT ST. THOMAS'S HOSPITAL; PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LONDON

IT was a natural result of the discovery of a pressor body in the adrenal gland, that disturbances in the level of the arterial blood pressure should be attributed to excessive or defective secretion of adrenaline. This theory of hypertension has, it must be admitted, never won any general recognition, though many suggestive facts may be adduced in its favour, and though it has been vigorously advocated by the French school.

Among the arguments put forward for an adrenal factor in the production of permanent hypertension are the changes reported in the adrenal glands of hypertensive subjects, the alleged increase in the adrenaline content of hypertensive blood, the vascular lesions produced by adrenaline injections, and the frequent association of glycosuria, possibly of adrenal origin, with essential hypertension. More definitely significant, however, is the occurrence of permanent hypertension, accompanied by cardiovascular and renal lesions resembling those of essential hypertension, in patients in whom are found tumours arising from the chromaffin cells of the adrenal medulla, the so-called paragangliomata.

We cannot therefore ignore the possibility that the adrenal glands may be concerned, in some instances at least, in the production of a sustained high blood pressure. Physiological opinion would probably be adverse to such a view, since it is not disposed to regard the adrenal as concerned in the maintenance of vascular tonus, nor as a gland which is continuously pouring its active principle into the blood stream, but rather as a supplementary mechanism to be called into play only in emergencies.

Cannon,[1] whose opinion is entitled to the highest respect, believes that the evidence is against any sustained discharge of adrenaline, since the extremely sensitive denervated heart of the cat shows no change in rate after one adrenal has been removed and the secretory nerves to the other severed. The normal heart-rate is not therefore dependent upon adrenaline. As is well known, he regards the function of the adrenals as the preparation of the animal for muscular activity; under the influence of adrenaline discharge blood is shifted from the splanchnic area to the vessels of the muscles and heart, and this shift may even occur without any rise in the general blood pressure. In his cats, in which the sympathetic system was completely removed, and in which one adrenal was denervated and the medulla of the other removed, life proceeded in a normal manner in the quiet environment of the laboratory. Except that the animals were sensitive to cold, and incapable of responding to excitement by a rise of blood-sugar and of blood pressure, they were to all appearances functionally intact. Their resting blood pressure was apparently slightly low, which was to be expected, since the blood-vessels throughout the body were freed from the control of the central nervous system.[2]

The effect of ablation of the adrenals upon the blood pressure is disputed. There can be no doubt that the terminal stages of adrenal insufficiency are accompanied by a low blood pressure, and that at this period the fall in blood pressure is not entirely, if at all, attributable to lack of adrenaline. It has long been known that in the final phase of adrenal insufficiency concentration of the blood occurs, a concentration which is not affected by repeated injections of adrenaline.[3] In man a similar rise in the protein content of the serum has been observed during the crisis. Since the fall in blood pressure in animals shows an inverse relationship to the hæmoglobin content of the blood, it presumably results from a diminution in the volume of the circulating fluid.[4] In suprarenalectomised animals, maintained in health by injection of cortin, withdrawal of the cortical extract leads to a fall of blood pressure and concentration of the blood, which can be corrected by resumption of the injections (and administration of fluid), the blood pressure ultimately regaining the figure at which it stood before the extract was withheld. The extremely low blood pressure of the crises of Addison's disease therefore appear to be due to cortical rather than medullary deficiency, the cortical hormone regulating the water balance between blood and tissues. A study of the blood-sugar, the level of which has been regarded as in part due to continuous adrenaline secretion, leads to the same conclusion. In the crises, both in man and animals, a normal blood-sugar content may be found, though hypoglycæmia is the rule.[5] The blood-sugar is, however, an unsatisfactory index of adrenaline secretion, since its level is within limits largely conditioned by carbohydrate ingestion, and since some workers believe that the cortex is also concerned in the storage and utilisation of carbohydrates.[6]

---

* The second Croonian lecture for 1934, delivered before the Royal College of Physicians of London on June 7th. Lecture I. was published in our last issue and Lecture III. will appear next week.

This terminal stage of hypotension is of less significance to us than the intermediate period between adrenalectomy and the onset of the symptoms which result from cortical deficiency; for, if the tonus of the vascular system is to any extent maintained by a sustained output of adrenaline into the blood, a fall of blood pressure might be expected to occur immediately after the adrenals have been removed. Unfortunately the experimental work upon this question has yielded conflicting results.

Some workers deny that ablation of the adrenals produces any immediate effect upon the blood pressure[7]; others find that a steady fall in the blood pressure follows bilateral adrenalectomy or ligature of the adrenal veins,[8] and that the blood pressure may be restored to a normal level if the adrenal vein of an intact animal is anastomosed to the jugular of the animal upon which the operation has been performed[9]; others, again, have observed a temporary fall in the blood pressure, followed by a rise, the suggestion in the latter case being that the adrenals function as an accessory mechanism in the maintenance of the vascular tone, and that its loss may be made good by the intervention of the vasomotor mechanism.[10]

The Blood Pressure in Addison's Disease

In default of physiological agreement, clinical observation of the human subject has a very definite value. This is especially the case since we have in Addison's disease a condition of chronic adrenal insufficiency which has not as yet been reproduced in animals, and since in man the blood pressure can be determined with ease, whereas considerable difficulties are met with in following the blood-pressure variations in animals over prolonged periods.

From the clinical standpoint, it is of course recognised that a low blood pressure is a cardinal symptom of Addison's disease, and that this hypotension is present during the remissions, between the crises, and before the terminal stage of extreme asthenia is reached. A low blood-sugar is also a common finding. The question, then, arises how far this hypotension and hypoglycæmia are the result of adrenaline deficiency. At one time an affirmative answer would have been given without hesitation; but it is now recognised that cases of typical Addison's disease occur in which the chromaffin tissue is to all appearances intact. In such patients the cortex of the gland shows fibrosis and atrophy, but the medulla is apparently healthy, though the blood pressure is at a low level and the blood-sugar content may be definitely subnormal.[11] At first sight such a finding would appear to definitely exclude any connexion between the low blood pressure of Addison's disease and medullary dysfunction, but it is doubtful whether such a conclusion is altogether justified. There is a rich anastomosis between the arteries of the cortex and medulla in the zona reticularis, and it is possible that cortical lesions may lead to interference with the medullary blood-supply. The question of a synergistic action between the two parts of the gland has also to be taken into consideration. Cramer,[12] on histochemical evidence, believes that the cortex participates in the formation of adrenaline, though preformed adrenaline is not found in the fresh cortex. Lastly, pituitary participation in the production of the low blood pressure cannot be excluded, since Kraus has observed that, in cases showing cortical fibrosis and atrophy, changes are present in the anterior lobe of the pituitary which are absent with the more usual tuberculous lesion of the gland involving the medulla.

Until we know more of the function of the cortex it is impossible to dogmatise as to the respective parts played by cortex and medulla in the production of the low blood pressure during the remissions of Addison's disease. In the acute crises of adrenal insufficiency in man, cortin, which contains no adrenaline, is stated to produce a moderate rise of blood pressure; in the remissions, the cortical extract, though it improves the general condition and the asthenia, is said to have little effect upon the blood pressure, which remains at a low level.[13] If this is the case, both cortical and medullary insufficiency may be concerned in the production of hypotension, the low blood pressure, which persists during the remissions, and which is unaffected by cortin, being the expression of adrenaline deficiency, while during the crises acute cortical insufficiency leads to a diminished blood volume and a further fall of pressure. It certainly seems improbable that lack of adrenaline plays no part in the production of the symptoms of Addison's disease, and Rowntree, who has had a unique experience of the treatment of these cases, believes that the Muirhead treatment, which consists of intensive adrenaline administration, often produces marked temporary improvement.

Hypertension due to Paraganglioma

Though it is uncertain whether adrenaline is concerned in the maintenance of normal vascular tone, and to what extent, if at all, the low blood pressure of Addison's disease is the result of chromaffin insufficiency, it remains possible that excessive secretion of the hormone may, in view of its known physiological action upon the blood pressure, be concerned in the production of hypertensive states. The emergency view of adrenal medullary function naturally biases us against the suggestion that adrenaline is responsible for permanent hypertension, but the question can only be settled by actual observation.

In this connexion the study of the symptoms and the pathological changes which are found in association with the paragangliomata is therefore of especial interest. There can be no doubt that these tumours are derived from the chromaffin cells of the adrenal medulla, or from the accessory chromaffin tissue, since their cells give a positive chromaffin reaction, and also the Vulpian iron chloride reaction for adrenaline. The presence of adrenaline has been demonstrated in the growths by physiological as well as chemical reactions. The amount present in a paraganglioma described by Kalk [14] was no less than 375 to 500 mg., as estimated by both methods, chemical and physiological, an enormous quantity when we consider that the total adrenaline content of the human adrenals is usually believed to be about 4 mg. The potentialities of uncontrolled adrenaline discharge from such a tumour may be gauged by the fact that 0·03 mg. introduced intravenously may temporarily raise the systolic pressure by 50 mm. Hg, and that an injection of 1 mg. has produced unconsciousness and collapse.

The symptoms presented by these patients are typical of excessive adrenaline discharge. Though in the majority of cases the details are incomplete, it is possible to build up from the literature a fairly complete picture of the course of the disease. In the earlier stages the attacks are usually acute and transient. In the well-known case described by Vaquez, the first symptom was the occurrence of brief attacks of hypertension lasting only some five to ten minutes. The blood pressure during the attack rose from 140/80 to 300/180 mm. Hg, and the pulse from 70 to 100. In a recently recorded case the rise of pressure during the attack was typical of that produced by intravenous injection of a moderate dose of adrenaline, the diastolic pressure rising but little and the pulse pressure increasing greatly.[15] Other symptoms of the attack are painful cramps in the extremities, colicky abdominal pain, anginal pain, mydriasis, dyspnœa, pallor, headache, and drenching sweats. Transitory albuminuria may follow an attack, and with the rise of blood pressure a rise of blood-sugar occurs with glycosuria. Retinal and cerebral hæmorrhage may result from the rise of pressure, and death may ensue from left ventricular failure with pulmonary œdema.

A female, 43 years of age, suffering from a paraganglioma of the adrenal, was recently admitted to my wards. She had first consulted her doctor, four years previously, for thirst, polyuria, and loss of weight, accompanied by attacks of severe throbbing headache, drenching sweats, and weakness. A glycosuria was then found which could not be controlled by diet; insulin treatment was instituted, but aggravated her attacks to such an extent that it was discontinued. A year previous to admission a retinal hæmorrhage occurred during an attack, and the blood pressure was found to be high. Since that time attacks of dyspnœa, precordial pain, and palpitations had occurred, without relation to exertion.

On admission the blood pressure was 180/120, with a forcible apex-beat and a loud aortic second sound; the pulse-rate varied from 100 to 120. Albumin, sugar, and acetone were present in the urine; the blood-sugar was 0·187 and the blood-urea 0·060 per cent. The tachycardia persisted in spite of rest in bed, and profuse sweats were noticed. Four days after admission an irregular pyrexia developed, accompanied by a leucocytosis of 17,500, with 88 per cent. of polymorphonuclears. On the eighth day she died with a sudden increase of the fever to 105°.

The post-mortem was performed by Dr. H. K. Goadby. A tumour of the right adrenal was present (4 in. by 2 in. by 2 in.), derived from the medulla, the cortex was spread over its surface in a thin layer, and on section the growth proved to be a paraganglioma. The first part of the aorta showed gross atheroma; the left ventricle was hypertrophied. The kidneys were finely granular, the capsule stripping with difficulty; microscopically, while the majority of the glomeruli were normal in appearance others showed varying degrees of fibrosis and hyalinisation. A considerable degree of vascular change was present in the kidney, the smaller arterioles being noticeably thickened and showing fibrotic and hyaline change; the medium-sized vessels showed thickening and fibrosis of the media. No cause for the terminal fever was discovered, and it may reasonably be regarded as a true adrenaline pyrexia.

The syndrome has also been noted in association with paragangliomata lying outside the adrenal. Thus, in a man of 53 suffering from intermittent glycosuria and polyguria, a tumour composed of chromaffin cells was found in the inter-renal region; cardiac hypertrophy and chronic nephritis were present. In default of definite paroxysms of hypertension while the patient is under observation, or of a history of such attacks, the diagnosis is often only made post mortem, the provisional diagnosis being insulin-resistant diabetes, uræmia, or a vascular accident resulting from essential hypertension.

THE PATHOLOGICAL CHANGES AND THEIR CAUSE

Two points are of special interest—the frequent development of permanent hypertension in these cases, and the occurrence of vascular or ichæmic nephritis.

The course of the hypertension appears to be variable. In some cases acute hypertensive attacks are superimposed upon a normal blood pressure; in others permanent hypertension may be present, and upon this may be superimposed hypertensive crises, during which the pressure rises to a still greater height; in others again the blood pressure is permanently high, and hypertensive attacks may be absent, but in some of these latter patients a history suggestive of such attacks may be obtained. In one case at least the transition from paroxysmal to permanent hypertension has been observed. It would seem that in the stage of permanent hypertension tachycardia is often present, and in such cases glycosuria, resistant to insulin, is frequently seen—findings which suggest that a continuous secretion of adrenaline is going on, and that the persistently high arterial pressure may be due to such hypersecretion rather than to organic vascular changes produced by the paroxysmal attacks.

The post-mortem appearances closely parallel those found in essential hypertension The left ventricle is considerably hypertrophied; the kidneys in some cases appear to be normal, in others they have been found to be red and granular, and microscopically have shown varying grades of vascular nephritis; the aorta usually shows well-marked atheroma, and advanced degeneration of the cerebral vessels may be present. In one case retinal arterio-sclerosis, with small hæmorrhages and patches of exudate, is reported. During life, in addition to the presence of albumin and casts in the urine, nitrogenous retention may occur.

It is obvious that the terminal picture of the disease resembles very closely that of essential hypertension, and that a rough parallelism may be traced between the course of the two conditions, since in both the hypertension is at the onset labile, but later tends to become more fixed.

The final proof that excessive adrenaline secretion is the cause of the symptoms in these cases is still lacking; adrenaline has not as yet been demonstrated in the blood of these patients during a crisis. In Vaquez's case this was attempted by Gley, but without success. In view of the technical difficulties this single negative finding is of little significance. Apart from the very close correspondence between the symptoms of the attacks and those produced by injections of adrenaline, the proved presence of large amounts of adrenaline in the tumour and the successful results of surgical intervention leave little room for doubt that excessive adrenaline discharge is responsible for the pathological changes present. Extirpation of a paraganglioma has in four instances led to the cessation of the paroxysmal attacks.[16]

Hypertension associated with other Tumours of the Adrenal

We have then in the paragangliomata a condition in which over-secretion of adrenaline leads to permanent hypertension and the associated cardiovascular and renal changes typical of essential hypertension.

It may be mentioned that, though other tumours of the medullary tissue, such as the ganglioneuromata, do not lead to hypertension, a few cases have been described in which permanent hypertension has been present in connexion with tumours of undoubted cortical origin, combined with other symptoms which are believed to result from cortical dysfunction. Such tumours usually show a structure resembling that of the adrenal zona fasciculata. The patient described by Murray and Simpson [17] is possibly an instance of this syndrome.

A female of 36 showed hirsuties, amenorrhœa, and a blood pressure of 200/112 in association with a cortical hypernephroma; the pulse-rate varied from 80–110. After removal of the tumour the blood pressure fell temporarily to 130, but was unstable, rising readily with excitement. Later it rose again to 200 with a pulse-rate of 112.

Similar but more convincing cases of hypertension in connexion with cortical hypernephromata and precocious sexual development have been described in children in whom a coexistent essential hypertension may be practically excluded. Thus in a fatal case in a child of 13 years the blood pressure was 158/85 and post mortem a malignant tumour of the cortex with secondary growths in the liver was found. Some of the older cases, in which no post-mortem was obtained, were almost certainly instances of the syndrome now described as due to a basophil adenoma of the pituitary, but a residuum remains in which a connexion between a tumour of the adrenal cortex and the raised blood pressure appears probable.[18] In definitely malignant tumours it is certain that we are not dealing with the adrenal cortical hyperplasia present in the pituitary basophil tumour. The blood pressure in the cortical adrenal tumours, when raised, does not apparently show the extreme instability characteristic of the early stages of the paragangliomata. There can be no doubt that hypertension is rare in the relatively common tumours of the adrenal cortex, in contrast to its almost invariable presence in association with tumours of the medullary chromaffin tissue. Its occurrence is of particular interest in connexion with the changes in the adrenal cortex and the associated variations in blood pressure met with in patients suffering from pituitary lesions, and also in view of the occurrence of a low blood pressure in those cases of Addison's disease in which the medullary tissue is apparently intact.

Adrenal Factors in Graves's Disease

Adrenal over-activity has also been invoked in explanation of certain of the vascular symptoms of the thyrotoxic state. The cardiovascular disturbances of Graves's disease in many ways resemble those produced by an intravenous injection of adrenaline. The characteristic change in the blood pressure, in at least the early stages of the condition, is a rise in the systolic pressure, the diastolic remaining at a normal or even a low level, and the pulse pressure as a result being greatly increased. The cardiovascular response to emotion is exaggerated. If we add tachycardia and a tendency to hyperglycæmia and glycosuria we have a syndrome strongly suggestive of adrenal activity.

If the adrenal is actually concerned in the production of these symptoms, it is conceivable that there is either an actual over-production of adrenaline or that thyroxine sensitises the tissues upon which adrenaline acts, as suggested by Trendelenburg. For both these possibilities evidence can be adduced. It is a well-established fact that thyroid feeding produces in animals definite hypertrophy of the adrenals, even in as short a period as two to three weeks. In prolonged experiments the adrenals may show an increase in weight amounting to as much as 50 per cent. over the controls.[19 20] The increase in size is, however, confined to the cortex, the lipoid content of which is considerably increased, while the medulla is generally believed to be unaffected. Herring alone believes that the medulla of the adrenal and the chromaffin tissue in general participate in the hypertrophy, and that the adrenaline content of the gland, as estimated by chemical methods, is increased. The cortical hyperplasia may be explained on Marine's theory of Graves's disease, according to which the adrenal cortex exercises an inhibitory influence upon the thyroid.

Surprisingly few data are available as to the condition of the adrenals in human thyrotoxicosis. It would seem that the adrenals of thyrotoxic patients are generally small, and that both medulla and cortex are diminished in size, though cellular hypertrophy has been described in the former.[21] The human findings, such as they are, do not necessarily negative the positive results obtained in animal experiments, since the human adrenals are obtained from severe cases which have terminated fatally. On the view that the adrenal cortex acts as an inhibitor of thyroid activity, they may be regarded as suggesting a primary adrenal cortical deficiency in the production of Graves's disease. In any case, they show little sign of the presence of over-active chromaffin tissue.

The sensitising of the tissues to the action of adrenaline by the thyroid hormone was at one time accepted as an undoubted fact, but the experimental results of the older experimenters can no longer be accepted, since they failed to recognise that there is a considerable latent period before the action of thyroxine becomes manifest.

It is doubtful, for instance, whether any significance is to be attached to the work of Levy,[22] who found a great enhancement of the pressor effect of adrenaline within one hour of stimulation of the cervical sympathetic, which is believed to be the secretory nerve of the thyroid. More recently it has been shown by König [23] and others [24 25] that removal of the thyroid leads to a definite reduction in the pulse and blood-pressure response to injections of adrenaline, while on the other hand there are indications that, after thyroid feeding for several days, the pressor effect of adrenaline is increased and that the isolated heart of such animals is responsive to dilutions of adrenaline to which the normal heart is insensitive. In the intact thyroxinised animal doses of adrenaline which are without effect in the normal animal produce various forms of cardiac arrhythmia, including auricular fibrillation, and may even prove fatal. The Goetsch adrenaline test for the presence of hyperthyroidism has, it is true, fallen into disuse, but its doubtful diagnostic value in clinical work is due rather to the fact that positive results are obtained in patients in whom no thyrotoxicosis is present, rather than to negative results in patients suffering from hyperthyroidism. Actually a very high percentage of positive results was obtained in thyrotoxic subjects.

The whole question has been again reopened by the discovery that thyroxine itself has a direct action upon cardiac muscle, increasing its rate, beat, volume, and oxygen consumption; the isolated heart of the thyroxinised animal continues to beat at an accelerated pace for many hours after its removal from the body, and the addition of thyroxine increases the rate of pulsation of fragments of embryo heart muscle beating spontaneously in tissue culture.[26] [27] In neither of these preparations can there be any question of the intervention of adrenaline, and it is necessary to assume that the thyroid hormone is capable of affecting the cardiac muscle directly. Though such a direct action of thyroxine upon the cardiac muscle may account for the basal tachycardia of hyperthyroidism, the participation of the adrenal in the cardiovascular symptoms of the disease is by no means excluded, since the heart, and probably also the vasomotor mechanism of the thyroxinised animal, are abnormally sensitive to adrenaline discharge.

Hypertension and Hyperthyroidism

Apart from any question of the relative importance of thyroid and adrenal factors in the production of the cardiovascular symptoms of Graves's disease, the relationship of thyrotoxicosis to hypertension and the course of the blood pressure in Graves's disease need some consideration.

At the outset no true hypertension is present; the systolic pressure is often elevated, but there is no corresponding rise in the diastolic, which may even be lower than in health. The blood-pressure findings suggest a vigorous contraction of the cardiac muscle with an increased beat volume, but without increase in the peripheral resistance. The possibility that a true hypertension with an increased diastolic pressure may develop as the result of thyrotoxicosis seems to have been originally suggested by Riesman. Boas and Shapiro [28] have described an interesting group of patients, predominantly female, in whom a gross rise of systolic and diastolic pressure is present, accompanied by signs suggestive of a thyrotoxicosis.

The condition was especially frequent at the menopause. Though in most of their patients no recognisable goitre was present and the eyes were not prominent, nervousness, excessive sweating, and loss of weight suggested thyroid hyperactivity. Ten patients out of 27 showed a basal metabolic rate exceeding the standard by more than 15 per cent. The diastolic pressure was not at the low normal level characteristic of frank hyperthyroidism, but was well above 100 mm. Hg, in some instances reaching 160 mm., and the blood pressure tended to increase over the period during which the patients were under observation. Many of their patients would in this country be classified as undoubted cases of toxic adenoma.

The interesting feature of these cases is the presence of a raised diastolic pressure in association with probable thyrotoxicosis. It may, of course, be objected that hyperthyroidism and essential hypertension were accidentally associated in these patients, and a similar objection applies to the series studied by Rosenblum and Levine.[29]

In their patients hypertension had originally been present in association with definite thyrotoxicosis; re-examining their cases at an interval averaging three years after partial thyroidectomy, the blood pressure was found to be as high as it had been before the operation, though the basal metabolic rate had fallen to a perfectly normal figure. The persistent high pressure was therefore completely independent of the presence of continued thyroid over-activity, a finding suggestive of coincident essential hypertension, though it is possible that the development of the hypertensive state had been in some way connected with the hyperthyroidism.

It is difficult to arrive at any definite conclusion as to the frequency with which true hypertension with a raised diastolic pressure is encountered in thyrotoxic patients. In a recent investigation of patients who showed no signs of active hyperthyroidism after partial thyroidectomy a remarkably high incidence of hypertension was noted by Bach and Bourne.[30]

At the time of examination the patients were gaining weight, and the pulse-rate was normal except in those cases in whom auricular fibrillation had supervened; the basal metabolic rate was not determined. Fourteen of 36 patients showed hypertension, and in all but two of these the diastolic pressure was above 90; four patients showing a raised blood pressure were in their third decade, a time of life at which essential hypertension is uncommon. The patients, as a whole, had suffered from active thyrotoxicosis for a considerable period.

Taking 140 and 90 mm. Hg as the upper limits of the normal systolic and diastolic pressure respectively, of 75 thyrotoxic patients whom I have examined 23 were definitely hypertensive. Excluding 17 patients in whom the disease had been present for less than two years, the percentage of cases showing hypertension is 39, a figure which agrees closely with that found by Bourne and Bach. In only 9 cases, however, was the diastolic pressure above 100 mm. Hg. The hypertensive group was definitely older and the disease was of slightly longer duration than in the patients with normal pressures. In a considerable proportion of the cases active thyrotoxicosis was present at the time of examination, but thyroid over-activity does not in the early stages of the disease lead to a rise in the diastolic pressure.

An elaborate study of the question of hypertension in hyperthyroidism has been made by Hurxthal.[31] The change in the blood pressure which followed operation was typically a fall in the systolic, accompanied by a rise in the diastolic, with a resulting reduction in the pulse pressure. He found that the basal blood pressure, taken at rest, in a series of 250 cases of exophthalmic goitre at an interval of 6 to 12 months after operation, ran closely parallel to the blood pressure of a control group of non-toxic goitres taken under similar conditions. The two groups were compared by age decades. Patients who had been operated upon for toxic adenomata of the thyroid showed a higher systolic and diastolic pressure than the controls in the fifth and sixth decades of life. Apart from this difference he could find no evidence that hyperthyroidism leads to permanent vascular disease. He supplies no data as to the length of time during which symptoms of active thyrotoxicosis had been present previous to operation.

It seems probable that there is an abnormal incidence of true hypertension with a raised diastolic pressure among thyrotoxic patients, more especially perhaps in cases where the thyrotoxic condition is of long standing. The hypertensive patients are not necessarily elderly; in my own series four were in the fourth and one in the third decade of life, but the duration of the disease in these cases had averaged eight years. Such hypertension apparently persists after the hyperthyroidism has been successfully dealt with by operation. No reason can be assigned for this increased blood pressure, but the possibility that the vascular system in hyperthyroidism is sensitised to the action of adrenaline remains open. The question is of some clinical importance and merits further investigation.

BASAL METABOLISM IN HYPERTENSION

The suggestion that the thyroid may be concerned in the production of hypertension naturally leads to the question of the basal metabolic rate of patients showing a high blood pressure. There would seem to be no doubt that an increase in the basal metabolism is commonly met with in hypertensive subjects. To judge from the figures available in the literature, an increase in the rate of more than 20 per cent. is frequent in essential hypertension, and in some instances the basal metabolism may exceed the standard by more than 50 per cent.[32] This increase is not necessarily associated with cardiac decompensation, nor does it appear to be related to the pulse-rate, to the presence of glycosuria, or to the coexistence of arterio-sclerotic renal damage. The rise in the basal metabolism does not run parallel to the height of the blood pressure, and in many patients with greatly increased arterial tension the basal metabolism may be at a perfectly normal level. Though at first sight the findings appear to be highly suggestive of an endocrine disturbance in essential hypertension, it is not improbable that the increased metabolism is the result of the cardiovascular condition and in no way connected with its cause.

Increased basal metabolic rates have been reported as occurring frequently in valvular disease of the heart,[33] even in ambulatory patients in whom the lesion is fully compensated; in decompensated cases with dyspnœa, rates as high as 70 per cent. above the standard may be found, and especially high rates are met with in association with the large heart of aortic insufficiency. The general run of the figures in patients suffering from valvular disease appear to be closely similar to that seen in essential hypertension. Though the hypertrophied heart and the vigorous action of the respiratory muscles in the decompensated cases must lead to an increased metabolism, the cause of the rise in the metabolic rate of cardiac cases in whom the cardiac lesion is compensated is not altogether clear, but the occurrence of this rise is certainly an indication for caution in interpreting the high metabolic rate of certain hypertensive patients as necessarily endocrine in origin.

The Adrenal in Essential Hypertension

There is then a group of patients in whom a permanently raised blood pressure is associated with the presence of a tumour of the chromaffin tissue and in whom the hypertension may be reasonably ascribed to excessive secretion of adrenaline; there is also the possibility that in some cases of persistent thyrotoxicosis true hypertension may ultimately develop, though here the part played by the adrenal is in doubt. Is there reason to believe that the chromaffin tissue plays an important rôle in the ætiology of what we call essential hypertension ?

No advocate of an adrenal theory of hypertension would suggest that the majority of essential hypertensives can be included in either group as at present recognised. Hypertensive patients with a past history of thyrotoxicosis are rare; still more infrequently do we meet with cases of essential hypertension in whom a history of the paroxysmal attacks of high blood pressure, characteristic of the paraganglioma, can be elicited. Since, however, permanent hypertension can apparently result from over-activity of the adrenal medulla, it might be argued that essential hypertension is actually adrenal in origin, though in the vast majority of cases it develops insidiously and without the dramatic symptoms of sudden and excessive adrenaline discharge.

The pathological anatomy of the adrenals of essential hypertensives admittedly affords little support for such a view. Though hypertrophy of the adrenals may be induced by stimuli which call for an increase in their activity, such as injections of insulin, and involves the medulla, such hypertrophy as is found in the hypertensive states is generally believed to be confined to the cortex. Nodular hyperplasia of the cortex was originally described by French authors as occurring in essential hypertension and in chronic nephritis, but the constancy of this relationship is disputed. The size of the medulla is difficult to estimate owing to its irregular shape. Goldzieher[34] and Wiesel appear to be alone in believing that the adrenal medulla is hypertrophied in hypertension, and that the phaocrome cells are increased in number.

One further observation of some interest but of doubtful significance is reported by Goldzieher. As is well known, the walls of the adrenal veins are peculiar in that they show a well-developed layer of longitudinal muscle. The function of this musculature is doubtful; it has been suggested that its contraction may close the lumen of the smaller vessels, or that it may compress the whole organ and empty the blood contained in it, together with its adrenaline content, into the general circulation. According to Goldzieher this muscular coat of the adrenal veins shows, on careful measurement, an indubitable hypertrophy in hypertensive states; its thickness is increased in renal disease, in essential hypertension, and in polycystic disease of the kidney. This hypertrophy he regards as the expression of prolonged adrenal hyperactivity, but it is possible that it may be correlated with the hypertrophy of the medial muscle of the arterioles in these conditions, as the result of the action of a pressor body in the circulation not necessarily derived from the adrenals.

Estimates of the quantity of adrenaline present in the glands of hypertensive patients are conflicting. It can only be said that even those who claim that it is increased find a comparatively slight excess, the amount of adrenaline present being in no way comparable to the enormous quantities present in the paragangliomata.

ADRENALINE CONTENT OF THE BLOOD IN HYPERTENSION

More definite conclusions as to the activity of the adrenal medulla might be drawn from the quantity of adrenaline present in the circulating blood. For a time any vasoconstrictor body present in the serum of hypertensives was accepted without hesitation as adrenaline, and for this reason the older work upon the subject is of little value. O'Connor, who adopted a more critical attitude, was able to show that bodies of this nature were formed during the process of clotting; they were not present in plasma or uncongealed blood, and differed from adrenaline in their resistance to aeration and in their physiological properties. Recently there has been a revival of interest in the question of the adrenaline content of peripheral blood, though it is admitted that its detection, if it is actually present, presents grave difficulties. Adrenaline is known to disappear rapidly from the circulating blood, though in our experience adrenaline added to blood in vitro is recognisable for at least 20 minutes by the intestinal strip method. A more serious difficulty is the extreme dilution in which adrenaline may be expected to be present; the highest concentration suggested for the adrenaline content of the blood of the adrenal vein is 1 : 360,000, and it is estimated that the adrenal venous blood is diluted approximately 200 times on reaching the general circulation. Consequently the maximum concentration of the hormone which we may expect to find in the peripheral blood is in the neighbourhood of 1 : 100,000,000, assuming that no loss occurs in its passage to the systemic circulation and in the process of estimation. Such dilutions are altogether beyond demonstration by chemical methods and approach the limits detectable by the exceedingly delicate physiological tests.

It is scarcely surprising, therefore, to find that recent attempts to determine the adrenaline content of the blood in various pathological conditions have given discordant results.

Kure,[35] for instance, using arterial blood transferred as rapidly as possible to the rabbit's ear, found that normal blood showed a vasoconstrictor action equivalent to a dilution of 1 : 2,000,000 adrenaline, and that the constrictor action of hypertensive bloods was twice as strong. Such figures can hardly be accepted, since they would indicate that the total circulating blood contained no less than 5 mg. of adrenaline, an amount equal to the total content of both glands and far in excess of any figure that has been suggested for adrenaline output. Other workers,[36] using the same method, but employing venous blood, find a more marked vasoconstrictor effect with hypertensive blood and with the blood of thyrotoxic patients than with normal bloods, but that the constrictor action was not due to adrenaline, since it was not abolished by ergotamine.

In an interesting series of experiments, Brandt and Katz,[37] using the three physiological test-objects—the rabbit's ear, the intestinal strip, and the enucleated frog's eye—examined the peripheral blood, venous and arterial, in conditions other than essential hypertension, in which adrenaline discharge might be expected to occur. They claim to have demonstrated typical adrenaline reactions, abolished by ergotoxin, in blood taken during insulin hypoglycæmia, a condition in which the symptoms of the reparative stage—pallor, sweating, tachycardia, and an increase in the pulse pressure—are typical of adrenaline discharge, and in which such discharge is believed to occur. They also found that adrenaline was present in the blood of patients suffering from vascular crises, that is in patients showing spasm of the arteries of the extremities, in angina, and in hypertensives during attacks of palpitation, pallor, and dyspnœa; during the quiescent periods in essential hypertension no adrenaline could be detected in the blood. If confirmed, these experiments would seem to be highly suggestive of the presence of adrenaline in the peripheral blood, venous and arterial, under certain conditions, since they were not limited to a single test-object and since the pressor activity of the blood was abolished by ergotoxin.

Our own experience, using the intestinal strip method, and venous blood, in which clotting was prevented by heparin, tested immediately after withdrawal, has been that the blood of normal individuals and of essential hypertensives showed no typical relaxing effect upon the intestine; an adrenaline-like inhibitory effect was not infrequently obtained with the blood of thyrotoxic patients, but was not actually due to adrenaline, since the reaction was unaffected by ergotamine.

It would seem that, though it is possible that adrenaline is demonstrable in the peripheral blood, under certain exceptionable conditions, in which discharge is supposed to occur, there is at present little reason to believe that the peripheral blood of hypertensive patients shows an increased adrenaline content.

SENSITISATION TO ADRENALINE

Even if no excess of adrenaline is present in the circulation of the hypertensive patient, it is conceivable that his vascular system might be sensitised to the hormone, and that the normal secretion of the gland might as the result evoke an excessive response. At one time it was suggested that cholesterol was such a sensitising body, and it was claimed that hypercholesterinæmia was common in hypertensive individuals. It is obvious, however, that an increase in the cholesterol of the blood is not necessarily followed by a rise in the blood pressure, since in such conditions as nephrosis and obstructive jaundice the quantity of cholesterol present far exceeds that found in essential hypertension, and yet the blood pressure remains at a perfectly normal level.

The suggested sensitisation of the vascular system to adrenaline has led to an extensive output of work upon the effects of adrenaline injection in various types of hypertension. It is impossible to study the sequence of events which follows such injections without being impressed with the complexity of the factors involved. Centrally the hormone produces an increase in the rate of the heart with coronary dilatation, on which may be superimposed inhibitory vagal effects; peripherally it leads to vasoconstriction, the response being conditioned by the degree of existing arterial tonus. My own experience, using the intravenous route to ensure absorption and a dose of 0·03 mg., has been that the response is almost entirely central; the injection is immediately followed by a great increase in pulse-rate and a marked rise in the systolic pressure; the diastolic pressure, as estimated by the auditory method, is often unaffected or at most rises by a few millimetres; the vascular tonus and resistance in the periphery is therefore not increased. No constant difference was noted between normal and hypertensive individuals, either as regards the increase in pulse-rate or pulse pressure. With this dosage and method of administration there seemed to be no evidence that the hypertensive vascular system responds abnormally to adrenaline.

If smaller doses are used it is claimed that the essential hypertensive is relatively insensitive to adrenaline, and that the initial effect of the injection is often a fall of blood pressure instead of a rise. Such a reversal of effect with minimal doses of adrenaline is well recognised as occurring in animals, but in the essential hypertensive the response is said to differ from that obtained in health and the fall in blood pressure has been cited as evidence of a "vagotonic" state. Attempts have also been made to demonstrate changes in the electrolyte concentrations in the blood which would account for such an increased parasympathetic tonus.[38]

It is alleged that the mean calcium content of the serum of essential hypertensives is at a slightly subnormal level, that the potassium : calcium ratio is higher than in health, and that, as a result, the assumed parasympathetic-sympathetic balance is upset in the direction of a parasympathetic preponderance. It is doubtful whether such speculations rest on any substratum of fact. Extreme variations of the serum calcium, such as we meet with in parathyroid tetany and in association with adenomata of the parathyroid gland, are not accompanied by corresponding changes in the level of the blood pressure, and in essential hypertension the cardinal sign of "vagotonia," a slow pulse-rate, is exceptional. Deicke and Hülse[39] find that an initial fall of blood pressure is uncommon in essential hypertension after minute doses of adrenaline, the reaction in the majority of cases resembling that seen in normal individuals; where a fall occurs, they believe it to be the result of defective filling of the left heart as the result of pulmonary vasoconstriction, since it is accompanied by a rise of pressure in the systemic veins.

Generally speaking, it may be said that all attempts to demonstrate that the vascular system of the essential hypertensive is abnormally sensitive to adrenaline have failed; the various suggested sensitising substances which have from time to time been brought forward as the cause of the condition have not stood critical examination, and the direct method of testing by adrenaline administration has shown that, if the vascular response of the hypertensive differs at all from that of the normal, it is in the direction of lowered, rather than heightened, sensitivity.

GLYCOSURIA

Indirect evidence of an adrenal factor in hypertension was at one time believed to be afforded by the frequent association of glycosuria and hypertension, the glycosuria being assumed to be of adrenal origin and to indicate excessive adrenaline discharge. There can be no doubt that in any extensive series of diabetics a considerable number of patients will prove to be hypertensive, but on analysis the abnormal incidence of hypertension is found to be limited to patients above 40 years of age; up to this age the blood pressures of diabetics and normal individuals run approximately parallel, with a tendency to low pressure among the diabetics; after the fortieth year the incidence of hypertension among the diabetics is about twice that found in non-diabetic individuals of corresponding age.[40 41] Similarly, in any group of patients who have come under treatment for symptoms attributable to hypertension, a proportion will show hyperglycæmia and glycosuria [42 43]; though this association does not, in my experience, occur in the exceedingly malignant, but rare, type of hypertension which occurs in the third decade. In some instances transitory glycosuria may be noticed to appear in a hypertensive patient while under observation and ultimately become permanent. The facts are most readily explained by the assumption that the ischæmic vascular lesion is apt to lead to a functional deficiency in the pancreatic insular tissue in hypertensives of some standing, a degenerative change occurring comparable to that seen in the kidney; of all organs of the body the pancreas, after the kidney, shows the most marked vascular change in essential hypertensives, and albuminuria and glycosuria are commonly associated in these patients. The occurrence of this type of lesion probably accounts for the frequent association of diabetes and hypertension after the fortieth year, that is, during the hypertensive period.

Against an adrenal origin of the glycosuria in these cases is the fact that the glycosuria met with in the paragangliomata is stated to be insulin-resistant, while that of the glycosuric hypertensive is not. Again, Cori [44] has shown that in man the hyperglycæmic response is elicited by half the amount of adrenaline necessary to produce a rise in the blood pressure; on this finding, if hypertension is of adrenal origin, we should expect glycosuria to be the rule rather than the exception in essential hypertension, unless some compensatory mechanism is developed.

THE HYPERTENSIVE FACTOR

It would seem that there is no adequate evidence that adrenaline is the factor concerned in the production of the raised blood pressure in essential hypertension. Admittedly, persistent hypertension is occasionally associated with the presence of adrenal paragangliomata, and in such cases the raised blood pressure is almost certainly the result of over-secretion of the hormone by the tumour. Such cases, though unimportant numerically, are theoretically significant, since they show that over-secretion of adrenaline may ultimately produce permanent hypertension, and that vascular and renal lesions resembling those found in essential hypertension may result. The recognition of such a possibility gives a fresh impetus to the search for a humoral factor with a pressor action in the hypertensive, but it is doubtful whether adrenaline is the body to which attention should be directed. In certain respects the symptoms of essential hypertension are not those of hyperadrenalinæmia; tachycardia in the earliest stages is infrequent, the diastolic pressure is raised from the outset, and, though hyperglycæmia and glycosuria are not uncommon in hypertensive patients, there are strong grounds for believing that they are not of adrenal origin.

HOSPITAL TREATMENT FOR A GUINEA A YEAR.—A scheme is being arranged by the Forbes Fraser Hospital at Bath whereby for a guinea a year a man and his family can ensure nursing and maintenance. There is no income limit, but the age limit is 60. The benefits are: (1) payment at £3 3s. a week for nursing and maintenance at the Forbes Fraser Hospital for not more than four weeks in any 12 months; (2) a similar payment for nursing and maintenance to a paying patient at any other hospital or nursing-home approved by the committee; (3) payment for ambulance, when necessary, with a maximum of £1 in any 12 months. The scheme makes no grant for the payment of doctors, which must be arranged by the contributor. No assistance is given in confinements or cases of mental or infectious diseases. Accident cases where maintenance charges in hospital are covered by legal compensation are also not included in the scheme.

AGGLUTININ RESPONSE TO RECENT ANTI-ENTERICA VACCINATION

By G. Stuart, O.B.E., M.D. Aberd., D.P.H.
DEPUTY DIRECTOR OF MEDICAL SERVICES (LABORATORY SECTION); AND
K. S. Krikorian, M.D. Beirut
SENIOR BACTERIOLOGIST, DEPARTMENT OF HEALTH, GOVERNMENT OF PALESTINE

In a paper published in the *American Journal of Immunology* in 1924 a claim was advanced by Felix that by means of qualitative serum analysis distinction could be drawn between agglutination due to protective vaccination and that occurring during the course of enterica disease. Thus whereas both large-flaking H agglutinins and small-flaking O agglutinins were produced in the serum of enterica patients, H agglutinins alone occurred as a result of T. or T.A.B. inoculation. In 1928 this observation was confirmed by Stuart and Krikorian, who found that unvaccinated persons suffering from enterica infections exhibited in their blood both H and O agglutinins, rarely small-flaking alone (3 cases in 14) and exceptionally the large type without the small (1 case in 14). On the other hand "in the sera of vaccinated human beings not so suffering," they continued, "there is a production of large-flaking labilotropic agglutinins only and in no dilution is there any evidence of small-flaking, stabilotropic agglutinin formation."

These contentions of Felix and of Stuart and Krikorian have since been challenged by Gardner (1929, 1930), Whitehead (1930), Smith (1932), Wyllie (1932), Horgan (1932), Mudd (1932), and Dulanay, Wikle, and Trigg (1932); O agglutinins in varying titre have been successfully evoked by all these workers in persons vaccinated by the ordinary subcutaneous route.

It occurred to us that the discrepancy might be explained by a difference in the methods of vaccine preparation. An experiment was, therefore, devised to determine, if possible, what influence, if any, the mode of manufacture might exert on the agglutinin-producing power of a vaccine.

EXPERIMENTAL EVIDENCE ADDUCED

From Rawlings's strain of *B. typhosus* a quantity of antityphoid vaccine was first prepared: a 24 hours' growth of the organism on agar was washed off with normal saline solution and standardised to contain 1000 million bacteria per cubic centimetre; thereafter the vaccine was killed in a water bath at 60° C. and divided into three equal portions, to one of which 1 per cent. phenol was added, to another 0·5 per cent.; the remaining third was left uncarbolised. These vaccines, *after only three days' storage* in the ice-chest, were used to inoculate rabbits, of which three series, each consisting of three animals, were then treated. Rabbits 1 and 2 of each series were in each case given by the subcutaneous route a vaccine dosage of 2 c.cm.; rabbits 3 of each series 1 c.cm. intravenously. Eight days later the rabbits were bled and their sera qualitatively and quantitatively analysed. They were then inoculated with a second dose of appropriate vaccine identical in every respect with that first administered and were thereupon returned to the animal house for further observation.

The results of the agglutination tests performed on the sera of the rabbits eight days subsequent to primary vaccination were remarkable (Table I.A): whereas animals treated with vaccine preserved with 1 per cent. phenol showed in their blood a relatively low titre of O agglutinins (1 : 500), those treated with the uncarbolised vaccine exhibited well pronounced O agglutination in a serum dilution of 1 : 10,000; in the series in which the 0·5 per cent. carbolised vaccine had been employed, the O agglutinin content proved to occupy an intermediate position. No difference in the H agglutinin production was found to exist among the several series dealt with. Repeat experiments afforded like results.

TABLES I.A AND I.B

Agglutination Titres in the Sera of Rabbits Protected with Carbolised and with Non-carbolised Antityphoid Vaccines

2	500	—	500	1000	—	1000	2000	100	5000
3	2000	200	10,000	5000	200	10,000	10,000	—	1000

Tables I.B and III. are inserted to show the results of agglutination tests performed on the same experimental rabbits' sera 15 days and 3 months respectively after the date of the animals' second inoculations.

It may now reasonably be inferred that in rabbits the administration of killed typhoid bacilli in vaccine form is capable of producing vital reactions similar to those evoked by living strains during enteric disease; it may further be suggested that the relative inability of ordinary antityphoid vaccines to elicit O agglutinin response in the serum of treated rabbits is due to an impairment of the O agglutinogens in such vaccines by the phenol or other coal-tar derivative invariably used in their preservation.

TABLE II

200	—	10,000	500	100	1000

Note.—T = *B. typhosus*. G3 = *B. enteritidis* Gaertner. O901 = O variant of strain 901 of *B. typhosus*. The figures under the heading "Living" indicate the titre of O agglutination. The figures under the heading "Formolised" indicate the titre of H agglutination.

Next, with a view to determining whether comparable reactions follow the use of such vaccines in human beings, we inoculated with T. vaccines 14 persons who were without history of enterica disease or of previous prophylaxis and whose sera contained at first no detectable agglutinins. The vaccines, prepared, stored, and taken into use as described above, were exhibited in a dosage of 0·5 c.cm. followed 8 days later by 1 c.cm.; 7 persons were treated with a vaccine containing 1 per cent. phenol, 7 with a non-carbolised vaccine. Serum analysis was made in each case 15 days after the second inoculation and again 3 months thereafter. Tables II. and IV. summarise the results obtained. The findings in Table II. go to show that in human beings just as in rabbits dead typhoid bacilli can evoke the production of both O and H agglutinins in a manner and degree similar to that seen to be developed in the course of enteric disease. Moreover it would again seem likely that the relative inability of anti-enterica vaccines produced and preserved in the usual way to induce the formation of O agglutinins is due to some deleterious influence exercised by the coal-tar derivatives on the heat stable antigen, an influence probably increasing with the duration of storage.

PERSISTENCE OF AGGLUTININS

In rabbits protected with two doses of non-carbolised antityphoid vaccine residual O titres of 1 : 200 and 1 : 500 were still demonstrable after three months; within the same period, however, O agglutinins had disappeared from the sera of rabbits treated with an identical dosage of carbolised vaccines (Table III).

TABLE III

Relative Persistence of O Titres in Sera of Rabbits Protected with Carbolised T. Vaccines and with Non-carbolised T. Vaccines—3 months after the Second Inoculation

—	—	100	500	100	500
100	—	5000	500	—	2000

Table IV. complements Table II. and shows that O titres of 1 : 100 may persist in human beings for at least three months after vaccination with carbolised (1 per cent.) T. prophylactic, and that O titres varying from 1 : 200 to 1 : 1000 may still be present after the lapse of an equal interval following treatment with non-carbolised vaccine. Specially noteworthy is the agglutination of *B. enteritidis* Gaertner G3 (Tables II. and IV.) effected by the sera of persons immunised by non-carbolised vaccine.

DISCUSSION.—SUMMARY

A study of the foregoing experiments will make it clear that in human beings O agglutinin formation takes place as readily and often in as high degree after inoculation with suitable anti-enterica vaccines as it does during the course of enteric disease. In this respect a better response has been obtained here with non-carbolised vaccines than with those preserved even for a short time in low concentrations of phenol. An explanation has been sought in the apparently adverse, although admittedly unknown, effect exercised by the phenol on the heat-stable antigen. It is known, for example, that when typhoid immune serum is brought into contact with the phenol-preserved suspension of *B. typhosus* known as Ficker's diagnosticum, the O agglutination altogether fails; it is suggested that in ordinary T. and T.A.B. vaccines the exposure of the O agglutinogen to the action of phenol over varying periods of time may ultimately lead to a loss of antigenic power and thus to an absence of O agglutinins in the vaccinated persons' sera.

Now it has been advanced by Felix that in the typhoid-paratyphoid group the bactericidal amboceptors as well as the complement-binding immune bodies are identical with the small flaking O agglutinin and owe their existence to the stable antigen, and this view has received the support of Weil (1921), Savage and White (1925), Balteanu (1926), and Arkwright (1927), the last of whom concludes that "the heat-stable, smooth O agglutinogen is probably identical with the antigen which produces resistance and with the smooth heat-stable agglutinable substance." It is indeed now agreed that in order to be efficient an antityphoid vaccine should produce antibodies against the stable antigen; but all anti-enterica vaccines do effect to a greater or less extent the formation of O agglutinins in the majority of human beings, provided such vaccines are of relatively recent manufacture and administered in adequately interspaced dosage. It is not, therefore, a question of finding a method of vaccination which will fulfil this demand for O agglutinin production, but a method which will ensure the maximum production and persistence of these antibodies. The investigation carried out here inclines us to the view that anti-enterica vaccines issued without the addition of a preservative, and inoculated shortly after preparation, best meet the case.

The appearance and persistence of O agglutinins in significant titres follow in human beings and in rabbits the use of ordinary recently prepared anti-enterica vaccines, but would appear to be more marked in the case of vaccines to which no phenol has been added as preservative.

RHEUMATOID ARTHRITIS AND ITS TREATMENT BY GOLD SALTS*

By Jacques Forestier, M.D. Paris
PHYSICIAN TO THE HOSPICE THERMAL REINE-HORTENSE, AIX-LES-BAINS

Since Mollgaard of Copenhagen demonstrated that injections of gold salts would arrest the progress of tuberculosis, this treatment has been applied widely and often very successfully. It was rational therefore to suggest that the same remedy might be of service in other diseases of infective origin. Extensive research has been carried out during the past five years on more than 500 cases of rheumatoid arthritis, with results that have justified this assumption; gold salts have, indeed, been far more successful than any remedy previously employed.[1] [2]

In 1928 a group of the severe types of polyarthritis were selected for trial with gold salts, and while at first a small proportion of cases showed reactions such as stomatitis and erythema due to overdosage, the net result after two years was improvement almost amounting to cure in 60 per cent. True rheumatoid arthritis, infectious arthritis (gonococcal or others) of the polyarticular or monoarticular type, and the attenuated conditions of tuberculous arthritis all respond readily to gold therapy, though it must be emphasised that the earlier the conditions are treated the quicker and more convincing the results. Another group responding favourably is spondylitis ankylosans, especially in its early stages. Confirmation of these results has been published by Slot and Deville,[3] Umber,[4] Zimmer,[5] and others.

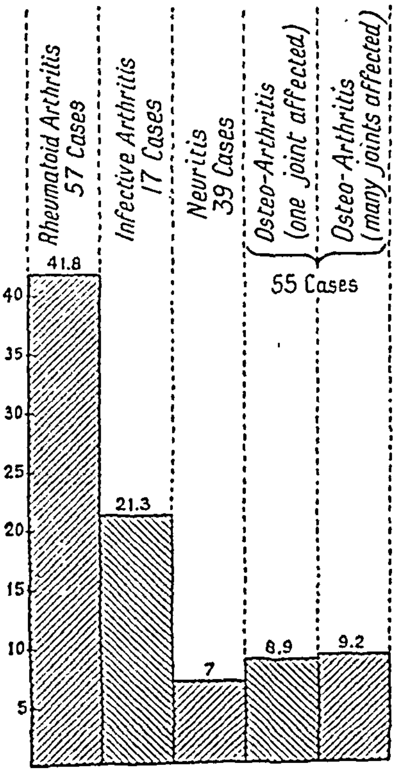

FIG. 1.—Diagram showing average figures for the sedimentation-rate (in millimetres) after one hour in various forms of rheumatism.

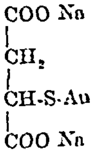
ACTIONS AND REACTIONS

The effect of treatment can be determined only by observation of the temperature curves and periodic determinations by the Vernes resorcin flocculation and the sedimentation tests (*Fig. 1*). *In the* former the range for normal subjects is from 5–20. Anything over 30 suggests a pathological condition infective in origin. In the latter test a high sedimentation-rate likewise denotes a pathological condition. Since cure, and not temporary improvements, is the objective, the treatment must be continued until the temperature curve and the respective tests show normal figures over a prolonged period (Fig. 2). It is equally important that a thorough clinical examination be made to ensure renal, hepatic, and other sufficiency.

Choice of Gold Salts.—The intramuscular route is best for the treatment of such a chronic disease, for the salts may be given by a skilled nurse or even the trained relations of the patient. The first salt I employed was auro-thio-propanol-sulphonate of sodium (*Allochrysine Lumiere*), but since 1932 gold salts in oily suspension have been employed. These are less liable to cause reactions while retaining their potency. More recently the aurothiomalate of sodium (Myocrisin)† has been used. It is water-soluble and lipo-insoluble, but is readily absorbed in oily suspension, and its formula is as follows:—



$$\begin{array}{l}\mathrm{COO\,Na}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{CH\text{-}S\text{-}Au}\\ |\\ \mathrm{COO\,Na}\end{array}$$

The aurothio-glycolate of calcium (Myoral) is insoluble in water and oil, hence it is absorbed more slowly. Myocrisin may be given in weekly injections of 0·1 to 0·2 g. The total amount for one series should be between 1·5 g. and 2 g. Several series should be given successively with intervals of six to eight weeks. Much larger doses have been given in certain cases, but it is not recommended as a routine for anyone with limited experience with gold compounds. The third gold salt used in oil suspension is aurothioglucose (*Oleo-Solganol B*).

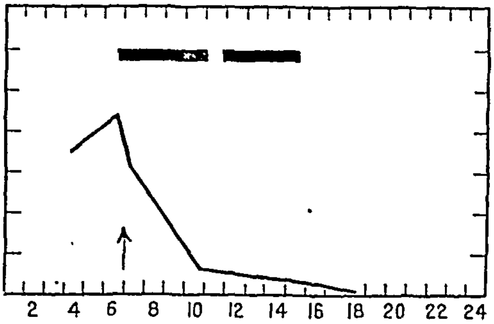


FIG. 2.—Graph of sedimentation-rate of the red corpuscles (first hour figures). Case of rheumatoid arthritis of 18 months' duration in a man, 57 years of age. Graph shows a rise in the sedimentation-rate before treatment and a rapid and steady fall to normal rate after two series of injections of gold salts (indicated in black). The dose of gold salts given was 2·6 g.

It is not advisable to administer gold salts orally at the present stage of our knowledge, and the salt chosen must be given in regular dosage with definite intervals of rest; otherwise failure or relapse will ensue after a partial improvement. The dosage necessary for treatment in rheumatoid arthritis is much smaller than that employed in tuberculosis. The allergic condition of arthritic patients explains the fact that they are more susceptible to the drug.

Reactions may be focal, general, or local. Local reactions are rare, for injections of gold salts cause no irritation with careful technique. Focal reactions include pain or increased swelling in the joints and are met with in about a third of the cases, diminishing from the third to the tenth injection. General reactions involving malaise, rise in temperature, and pulse-rate are rarely encountered. Pruritus and urticaria may be present, but unless severe they do not indicate change of treatment.

Attempts to treat patients with incomplete or single series of doses have met with no success, and only lead to relapse after improvement has begun.

---

* A summary of the Hunterian lecture of the Hunterian Society for 1931.

† Myocrisin is manufactured in England by Messrs. May and Baker, Limited.

Other reactions described by Milián under the term "biotropisme" may reveal symptoms of another existing disease hitherto unsuspected. In a few cases boils and herpes zoster have been noted, all apparently due to latent disease. Their presence, however, need not prevent treatment, and they gradually disappear.

Untoward Symptoms.—Albuminuria and renal insufficiency are only seen in predisposed patients. Disturbances of the skin and mucous membranes are met with most often, and are generally proportionate to size of dosage. Diarrhœa is occasionally experienced. As a rule the reactions are not sufficiently frequent or grave to interfere with the course of treatment, though many German authors advocate 40–80 g. of glucose given orally during the entire course of the treatment to obviate skin trouble. In France total hepatic extract grs. 10 twice daily by mouth, or twice a week by injection, is given. Thiosulphate of sodium and magnesium is also useful in preventing reactionary symptoms.

RESULTS

Clinical Results.—The first sign of improvement is relief of pain, and the patient is able to perform movements impossible before treatment. The second sign is reduction of swelling and its eventual disappearance. There is improvement in the general health, appetite increases, the skin looks more healthy, and there may be gain in weight. The temperature curve is the surest indication of the progress of cure.

When the soft tissues of the joint alone are involved gold salts will completely restore the function, but where the condition is long standing with muscular atrophy and eroded cartilages, fibrosis, and retractions treatment is not so successful. The process of chronic inflammation can, however, be stopped and the progress of the disease arrested.

A patient of 35 years had been affected for 13 years with polyarticular rheumatoid arthritis of both knees, one hip, both wrists, and an ankle. She could go with difficulty a few steps on crutches and was in constant pain. Two series of injections of gold salts were administered, and ten months later she was able to walk with a stick and to resume her work. The improvement was maintained by regular series of injections of gold salts at wide intervals.

Laboratory Results.—When laboratory tests have returned to normal figures a last series of injections is usually given. The patient is then asked to return at three-monthly intervals for the next two years for sedimentation-rate and resorcin-flocculation tests. If these remain normal and no other symptoms are present no further injections are given.

The sketches (vide Fig. 3) by Hans Jansen of Copenhagen form a basis for comparison of joint changes, which will reveal to the physician the "cleaning off" process of the joints.

FIG. 3.—Diagram using Jansen's ciphers, demonstrating joint changes before and after treatment (same case as in Fig. 2). The improvement in the joints corresponds to the fall to normal of the sedimentation-rate curve.

Summary of Total Results.—Over 500 patients have been treated, and of these 70–80 per cent. have responded well to gold therapy. Among these 50 per cent. of recent cases and 20 to 30 per cent. of cases of more than two years' duration have been permanently cured by 2–5 series of injections, and remained cured with no further treatment for two or three years. Such figures show the importance of early treatment, and compare favourably with other therapeutic measures in rheumatoid arthritis.

Vaccine therapy is of little use except in very early cases, but endocrine preparations may be given complementary to gold salts, especially in middle-aged women, and when once the inflammatory process has been reduced various forms of physiotherapy and spa treatment may be advised with advantage.

Twelve chronic cases with irreducible vicious ankylosis of one or many joints had these reduced under anæsthesia after preliminary injections of gold salts. There were no inflammatory reactions in spite of such drastic treatment. Passive and active mobilisation were started two days after the operation. A re-education of the joints was practised in the thermal swimming pool. Bedridden patients were made to walk after four to six years' invalidity.

Interpretation of Results.—The hypothesis is put forward that the development of rheumatoid arthritis is accompanied by tuberculous infections, but that it requires another infective element such as tonsils or teeth to provide it. Gold salts appear to be the most active means of treatment for rheumatoid arthritis, and this condition is amenable to cure in a very considerable proportion of early cases.

COOLEY'S ANÆMIA

BY ALAN MONCRIEFF, M.D., F.R.C.P. Lond.

PHYSICIAN TO THE CHILDREN'S DEPARTMENT, MIDDLESEX HOSPITAL; PHYSICIAN TO OUT-PATIENTS, THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON; AND

LIONEL E. H. WHITBY, C.V.O., M.D. Camb., F.R.C.P. Lond.

ASSISTANT PATHOLOGIST, THE BLAND SUTTON INSTITUTE OF PATHOLOGY, MIDDLESEX HOSPITAL

IN 1927 Cooley drew attention to an anæmia occurring usually in children of Mediterranean parents, associated with splenomegaly, a definite type of mongoloid face, and characteristic changes in the bones, particularly those of the skull and hands. The characteristics were those which in England might at one time have been grouped under the name of von Jaksch's anæmia, and it was in an attempt to define at least one definite disease as conforming somewhat to von Jaksch's original descriptions that Cooley separated the condition from the many other anæmic states of infancy and childhood. On account of its predilection for the Mediterranean races the condition is sometimes known as "thalassæmia."

Cooley has described one case in an English girl but the majority of others, such as those of Capper, have been in children of Mediterranean stock. The bony alterations caused by hyperplasia of the bone-marrow were first described by Brannan and definitely demonstrated with radiograms by Cooley, Witwer and Lee, Vogt and Diamond, as well as by Whipple.

The following case exhibits most of the clinical and hæmatological features which Cooley describes. We believe it to be the first example in a child to be reported in this country.

CLINICAL RECORD

The patient was a girl, aged 1 year and 6 months, the only child of Greek parents. The father and mother are not related and are both essentially healthy, although the father is stated to be rather anæmic and a paternal grandmother has been anæmic for many years. The child was born in the Middlesex Hospital on Nov. 1st, 1932, and weighed 7 lb. 3 oz. There are no other children in the family but the mother had a miscarriage in 1931, 13 months before the birth of this child. The child was normal at birth, not jaundiced, and progressed normally with breast-feeding until about three months of age. She was brought regularly to the infant welfare department of the Middlesex Hospital and then failed to attend for nearly seven weeks, during which time it was noted that she had become very pale. There was some difficulty over feeding at this time, the supply of breast-milk being insufficient and complementary feeding with a dried milk containing extra iron was instituted. Shortly after this, at the age of five months, corresponding to another change in the diet by the mother who began to give Grade A cow's milk on her own initiative, the baby had an attack of screaming and colic, with vomiting and blood in the stools. She was admitted for observation as a possible case of intussusception, but there was no tumour to be felt and all symptoms rapidly disappeared.

The child then continued to attend the infant welfare department fairly regularly and in April, 1934, suffered from an acute upper respiratory tract infection, after which the pallor became more noticeable and an enlarged spleen was felt. She had from the ninth month onwards been taking a good mixed diet. She was admitted for further investigation on April 21st.

Physical examination.—She is a moderately well-nourished child, weighing just over 19 lb. There is a curious tint to the skin which appears to be a mixture of pallor and pigmentation of the race. The mucous membranes are all pale—there are no bruises or petechiæ. The face is not abnormal in appearance and there are no abnormal swellings to be felt over the skull or other bones. The heart is rapid (rate 130–140 at rest) but not enlarged, and there is a systolic murmur at the apex. The spleen is markedly enlarged but not unduly hard. The liver is felt about 1 in. below the costal margin. The lymphatic glands are not enlarged except for a few small glands in the neck. The lungs are normal. Genito-urinary system normal and urine (see below) does not contain albumin or sugar. There are 16 teeth, all in good condition. The tonsils are not enlarged. The central nervous system presents no gross abnormality. Optic fundi pale but no hæmorrhages.

Blood examinations gave the following results:—

Date	April 10th.	April 25th.	May 4th
Red cells per c.mm. ..	3,160,000 ..	2,970,000 ..	3,070,000
White cells per c.mm. ..	18,600 ..	9,200 ..	22,800
Hæmoglobin per cent. (Haldane)	38 ..	40 ..	40
Colour-index	0·5 ..	0·7 ..	0·65
Differential count per cent.—			
Neutrophil polymorphonuclears	34 ..	25 ..	23
Lymphocytes	62 ..	70 ..	65
Large mononuclears ..	3 ..	5 ..	10
Eosinophil polymorphonuclears	— ..	— ..	2
Mast cells	1 ..	— ..	—
Myelocytes	— ..	1 seen ..	—
Myeloblasts	— ..	— ..	—
Anisocytosis	+ + + ..	+ + ..	+
Poikilocytosis	+ + ..	+ ..	+
Polychromasia	+ + ..	+ ..	+
Reticulocytes per 100 red cells	— ..	5 ..	—
Normoblasts per 100 white cells	17 ..	10 ..	3

Price-Jones curve (see Figure) shows broad base and high coefficient of variation. Modal means by halometer 7·2 μ. Fresh blood preparations show no sickling—this to exclude the occurrence of sickling in Greeks as described by Cooley and Lee (1929). Fragility of red cells showed a slightly increased resistance to saline solutions when tested quantitatively. Hæmocrit reading showed: volume index, 0·87; saturation index, 0·8; Wassermann reaction, negative.

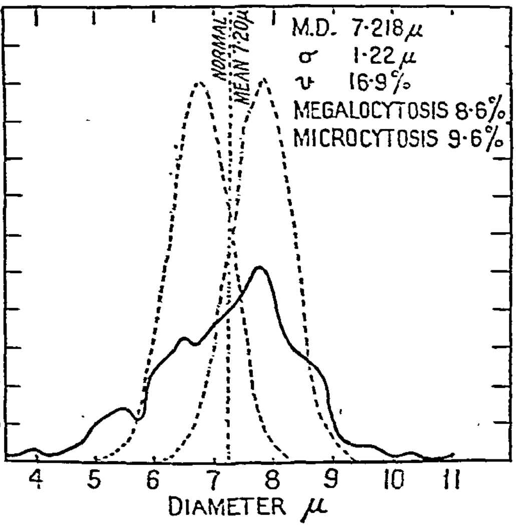
Biochemical investigations.—Blood-urea 26 mg. per 100 c.cm., non-protein nitrogen 25 mg., hæmoglobin 5·5 mg.; plasma proteins: albumin 4·6 mg. per 100 c.cm., globulin 3·0 mg., fibrinogen 0·24 mg., cholesterol, the low figure of 170 mg.; calcium, 10·0 mg.; phosphates, 5·0 mg.; phosphatase 13 units (method of Jenner and Kay, 1932). The figure of 13 units falls within the normal limits of 11·7–14·2 as determined by Dr. J. D. Robertson on a group of four children at this age-period. Van den Bergh test gave a faintly positive direct delayed reaction and a positive indirect reaction. The serum contained 2–3 units of bilirubin. The fæces contained bile-pigment and the urine contained urobilin but no bilirubin or urobilinogen.

Radiographic examination.—All the bones show generalised rarefaction, with thinning of the cortex. The metacarpals show a slight degree of trabeculisation, but this is not definite in the other bones. The vault of the skull shows some thinning of the tables and the medulla is increased in width. Radiating spiculation is also seen.

OBSERVATIONS POST MORTEM

The patient died when an anæsthetic was being given for the purpose of transfusion. The following were the macroscopic and histological changes in the various tissues.

Macroscopic.—The skull bones were greatly thickened but so soft that it was possible to push a scalpel through with but little force. The skull itself was discoloured, being a light purple colour, whilst hard calcareous plaques were present. These were most marked in the occiput, being there about the size of a shilling, but smaller plaques were present in all the skull bones. The bony tissue of the femur was so thin that on cutting out a piece of it the shaft cracked across. There was a thin bony covering over dense dark red bone-marrow. The marrow was about the size of a pencil in thickness, was easily detached, and firm enough to be removed without breaking. Bony trabeculæ were eroded, and the inner plate of the shaft was quite smooth. The spleen weighed 3½ oz. but was not as large as had been suspected on clinical examination when the patient was first seen; the Malpighian bodies were small. Of other organs, the gut showed prominent Peyer's patches and hæmorrhages into the mucosa; the lymph glands, except for the tonsillar glands, were not enlarged; the liver was slightly large and a little pale; the kidneys were not fatty, whilst the heart, though pale and flabby, was not as much affected as was anticipated.



Red cell distribution curve showing broad base and high coefficient of variation.

A microscopical examination was made by Dr. R. W. Scarff and Dr. A. T. B. Goldsmith, of the Bland-Sutton Institute, who reported as follows:—

Bone-marrow.—The portion received for section shows a very marked hæmopoietic reaction. There are islands of hæmocytoblasts surrounded by erythroblasts. The majority of the latter have basophil cytoplasm, some are polychromatic, and a few are eosinophilic. There are comparatively few normoblasts and erythrocytes. Between these islands of erythropoiesis are a few myelocytes. The majority of these are eosinophil in type. There are a few polymorphonuclear leucocytes scattered throughout the marrow, and megakaryocytes are very numerous. In the portions sectioned there are very few capillaries visible, and fat cells are scanty. The changes are indicative of a marked erythroblastic reaction, with early maturation of the cytoplasm of the erythroblasts—i.e., a shift back to megaloblastic erythropoiesis.

The *liver* shows cloudy swelling. Free iron is present in small quantities, chiefly in the portal tracts and around the periphery of the lobule. The sinusoids are dilated and contain blood, with many nucleated corpuscles, some of which have eosinophil, others polychromatic, cytoplasm. These cells are present in the capillaries of other organs—e.g., stomach and kidney. There are no islands of hæmopoietic tissue.

Spleen.—The pulp contains nucleated red cells of megaloblast and normoblast type, and many megakaryocytes. There are also present numerous myelocytes—many of these again being eosinophil. No islands of erythropoietic tissue are present, and no "foam" cells.

Stomach.—There is some atrophy of the mucosa, and small follicles of lymphoid tissue are present in the submucosa, which is infiltrated by numerous eosinophil polymorphonuclears. Nucleated red corpuscles are present in the capillaries.

The kidney shows some cloudy swelling of the tubules, but no other definite abnormality.

The lymph glands show persistence of normal follicular structure. Nucleated red corpuscles are present in the capillaries, but there are no erythroblasts in the gland stroma.

The findings in the bone-marrow are similar to those described by Turnbull (1934) in the marrow from an English girl of 19.

COMMENT

Cooley's anæmia appears to be a definite clinical entity and is probably a blood dyscrasia appearing as a recessive in the Mediterranean races. It is therefore comparable to the sickle cell anæmia of the negroid peoples. The case described will provide an opportunity for further observation in that the mother is again pregnant and the infant after birth can be examined to determine whether it has also inherited the condition and, if so, at what age it is first evident. The patient herself did not respond to treatment with iron and a blood transfusion produced some definite improvement. At an attempt at a second transfusion the patient unfortunately died under the anæsthetic.

We would emphasise that though Cooley has clearly defined a disease entity the features do not express the concept of von Jaksch's anæmia as understood by modern English pædiatricians. Advances in hæmatology and clinical knowledge now prevent the inclusion of leukæmic cases in the von Jaksch category and the syndrome is no longer a convenient dumping ground for all the unexplained anæmias and splenomegalies of infancy. Von Jaksch's anæmia is a useful term even though the conception of it must be somewhat elastic. The term implies that in the opinion of the clinician and hæmatologist the prognosis is not hopeless—a feature emphasised by von Jaksch himself. In contrast to Cooley's group, there is not only this relatively favourable outlook if treatment with iron or transfusion is energetically pursued, but there is also no constant familial trait (twins with the condition have, however, been reported) and no bony changes other than those due to associated rickets—a by no means invariable complication. Von Jaksch's anæmia appears to be a subacute hæmolytic anæmia, probably the result of infection in which there is in addition to the red cell changes a definite reaction on the part of the leucoblastic tissue resulting in the appearance of myeloid cells in the blood.

This case of Cooley's anæmia was shown at the Royal Society of Medicine (section of disease in children) on May 25th.

We wish to thank Dr. J. D. Robertson of the Courtauld Institute of Biochemistry for his many investigations and for the trouble taken in providing us with normal control figures. We are also grateful to Dr. F. G. Nicholas for help with the radiological diagnosis.

NON-SPECIFIC PROTEIN THERAPY IN ASTHMA

By Thomas S. Nelson, B.M. Oxon., F.R.C.P. Lond.
PHYSICIAN TO BROMPTON HOSPITAL, AND ASSISTANT PHYSICIAN TO ST. GEORGE'S HOSPITAL, LONDON; AND

Geoffrey Duckworth, M.R.C.P. Lond.
MEDICAL REGISTRAR (IN-PATIENTS) AT ST. JOHN'S HOSPITAL, W.C., AND CLINICAL ASSISTANT AT BROMPTON HOSPITAL AND AT VICTORIA HOSPITAL FOR CHILDREN, CHELSEA

The purpose of this paper is to supplement a previous one [1] written by Dr. Arthur Porter and one of us (T. S. N.), in which were recorded some effects of injection of proteins in cases of bronchial asthma. The protein therapy already described has been continued and further experiments along similar lines have been made.

A large number of apparently dissimilar substances have been used in attempts to relieve the condition of the asthmatic, with varying measures of success: bacterial vaccines; tuberculin; broth, as used by us and named "B.B.W."; peptone, as advocated by Auld; cow's milk; and sulphur. Van Leeuwen used a 0·5 to 1·0 per cent. suspension of sulphur in olive oil, giving 1 c.cm. intramuscularly. It was followed by a local and general reaction and an improvement in the asthmatical condition, and he considered it more reliable than milk. Autohæmotherapy and autoserotherapy have also been used. An interesting substance is the proteose described by Oriel.[2] In his last paper Dr. Oriel comments on the difficulty of finding, among the various substances used, the common factor that leads to the amelioration of the asthma. We also are seeking some light on this problem, for in it may be concealed the missing links in the story of allergy.

ANAPHYLAXIS IN ANIMALS AND ATOPY IN MAN

For many years it has been recognised that when an antigenic substance gains access to the blood the body seeks to protect itself by forming an antibody whose function it is to render the foreign substance innocuous. These antibodies at first circulate in the blood but eventually largely disappear, remaining in certain of the tissue cells. If, during the period of circulation of the antibodies, more of the antigenic substance reaches the blood, an interaction takes place which is not accompanied by any bodily disturbances. If the antibodies are sessile upon some protein molecule the reaction occurs in or on the surface of the cells, causing marked functional disturbances.[3]

A very similar though actually different condition, known as atopy, occurs in man.[4] It is an inherited hypersensitivity, or tendency to become hypersensitive to certain proteins. Its clinical manifestations are seen in asthma, hay-fever, urticaria, some forms of eczema, almost certainly migraine, and perhaps even epilepsy. The nature of the reaction is unknown but a histamine-like substance is formed. This substance may perhaps be liberated from the tissue cells [5] as a result of a change in the permeability of the cell envelope caused by an alteration in the colloidal state.[6] In passing, it is interesting to note that adrenaline, which is beneficial in atopic diseases, is a natural pharmacological antagonist to histamine.

THE COMMON FACTOR

If it were possible to bring about a *circulation* of antibodies (to the offending allergens) one would expect the sensitised cells to be consequently protected. There is experimental and clinical evidence to suggest that when the antibody-forming tissues—probably the reticulo-endothelial system of cells—are stimulated to form antibodies to a particular antigen, the response is frequently general as well as particular.[8 9 10] By this we mean that antibodies which were produced at previous dates in response to different antigens are produced again. Boyd [11] considers it probable that in non-specific protein therapy it is the cells of the reticulo-endothelial system which respond. This would offer a rational explanation of why injections of protein and substances which may stimulate antibody formation are beneficial. And the common factor may be, we suggest, the ability to knock off, as it were, the sessile antibodies.

Examples of intercurrent disease benefiting the main affection are not difficult to think of. It may act in a somewhat similar manner—e.g., malaria in general paralysis—and Clark states that chronic gonorrhœa has been successfully treated with typhoid vaccines. Other examples are seen in nature, as when the course of chronic disease is greatly improved after an acute illness. Lobar pneumonia has such an effect on asthmatics. It is, however, not easy to formulate an hypothesis that explains all these phenomena satisfactorily.

The reason why sulphur should be beneficial is not evident. One school of thought attributes the action to its colloidal state. Van Leeuwen's preparation consists of a suspension in oil. One would expect a colloidal preparation to be precipitated by the salts of the subcutaneous tissues or muscles. In this event, the substance is deposited in a very finely divided state and highly active form. One milligramme intramuscularly will give rise to a brisk hyperpyrexial reaction. The good results sometimes obtained by using colloidal sulphur in the treatment of other conditions are commonly held to be due to hyperpyrexial reaction, which is accompanied by certain blood changes. We have deliberately refrained from using pyrexia-producing doses. The actual dosage has varied between 0·5 c.cm. of a 1 : 10,000 to 1 c.cm. of a 1 : 1000 preparation. The most useful doses usually lie between 0·2 and 0·8 c.cm. of the latter strength.

We do not propose to discuss the metabolism of sulphur but would recall that sulphur plays an important part in some oxidative processes,[12] and that one of the body's chief ways of dealing with poisonous substances is by oxidising them to simpler constituents. The noxious substances indol, skatol, and phenol, formed in the gut, are, after oxidation, excreted in the urine combined with sulphur. Voegtlin has suggested that salvarsan acts by uniting with the glutathione of the spirochætes and arresting oxidation. The exhibition of sodium thiosulphate in salvarsan poisoning is recognised as a helpful proceeding. Though the reason for this benign action is obscure, it seems certain that the body proteins find freely available sulphur of the utmost assistance in certain protective reactions.

In addition to colloidal sulphur (which was kindly supplied by Messrs. Crookes Ltd. in the first place) we have used a protein of vegetable origin. It was a matter of some difficulty to obtain one that was freely soluble in water, so that it could be kept as a standard solution and diluted to our requirements. With the help of Mr. G. W. Spence, dispenser to the Brompton Hospital, success was achieved with the soya bean.[13] This preparation was used in a strength which should correspond approximately to the "B.B.W." So far the results obtained have not been very encouraging, but we have not yet subjected it to exhaustive tests.

RESULTS

The results of our recent work are published in the Tables appended. The cases have been divided up, this time, into degrees of severity: (1) mild; (2) moderate; (3) severe. This grading is only relative because, before any case is admitted to the clinic, thorough trial has been made with the usual medicaments, dietary and hygienic advice offered, and any desirable operative measures that would correct defects of the upper respiratory tract performed. Group 1 includes those who get attacks several times yearly, sometimes lasting for weeks but with fairly long free intervals intervening. Group 2 includes those who have been getting severe attacks monthly, or more often, frequently associated with nightly bouts of "tightness" of the chest. Group 3 includes those who have been getting severe attacks weekly, or even daily, sufficient to interfere with occupation and comfort.

The results have been put into four classes, as before, marked A, B, C, and D. "A" signifies very much improvement. The patient is practically free from any attacks and those which may occur are milder in character and shorter in duration. "B" signifies much improvement. The attacks are definitely less in frequency and milder in type and duration. The patients express themselves as being "much better since the injections." "C" means improvement. There is definite diminution in the frequency of the attacks and/or lessening of severity, but troublesome bouts persist. Commonly it is the character of the paroxysm which is altered. Nightly spasms are common. "D" means no improvement whatever.

TABLE I

General Results in 46 Cases of Asthma

Explanation of grouping is given in the text

Per cent. ..	32·6	32·6	32·6	2·2	100

A striking feature is the regularity with which the majority of patients attend for prolonged periods. If, after the first few injections, a patient is not improved he or she would be expected to stop coming. This has happened in a few instances but the majority persevere until an effective dose and preparation have been found. The multiplicity of substances used is not necessarily a confession of the inadequacy of any particular one. Some people respond to one substance better than others, and vice versa. Table II. shows that "B.B.W." holds the first place therapeutically. Colloidal sulphur is promising and forms an interesting addition to our armamentarium. The number of cases treated with soya bean is so far too small to justify a conclusive opinion.

The cases treated with autogenous vaccines need an explanatory note. We have long held the opinion that one of the types of asthmatic most resistant to treatment is that in which the patients are hypersensitive to catarrhal organisms, usually of streptococcal type. These people carry their own provocative agent about with them and require only a trivial exciting cause to precipitate an attack. It is interesting to note that Knott and Oriel have detected histamine-like substances in asthmatic and other sputa[11] and suggest a bacteriological origin. These possibly histamine-producing organisms, when situated in the bronchioles, might well cause asthma by liberating histamine in situ. These people are very sensitive to cold air, which seems at once to cause an attack. They are intensely sensitive to injections of autogenous vaccines administered in normal therapeutic doses; in fact, a very alarming reaction may be caused. Our vaccines are well diluted and we commence with very small doses. The results are not particularly good but better than those obtained with other agents in this class of case.

Besides these results, obtained from cases attending the Brompton clinic, we have reports from various practitioners in different parts of the country who have been using "B.B.W." for a number of years with encouraging results. Experience is required to obtain the best results, and correct dosage is essential. Where failure has been reported we have often detected some error in size of dose. In one case we were able to permit the patient, a man of intelligence, to administer "B.B.W." to himself. The result has been most satisfactory, particularly in view of the fact that it was a very bad case and had failed to respond to other therapy. The injections are usually given weekly or fortnightly.]

SUMMARY

(1) We confirm our previous conclusion that protein injections are markedly beneficial in asthmatics. (2) Colloidal sulphur produces good results and its addition to our therapeutic weapons is justified. Our best results have been obtained with "B.B.W." (3) We reassert that the treatment forms a short-time prophylaxis. (4) We suggest that the common factor, which various apparently dissimilar substances possess, of causing good effects in asthma may be the property of reawakening the antibody-forming tissues to produce and circulate antibodies; a particular stimulus causing a general as well as a particular response. (5) There seems to be a strong probability that the hypersensitivity, or tendency to develop hypersensitivity, is inherited as a Mendelian dominant character. Thus the prospect of absolute cure of atopy is a little gloomy.

Clinical and Laboratory Notes

A CASE OF ANÆMIA

BY KENNETH M. MACLEOD, M.R.C.S. Eng.

LATE HOUSE PHYSICIAN, THE HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL

A MAN, aged 33, a fried-fishmonger by trade, was admitted to the Hampstead General Hospital on Jan. 25th, 1933, complaining of painful swelling of the left knee for the past ten days. There was no history of injury. The swelling had been aspirated by his doctor on the evening before admission and fluid resembling blood was understood to have been withdrawn.

CLINICAL RECORD

Past History.—Penile sore 14 days before admission (Wassermann reaction negative). Facial abscesses during latter part of previous autumn. All teeth extracted before Christmas, 1932. His wife and friends had noticed that he was getting paler since the previous October (1932). No other serious illness.

Family History.—Married 8 years; wife healthy, no children. Father died, aged 49, of "tumour of liver." Mother died, aged 56, of aortic disease with infective endocarditis. No sisters or brothers.

Condition on Admission.—Temp. 98° F., pulse-rate, 92, resp. 20. A pale, thin man, rather toxic looking, but colour of lips and ears good. Edentulous. Gums apparently healthy and no evidence of gingivitis. Throat, heart, and lungs: nothing abnormal found. Blood pressure: 120 systolic, 70 diastolic. Obvious swelling (apparently superficial) of the left prepatellar region, with blue discoloration of the overlying skin. Joint movements somewhat limited but patently no involvement. The superficial subinguinal glands were enlarged and tender on the left side. On the right there was one enlarged tender gland with some reddening of the overlying skin.

On the evening of admission the skin over the left prepatellar region broke down, allowing drainage of a thin, watery, blood-stained "pus," and leaving a discharging sinus (culture of this fluid revealed hæmolytic streptococci). Blood culture was negative.

Investigations.—On Jan. 27th a blood count showed:

Red cells ..	.. 2,676,000	Polymorph	36%
White cells	.. 3,200	Lymphocytes	53%
Hæmoglobin	.. 62%	Path. large lymphocytes	8·5%
Colour-index	.. 1·1	Hyaline	2·5%

The report was as follows: "Anisocytosis and poikilocytosis are slight but there are a number of obvious megalocytes and the average size of the red cells is considerably increased. There is considerable polychromatophilia. In counting 200 W.B.C. there were seen: 15 normoblasts, 10 macronormoblasts, and 7 megaloblasts. 14 per cent. of the polynuclears are 'band' forms. Platelets are probably reduced but not very markedly so. A very unusual picture, but, on the whole, more like aleukæmic lymphatic leukæmia than pernicious anæmia."

Gastric analysis (without histamine) on Feb. 2nd showed no significant abnormality, fractions obtained at 20 minutes' intervals giving the following results:

	Free acid. (Both as c.cm. of N/10 HCl %.)	Total acidity.
Residuum	0	20
Specimen 1	0	16
„ 2	22	40
„ 3	30	50
„ 4	25	40
„ 5	40	54
„ 6	52	62
„ 7	50	60
„ 8	—	—

Continued secretion masked by regurgitation: emptying time rapid, the meal being nearly all out by tube No. 4. Starch: absent in fasting; trace in No. 6; + + in remainder. Occult blood: trace in fasting. Bile tinge: + in all except No. 2; strongest in Nos. 5, 6, 7. Mucus: + + in fasting; + + in Nos. 1, 2; trace in remainder.

Both Wassermann and Meinicke reactions were negative Van den Bergh reaction: direct test, negative; indirect. test, 1 (i.e., slightly increased). A fragility test (April 11th) showed no excessive fragility of the red cells, the figures being:

% strength of salt solution.	% of hæmolysis.	% strength of salt solution.	% of hæmolysis.
0·50	0	0·38	50
0·48	0	0·36	78
0·46	2	0·34	95
0·44	5	0·32	99
0·42	8	0·30	100
0·40	15		

Course of Illness.—Iron (ferr. redact. grs. 30 t.d.s.) and liver extract were given for a month, with but little change in the patient's general and local condition. His blood picture, however, revealed a steady and progressive deterioration. On Feb. 23rd it was:

Red cells ..	.. 1,880,000	Polymorph	41%
White cells	.. 4,400	Lymphocytes ..	57·5%
Hb. ..	.. 38%	Hyaline	1%
C.I.	.. 1	Eosinophil	0·5%

"Marked anisocytosis and poikilocytosis and polychromatophilia. Some punctate basophilia. In counting 200 W.B.C., 51 normoblasts and 15 macronormoblasts were seen. 16 per cent. of the polys are 'band' forms. The average size of the R.B.C. is normal." There was no appreciable pyrexia but his pulse-rate varied between 70–90.

On Feb. 25th I did a bone-marrow "puncture." Under local anæsthesia a small portion of red marrow was obtained from the upper end of the right tibia, and the following report came from the pathologist: "Macroscopic: marrow partly fatty. Smears: no organisms seen. Films: mostly red cells, a few nucleated but no obvious megaloblasts; white cells are rather scanty; lymphocytes appear to be more numerous than usual but they seem normal. Cultures remain sterile after six days' incubation. Histological examination of cut sections: the marrow shows no evidence of erythroblastic, megaloblastic, or leucoblastic reaction, the blood-cells present being probably of operative origin."

On Feb. 27th a transfusion of 500 c.cm. of citrated blood was given, with considerable temporary improvement.

This however was not maintained in spite of supplementation with Hepatex intravenously, and reduced iron. In the meantime the left inguinal glands began to break down, producing a small amount of blood-stained "pus" in which were found some degenerated polynuclear and lymphocytic cells—but no organisms either in film or culture. The infected knee at this time appeared to be slowly healing and epithelialising, but still looked unhealthy.

Blood transfusions were given subsequently at weekly intervals until the general and local condition seemed quite fair. His hæmoglobin rose to 70 per cent. and the red cells to 4,300,000, but his white cells remained low, at one time dropping to 800 (56 per cent. polymorph and 38 per cent. lymphocytes). Pentose nucleotide injections improved the leucopenia somewhat but proved too harassing for the patient and had to be discontinued. The blood transfusions were then stopped to see if the improvement would be maintained, but unfortunately it was not, and his hæmoglobin and red cells progressively diminished in spite of iron, arsenic, X ray therapy, liver, and antistreptococcal serum until May 26th (when he took his own discharge) at which time his hæmoglobin was 32 per cent., red cells 1,640,000, and white cells 1800.

Between May 26th and June 27th (when he was readmitted to hospital) he was seen in the out-patient department at weekly intervals, and was obviously going downhill rapidly, with urgent dyspnœa, anginal pain, and epistaxis. He finally yielded to persuasion and was readmitted. At this time his blood was as follows:—

Red cells	730,000	Polymorph	29 %
White cells.. ..	5,200	Lymphocytes ..	59 %
Hb...	17 %	Hyaline	12 %
C.I.	1·1		

"A fair amount of anisocytosis (including some megalocytosis), poikilocytosis, and polychromatophilia. The average size of the R.B.C. is slightly increased. Platelets are present in moderate numbers. There are about twice as many nucleated R.B. cells as there are W.B.C. They include normoblasts, microblasts, macronormoblasts, megaloblasts, and an occasional gigantoblast. Some of the cells classified as lymphocytes have the appearances suggestive of lymphoblasts."

On admission the temperature was 99° F., the pulse-rate 120, and the respirations 32. He was urgently dyspnœic and looking very ill. He was transfused twice without very much improvement, had numerous epistaxes, developed a terminal pneumonia, and died on July 14th.

OBSERVATIONS POST MORTEM

Macroscopic.—Pale, rather thin body. Numerous necrotic areas in both inguinal regions and left knee. The tonsils were not very large but contained pus. Terminal local broncho-pneumonia. Heart showed petechial hæmorrhages under the visceral pericardium of the right auricle, pulmonary artery, and commencement of aorta. There were also numerous white points of pin-head size, surrounded by a red areola, under the endocardium of both auricles and ventricles (especially on the right side). Liver: showed one or two parenchymatous, subcapsular white areas, similar to those in the heart. Spleen: slightly enlarged (8½ oz.); rather pale and soft. Kidneys: somewhat large and pale; capsules strip easily. Suprarenals: normal. Marrow (upper end and shaft of humerus): pink.

Microscopic.—Examination of the *marrow* revealed only leucoblastic and erythroblastic activity—not abnormal in type. Sections from the broken-down glands showed caseous areas surrounded by large, swollen (probably endothelial) cells, fibroblasts, and an occasional giant cell. No tuberculosis or other organisms seen. No obvious endarteritis or peri-arteritis. The *kidney* section showed some cloudy swelling and a subcapsular area consisting of Gram-positive cocci (probably in a glomerulus) surrounded by a necrotic tissue containing mononuclear cells and outside this a hæmorrhagic zone. Organisms were not seen beyond the central mass. The *liver* showed some central zonal necrosis with some periportal round-cell infiltration. A small subcapsular area of degeneration with polymorphs and mononuclear cells—probably the edge of structure similar to that seen in the kidney. No organisms could be found in it. *Spleen:* rather bloodless; reduction in Malpighian bodies, and some excess of polymorphs. *Heart:* the section unfortunately missed all of the pin-point areas, but what was probably the edge of one showed a mononuclear infiltration; Gram-positive cocci and Gram-positive bacilli are present. The *tonsils* showed heavy streptococcal infection of the crypts, spreading into the gland substance; mononuclear reaction only. A *cœliac gland* showed reduction in the number of lymphocytes with apparent increase of reticulum cells and endothelial cells. A *cervical gland* showed the same changes.

Thursfield[1] states that "wherever there is, even in the absence of a leucocytosis, a predominance of abnormal cells, whether these be myelocytes or 'lymphocytes,' to the extent of 25 per cent. or over, of the total, the disease is leukæmia." This definition, however, would include the group of cases described by Turk as examples of the "lymphatic reaction," which are commonly associated with sepsis. In the case described one cannot say with certainty which preceded the other, the sepsis or the hæmoblastosis; but it seems likely that the septic focus was the originator of the blood changes.

A study of the blood counts indicates that there was no failure on the part of the blood-forming organs to produce cells; in fact, there was every indication of excessive activity (numerous immature red cells, "shift to the left" of the polymorphonuclears, and erythroblastic and leucoblastic activity of the bone-marrow). This suggests that either these cells never reached maturity or (what appears more likely) that they matured but degenerated or were destroyed. This is borne out by the results of the van den Bergh test. Furthermore, the leucopenia was in the nature of an hypogranulocytosis; the total number of lymphocytes was diminished hardly at all, whereas the total number of *mature* polynuclears was reduced extremely. It is interesting to note in this connexion that one of the usual features of agranulocytosis—namely, necrotic, non-suppurative ulceration—was present in this case throughout the period of observation. The absence of any appreciable pyrexia throughout the entire course of the illness is, I think, remarkable.

Pathological examination of the lymphatic glands and reticulo-endothelial structures does not shed much light upon the ætiology of the condition, although it is suggestive of a circulating infective process.

I should like to express my indebtedness to Dr. C. Rickword Lane, who was responsible for the pathological investigations, to Dr. A. J. Scott Pinchin for permission to publish the case, and to Dr. Vincent Smith, my predecessor, some of whose notes I used freely.

A RADIOPAQUE CONCRETION IN THE APPENDIX

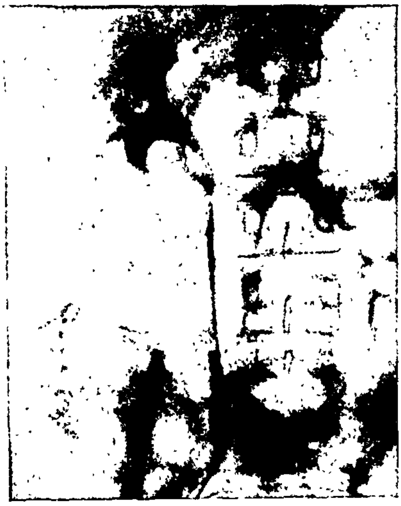
BY DAVID LEVI, M.S. Lond., F.R.C.S. Eng.
SURGEON TO THE INFANTS HOSPITAL, VINCENT-SQUARE, WESTMINSTER

A. B., aged 19 years, a patient of Dr. P. W. Boobbyer's, had enjoyed good health till 18 months ago. He first noticed pain below the right costal margin. The pain radiated down the right leg and was accentuated by exercise. There was no nausea or vomiting. The bowels were regular in their action, and there were no other urinary symptoms. The attack of pain lasted a week and then passed away. Recently the attacks have been coming on more frequently.

---

[1] Thursfield, J. H., in Price's Text-book of Medicine, London, 1929, p. 721.

On March 6th, 1934, he had another attack of epigastric pain which settled in the right loin. Again there was no nausea or vomiting and the bowels were regular. The patient was seen for the first time on March 7th when he had tenderness high over McBurney's point and in the right loin. There was a little rigidity of the muscles of the right loin. On an X ray examination of the urinary tract Dr. H. Courtney Gage reported as follows: “Shadow right side just below iliac crest. It appears in the lateral view behind the anterior border of the bodies of the vertebræ—very suggestive of a stone in the lower pole of the right kidney, but should be confirmed by pyelography or excretion urography if operation is contemplated. There is too much gas in the colon to show the kidney shadows.”



Pyelogram showing circular shadow outside the urinary system.

A pyelography was then performed and this demonstrated (see Figure) that the shadow was outside the urinary system. The patient developed more acute symptoms which pointed to the appendix, the abdomen was opened, and an acutely inflamed appendix lying in the external paracolic sulcus was removed. The appendix was a very long one, and its tip was attached to the lower pole of the right kidney. When the appendix was opened it was found to contain a concretion. On examination this concretion was found to be composed of almost pure $Ca_3(PO_4)_2$. Dr. Roche Lynch kindly analysed the concretion, and his report is as follows: “Traces of organic matter. Traces of $(COO)_2Ca$. No uric acid. But the rest—i.e., practically all—$Ca_3(PO_4)_2$.”

The patient made an interrupted recovery, and on subsequent X ray examination the shadow had disappeared. This case is briefly recorded because of the rarity of a calcium phosphate fæcalith. The appendix and stone are in the St. Mary's Hospital museum.

ENCEPHALITIS AND POLYNEURITIS DUE TO PREGNANCY TOXÆMIA

By Theodore Brocklehurst, M.R.C.S. Eng.

Korsakoff's psychosis associated with pregnancy is sufficiently rare to warrant publication of a severe case. The rapid improvement which followed termination of the pregnancy was so striking as to leave no doubt of the association of the two conditions.

The patient, then a woman of 23, first came under my care in April, 1933, immediately after her return to this country, and the following record is based largely on reports and case notes made by medical officers in India, which have been forwarded for my information.

The family history was normal. During childhood the patient had the usual complaints; in 1927 her appendix was removed and in 1928 she had herpes zoster. For years there had been occasional migrainous headaches associated particularly with menstruation, but there had never been any vomiting or eye symptoms with them. There had been dysmenorrhœa for some years, and, since her marriage, vaginismus and dyspareunia.

The first pregnancy started two years after marriage, but miscarried at the end of the second month. The second started three years after marriage, in March, 1932, while she was with her husband in India; she was very anxious to have a child. In April nausea and vomiting commenced and she was forced to take to bed. The vomiting occurred several times daily and she could retain no solid food. She was extremely weak on her legs and could not be persuaded to eat; but this anorexia and vomiting which continued until July was probably partly due to psychological causes, for she had been told alarming tales of her mother's first pregnancy. During this time the temperature was normal except for two brief periods when it reached 103° F.

In June, 1932, a retroverted gravid uterus was diagnosed, and an attempt to correct this under anæsthesia was made. Shortly afterwards she was moved into another hospital in India, and then the toxic affection of the nervous system became manifest. Her legs became extremely weak, but the arms less so, as she was able to pull herself up in bed: her deep reflexes were all absent but her sensations were reported on as normal. Then at the end of July her memory for recent events began to fail, so that although she was able to recognise friends she had not seen for three or four years, she was not able to tell where she was, and could not recall the events of the previous day. Her talk and behaviour became foolish, and she fabricated accounts of where she was and what she had been doing. Throughout she was able to recognise her husband. She repeatedly moved her head from side to side and had a vacant stare.

At this time nystagmus was recorded. For some weeks in July and August she was incontinent of urine, and for some days a temporary aphasia was noticed; also there was failure of accommodation of near objects. At no time was there more than a slight headache, and there was no photophobia or diplopia. At this time shock therapy with T.A.B. vaccine was tried, but without benefit.

The vomiting had ceased at the end of July, but the patient continued to take very little food. Her mental condition improved slightly with the cessation of vomiting, but deteriorated gradually again later. The drowsiness, the mental condition, and the weakness of the limbs became progressively worse, and her general condition became so critical (she lost weight from 10 st. to 5 st.) that at the end of October it was decided—much against her wishes—to terminate the pregnancy. Within two days her mental condition was noticeably improved; she steadily gained in strength, and her mental condition was such that by Christmas Day, 1932, she was able to converse freely with her husband and eat a good Christmas dinner.

Between April and October, 1932, various investigations were performed. The urine never contained more than a trace of albumin, and no pus or micro-organisms. The stools contained no ova, cysts, or pathogenic micro-organisms. In August the blood count was normal, the Wassermann and Kahn reactions in the blood were negative, and no agglutination to *Brucella melitensis* or *abortus* occurred. The cerebro-spinal fluid showed normal cell and protein values. In October the urea-concentration test at two hours showed a result of 3·4 per cent.; at this same time her muscle reactions showed no definite reaction of degeneration, but all the leg muscles gave a sluggish response to faradism.

At no time had there been a craving for, or opportunity to obtain, alcohol; and there was no suggestion of a diphtheritic infection.

When the patient came under my care in April, 1933, she was still emaciated, and had a partial amnesia for the events of her illness. On examination, apart from her emaciation, the only abnormal physical signs were found in the nervous system. Her speech was rather slow, but otherwise her mental powers were normal. The cranial nerves were all normal, apart from a little pallor of the optic discs. The trunk muscles were weak but not markedly so. The arms showed general weakness and wasting, particularly in the small muscles of the hands; and the only deep reflex obtained was a slight response in the left triceps. The legs showed a more marked degree of muscular weakness and wasting, particularly in the muscles below the knees, and there was complete inability to correct foot-drop. The ankle-jerks were absent but a slight response was obtained in the left knee-jerk on reinforcement. The abdominal reflexes were absent and the plantars both extensor. The deep sensations were all present and normal, including vibration sense, although the calves were excessively tender. The superficial sensations were diminished peripherally: the patient had noticed when she was having massage that she was unable to feel clearly below the ankles, and with a dragged pin and to heat and cold there was progressive diminution of sensation of glove and stocking distribution, below the elbows and knees.

With massage, faradism, and re-educational exercises the patient continued to improve, so that by November, 1933, she was able to walk with the aid of sticks, her deep reflexes were showing evidence of return, and her plantars flexor.

This patient was seen in consultation with Dr. E. C. Warner in July, and with Dr. Gordon Holmes in August, 1933. They agreed with the diagnosis and gave an excellent prognosis, which has proved correct, as the patient is now able (September, 1934) to lead a normal life. The reflexes and superficial sensations are now normal. The patient's husband having died, the question of further pregnancy does not arise.

Bexhill-on-Sea.

MEDICAL SOCIETIES

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION

On Sept. 14th and 15th this association held a jubilee meeting at Eastbourne, various social functions being arranged as well as a discussion, over which Dr. J. A. H. Brincker presided.

Acute Streptococcal Throat Infections

Dr. J. Alison Glover, of the Board of Education, opened the discussion, reading a joint communication by himself and Dr. Fred. Griffith of the Ministry of Health. Dr. Glover explained that no school would be named, as it was important to preserve the confidential character of the information which the Ministry had at its command. These throat infections, he said, were a constant source of trouble and anxiety to both headmaster and school medical officer. The primary and most prevalent streptococcal disorder was acute tonsillitis, an endemic and epidemic infectious disease with an incubation period of two to four days, whose main incidence was at puberty. Infection could be conveyed by milk, tableware, handkerchiefs, pencils, and by droplets from the nasopharynx. Transmission by milk had resulted in many severe outbreaks in different parts of the world, but in schools the chief means of spread was by droplets. With the exception of infection with the Klebs-Löffler bacillus, acute tonsillitis was almost invariably due to hæmolytic streptococci. The annual attack-rate for the navy in 1932 was 2·7 per cent.; at Guy's Hospital Close found that 6·7 per cent. of all patients attending the out-patient department for the first time attended on account of this infection. Captain S. F. Dudley found at Greenwich Royal Hospital School an attack-rate of 4·8 per cent. per term. The disastrous effects of the malady were due to the serious complications which often followed it, such as otitis media, mastoiditis, meningitis, septicæmia, and pneumonia; rarer sequelæ were acute rheumatism and nephritis. One of its greatest dangers was its concurrence with outbreaks of measles. For many years it had been known that cases of tonsillitis without rash occurred during an epidemic of scarlet fever side by side with cases having the usual rash fully developed. In 1887 Mantle drew attention to the close alliance of the conditions found in epidemics of sore-throat and of scarlatina, and this had been confirmed by the serological work of Dr. F. Griffith. It seemed clear, indeed, that acute tonsillitis and scarlet fever, apart from the presence of a rash and the possibly greater risk of nephritis in the latter disease, were almost identical, both bacteriologically and epidemiologically. Hæmolytic streptococci in the throat were capable of producing varying clinical pictures in different persons, these differences being often seen in different boys in the same dormitory: one boy might show nothing more than a healthy carrier state, another a feverish pharyngitis, another a definite tonsillitis, a fourth scarlet fever. In a certain proportion of the healthy community the *S. pyogenes* was always found, the actual proportion varying with the locality and the season, as well as with the hygienic surroundings. This healthy carrier-rate varied greatly, and in residential schools it was as a rule probably somewhat higher than elsewhere. During epidemics of tonsillitis this carrier-rate might become very high. Investigation seemed to show that certain serological types of the pyogenes group were specially equipped to produce the complete scarlet fever syndrome. Members of the profession as well as the laity were still inclined to regard an epidemic of scarlet fever in a school as merely the occurrence of a number of cases of a well-defined clinical type; and to devote attention to tracing the spread from case to case, believing that isolation of all suspected cases would check the progress of the epidemic. Sometimes this attitude seemed to be justified; but often the matter was much more complex, especially when the infecting strain was of low toxigenicity and part of the school population was Dick-immune. In one term at a large public school there were many cases in a mixed epidemic of this kind, with 43 cases of pharyngitis, 101 of tonsillitis, and 16 of otitis media. Yet there were only 4 cases of rash, none of which were considered to be scarlet fever. The causal organism isolated from a considerable number of these cases justified the view that the whole of that epidemic was due to Type 1 scarlatinal streptococcus. In this outbreak, also, a change of clinical type was seen. Dr. Glover showed diagrams illustrating the incidence and clinical type of cases, correlated with the serological type of infecting streptococcus in epidemics in nine schools.

Otitis media was a cause of great anxiety to school doctors; most often it followed tonsillitis, influenza, scarlet fever, or measles. Probably at least three-fifths of the cases of otitis media in schools were due to hæmolytic streptococci. Not only was the ear condition dangerous in itself, but Macleod Yearsley had stated that 29 per cent. of acquired deafness was due to otitis after measles, and 34 per cent. to otitis following scarlet fever. Dr. Glover considered, however, that owing to the higher age grouping, tonsillitis in the public school was a much more common cause of otitis than either measles or scarlet fever. The importance of dormitory infection in producing such sequelæ as otitis media was suggested by the fact that, whilst the incidence of tonsillitis, measles, and influenza during the four years 1930 to 1933 was substantially the same in the case of the boys and of the girls in well-to-do public boarding schools examined by the Medical Research Council in its inquiry into epidemics in schools, the incidence of serious complications due to streptococci and pneumococci was shown to be significantly lower in the case of girls. It was suggested that among the causes of the difference were the greater care given to girls, their superior discretion when ill, and their better nutrition ; but Dr. Glover believed that the main reason for the beneficial difference was that nearly all the girls slept in large and well-ventilated cubicles whilst most boys slept in dormitories, many of rather antique design. On the question of whether the occurrence of otitis had a definite relation to the use of swimming baths, Dr. Glover said that, while he was a strong advocate of pure water for baths, it was found that the highest incidence of otitis media in schools occurred in the Lent term, when little swimming was done. Acute rheumatism among well-nurtured children of public schools was a much less common complication of tonsillitis than was otitis media ; it seemed to require a further, an unknown, factor in addition to the throat infection to set up acute rheumatism. Possibly this other factor was some vitamin deficiency.

PREVENTION

Epidemics of tonsillitis usually indicated, Dr. Glover submitted, the existence of unsatisfactory hygienic conditions in the establishment, either in the school itself, or in the sick room or sanatorium. Epidemics of tonsillitis or the occurrence of droplet cases of scarlet fever or otitis media in schools were generally associated with a high carrier-rate of hæmolytic streptococci ; and, again, epidemics of tonsillitis or otitis and high carrier-rates of hæmolytic streptococci were, usually, signs of the existence of environmental conditions favourable to a rapid transmission of infection. It was very important to keep carrier-rates low. In most school epidemics the infection was wafted in droplet form from one nasopharynx to another in dormitory, class-room, common-room, changing-room, dining-room, tuck shop, and church. Of these the dormitory seemed to be the most important, for in it there was undisturbed proximity of the healthy with the infected for a number of hours on end, and infectivity was heightened by closure of doors, and, in bad weather, of windows. The Board of Education had laid down and required for 20 years the following spaces : for dormitories at least 3 ft. between beds, and a floor area per bed of not less than 65 sq. ft., and a cubic space per bed of 700 cu. ft. Ventilation must be adequate and "through," windows being on opposite sides of the room. For cubicles, if partitions were not carried to the ceiling, 65 sq. ft. and 700 cu. ft. were adequate ; when partitions were carried to the ceiling, 100 sq. ft. and 1000 cu. ft. were required, and for sick rooms not less than 6 ft. between beds and a window between each two beds.

The placing of beds heads to tails did not appeal particularly to Dr. Glover. It was extremely dangerous to overcrowd the sanatorium when a school was visited by an epidemic ; patients should be separated by not less than 6 ft.

Dr. Glover said he was unable to deal with prophylactic immunisation owing to lack of time.

Discussion

Dr. L. R. LEMPRIERE (Haileybury) stressed the great anxiety which these epidemics caused to the school medical officers. His impression was that they were recently on the increase. It was difficult to know how to prevent these outbreaks ; medical officers would be only too glad to keep down the carrier-rate if they could. The general hygiene of public schools had improved to a remarkable extent, but he doubted whether the internal hygiene of the public school boy had improved much, notably the attention paid to keeping his nose clean. Scarlet fever had definitely diminished in schools. Where there was a large total of septic cases there was usually a clay soil.

The MAYOR OF EASTBOURNE (Mr. G. Thornton) thought bathing had much to do with the occurrence of otitis media, whether the bathing were in public baths or in the sea. In his school he thought morning and night gargling as a routine had much to do with its freedom from serious infections.

Mrs. LILIAS M. JEFFRIES (Roedean) agreed as to the danger of otitis following bathing. For sleeping she favoured the cubicle system, though she was not able to say that this reduced the amount of nasopharyngeal disease in comparison with that found in dormitory sleeping. Many dormitories were very imperfectly ventilated. She did not think the importance of consuming only milk which had been pasteurised was sufficiently stressed.

Dr. W. G. WILLOUGHBY (M.O.H. for Eastbourne) also thought that epidemics of throat infections in schools seemed of late to be on the increase ; serious mixed infections, indeed, seemed to have practically dated since the war. At the same time, the cases of scarlet fever were less severe now than formerly. It was of little importance to insist on a certain minimum cubic space unless the air was frequently renewed. He thought the window space in living rooms should be one-tenth the floor space, and that half the window should be openable. He agreed with daily gargling, but deprecated indiscriminate nose syringing. In Eastbourne the policy of thorough isolation in suspected scarlet fever cases had been most successful. He asked as to the possibilities of producing a serum for protecting school communities against these throat infections.

Dr. W. H. BRADLEY (Downside) said his school experience had taught him that overcrowding was the most important factor in the spread of streptococcal diseases. Since circumstances had reduced the population of a particular school and had thus made possible a more generous spacing for each boy, the medical officer had had little to do. He urged medical officers to keep a careful watch on the behaviour of cases of disease, especially as the clinical picture varied so much.

Dr. E. H. R. HARRIES (London) said that from the throats of a large number of children sent into the North-Eastern Fever Hospital with definite clinical scarlet fever a pure culture of hæmolytic streptococcus was obtained. He urged this testing as an early bacteriological aid in doubtful cases ; naked-eye evidence of hæmolysis was quickly obtained. In his hospital it was used as a routine. Recent work separating the hæmolytic from the toxigenic properties of the pyogenes was very valuable. He attributed the rarity of secondary infections at his hospital to the insistence on at least 12 ft. of wall space for each patient. The use of scarlet fever antitoxin was worth while, even in mild cases ; it certainly reduced the complication-rate.

Dr. E. KAYE LE FLEMING (Canford School, Wimborne) considered that the great problem awaiting solution was wherein lay the resistance of the individual to the streptococcus, why it was lost, and how it could be regained. Overcrowding he regarded as more important than bathing. He thought the open-air dormitory would solve 90 per cent. of these epidemic troubles, but both parents and headmasters required educating as to the value of this plan. He would like to see an illness chart drawn up by the association, in collaboration with the Ministry of Health, for use in schools.

Dr. R. E. SMITH (Rugby School) contended that much could be done to render scarlet fever a preventable disease, and parents should be told of the possibilities in this direction. As to bathing, boys should be told never to jump into the water unless they at the same time held their nose. Many young boys had not achieved immunity against scarlet fever, and parents should see that their sons had been so immunised before sending them to a public school.

Dr. W. ATTLEE (Eton) urged that some revision of the present quarantine rules should be made, as it was a needless waste of time to insist upon quarantine for such conditions as rubella. He agreed with all that had been said as to the importance of avoiding overcrowding. Separate sleeping rooms was the system at Eton, and not more than two or three cases of hæmolytic throat infection were seen at one time; there was no general spread. More efficient ventilation in schools should be accompanied by sufficient heating of the rooms.

The PRESIDENT held that improvement in the personal habits of boys would do much to lower the carrier-rate of these diseases. He agreed with Dr. Attlee's remarks on quarantine regulations. He spoke of the immunisation of nurses in the L.C.C. service, but said that there was not the same certainty yet in the matter of scarlet fever as in diphtheria.

REVIEWS AND NOTICES OF BOOKS

The Legal Aspect of Industrial Diseases

By C. H. SPAFFORD, of the Middle Temple, Barrister-at-Law. London: Butterworth and Co., Ltd. 1934. Pp. 273. 21*s*.

UNDER the various Workmen's Compensation Acts in this country the employer is compelled to pay compensation to a workman who may be incapacitated from earning "by reason of an accident arising out of and in the course of his employment." In order to prove an accident, however, there has to be definite evidence of trauma. It was recognised soon after their passing that the wording of the Acts did not afford a workman such full protection a was originally intended. Incapacity for earning was frequently found to be due to a disease peculiar to the work in which a man had engaged; his incapacity therefore, although not due to an accident, nevertheless "arose out of and in the course of his employment." Attempts were then made to grant the necessary protection by issuing schedules of industrial diseases so that a workman suffering from any of the named diseases could claim compensation.

Much confusion of thought has arisen from attempts to interpret the law of disablement from "industrial diseases" in terms of an "accident," and Mr. Spafford's main task in this admirable book has been to show how, and when, an industrial disease becomes, in law, an "accident." In the first place the workman must establish that he is suffering from the specified disease, and secondly that he is incapacitated from earning. He must prove his points by producing a certificate from a certifying surgeon. When, therefore, he is in possession of the certificate, he is in a position to prove the "happening of the accident" which has resulted in his incapacity. But still, as in this hypothetical accident there was no sudden beginning but rather a gradual onset of disease, the date of the "happening of the accident" remains to be established. Mr. Spafford quotes several judgments in the Court of Appeal, and then sums up the position as follows:—

> "The most reasonable interpretation to put on the words 'the happening of the accident' and the one which does not contravene any of the judgments in the House of Lords and in the Court of Appeal, is that the accident is created or crystallised by the combination of: (*a*) The disease. (*b*) The disablement due to such disease. (*c*) The giving of the certificate of disablement or suspension. That is to say, the certificate being given the hypothetical accident comes into being for the first time, but relates back to the date of disablement as fixed by the certificate."

In all cases of industrial disease much depends upon the certificate of the certifying surgeon. It is essential that this should be made in the proper form; a whole chapter has been devoted to this certificate. An appeal lies from the finding of the certifying surgeon to a medical referee who is a legally qualified medical practitioner appointed by the Secretary of State for the purpose of the Act. The duties and powers of the medical referee are set out very clearly, and in the appendix are found the forms that should be used by him or by the certifying surgeon for all occasions. This appendix, which with the index fills very nearly half the book, also sets out at length the Workmen's Compensation Acts and extracts from the Workmen's Compensation Rules, notably those relating to certifying surgeons and medical referees. The index is complete and clear, and the book as a whole is light in weight and well printed. It should prove of the greatest assistance to those engaged in the study of the various aspects of workmen's compensation, particularly to the claims managers of insurance companies, medical referees, and certifying surgeons.

Annals of the Pickett-Thomson Research Laboratories: Influenza, Part II.

By D. THOMSON, O.B.E., M.B., Ch.B. Edin., D.P.H. Camb., and R. THOMSON, M.B., Ch.B. Edin. London: Baillière, Tindall and Cox. 1934. Pp. 916. £3 3*s*.

THIS volume completes the monograph on influenza produced by the Pickett-Thomson Laboratories. It follows the usual practice adopted in these monographs of citing all the available evidence irrespective of the value which the authors might attribute to it; anything in the nature of a critical review is confined to the summing up which is given at the end of each chapter and again in the final chapter. This is probably a wise policy, considering the difficulty of assessing the importance of recent work. The opening chapter on the complications and sequelæ of influenza occupies one-third of the book, which is not surprising considering how manifold these are. Following this are chapters on the effect of influenza on such physiological states as menstruation, pregnancy, labour, and puerperium, and on various pathological conditions, diseases of women, pulmonary tuberculosis, and other diseases. The pathology of influenza, its epidemiology, mode of transmission, vaccine and serum prophylaxis and therapy, preventive measures, and treatment form the subjects of the remaining chapters. An addendum describes work published too late to be incorporated in the appropriate chapter, and the volume ends with the authors' summary and conclusions relating to all the subjects dealt with in the whole of this monograph. Here one finds little to criticise. The conclusions drawn from the available evidence appear to be sound. The authors are firm adherents to the view that influenza is primarily a virus disease and give due recognition to the work of Smith, Andrewes, and Laidlaw. In common with most observers they recognise the importance of secondary invaders, Pfeiffer's bacillus, pneumococci, streptococci, and the like, and they stress the probability of virus and secondary invader acting together as one symbiotic agent in certain phases of influenza epidemics. In this respect they do not overlook the important researches of R. E. Shope on swine influenza. They rightly attribute prime importance to direct transfer from case to case in the mode of spread in this disease, and their conclusions as to preventive measures reflect what has been found to hold good in practice. Vaccine prophylaxis against the secondary invaders —we do not yet know what can be done in this way against the primary causal agent—is here held to be of value. This view is in keeping with that recently expressed by Dochez, but on the whole the authors' summing up of the therapeutic use of vaccines is probably tinged with undue optimism. It is interesting to note that after citing the literature on the drug treatment of influenza they conclude that the most important measures in treatment are to keep the patient warm in bed, encourage sweating, keep the bowels open, and reserve stimulants for the end of the disease and convalescence. Perhaps they are right.

Epidemic Myalgia—Bornholm Disease

By Ejnar Sylvest. With a foreword by Dr. T. Madsen. Translation from the Danish by Hans Andersen, M.D. London: Humphrey Milford, Oxford University Press. 1934. Pp. 155. 7*s.* 6*d.*

This remarkably complete monograph on epidemic myalgia is the work of a Danish general practitioner, not attached to any hospital or laboratory. In the summer of 1930, while on vacation, he observed several cases of this disease on the Danish island of Bornholm. This was the beginning of his exhaustive studies. It was on his initiative that the Danish medical authorities made epidemic myalgia notifiable in October, 1931. The fact that 10,965 cases were reported in Denmark alone between August, 1930, and April, 1934, emphasises the numerical importance of a disease which, according to Dr. Sylvest's investigations, was apparently observed in Denmark in 1897, and in Norway as long ago as 1872. The author traces its incidence in other countries such as Iceland, North America, England, New Zealand, Finland, Germany, Sweden, and Portugal. Special chapters are devoted to clinical features, epidemiology, and seasonal distribution. The hospital surgeon especially should note these details for the occasion may arise when their recollection may inhibit an impulse to verify by a laparotomy suspicions of appendicitis, perforated ulcer, or some such catastrophe to the great advantage of the patient and to his reputation.

Treatment of the Commoner Diseases met with by the General Practitioner

By L. F. Barker, M.D., Professor Emeritus of Medicine, Johns Hopkins University. Philadelphia: J. B. Lippincott. 1934. Pp. 319. 12*s.* 6*d.*

Prof. Barker's intention in this book on treatment is to give as much practical everyday help to the general practitioner as he can. He has not tried to cover the whole field of medicine, nor indeed to go deeply into any one particular branch of it, but rather to review and comment on those subjects which are of especial importance in general practice. Although mainly directed towards treatment questions of diagnosis are not ignored and many of the brief descriptions of diseases and their symptoms are very good. Prof. Barker writes in an easy style and throughout these pages there is evidence of his wide outlook on general medicine.

Few conditions met with in general practice are omitted. Most of the treatment is given in sufficiently detailed and precise terms to avoid confusion, but the large number of references will enable readers to consult original sources where desired, the full titles being given. There is indeed much in this book that should stimulate practitioners to further reading and not a little that may be new to many of them.

Gould's Pocket Pronouncing Medical Dictionary

Tenth edition. By the late George M. Gould, A.M., M.D. Revised by C. V. Brownlow. London: H. K. Lewis and Co., Ltd. 1934. 10*s.* 6*d.*

The scope of this dictionary, which is not paged, is indicated by the statement that it contains over 40,000 words. The size is only 6 × 3½ × 1 in. It thus fulfils its primary aim of a "carry-me-with-you aid." This is the sixty-eighth printing, and there are few faults to find with the proof-reading, but we must again point out that a megohm is not "one-millionth part of an ohm," and the spelling of German names —e.g., Kupffer, Aschheim—requires attention. The "dram" or "drachm" is defined simply as "a weight of sixty grains," which does not prepare the reader for the shock of finding in the table of weights and measures a dram which contains 27·34375 grains. So long as we continue to use these strange measures the lexicographer must keep us right about them. The untravelled reader will be grateful for the imitated pronunciation of many words and names; the remark that "Cruveilhier" is pronounced as "kroo-va-ya" is successful, but there is no need to pronounce "Collier" as "kol-yer." This much of criticism does not detract from the value of the dictionary as a benevolent companion who does not intend to mislead and only by misfortune does so.

Black's Medical Dictionary

Twelfth edition. By John D. Comrie, M.D., F.R.C.P. Edin. London: A. and C. Black, Ltd. 1934. Pp. 1003. 18*s.*

This dictionary is intended to assist nurses, teachers, health visitors, employers, and various boards dealing with problems affecting health and others who desire information or guidance expressed with as little technicality as possible. It was first published in 1906 and this edition completes 92,000 copies. There are 500 illustrations in the text and two full-page plates in colour. It is an interesting and useful book for the purposes stated.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 22, 1934

A CROSS-SECTION OF THE PUBLIC HEALTH

IN his annual report [1] to the Minister of Health, which appeared on Wednesday last, Sir GEORGE NEWMAN remarks that the high standard of recent years is being well maintained. Unemployment, undernourishment, and preventable malady and accident seem, he says, to be the unavoidable concomitant of current civilisation in Western Europe in the present day, and we must not assume that our continued good national health can wholly preclude the effects of such conditions falling upon certain sections of the population. Yet we are suffering less than other nations, and as a whole the health of the unemployed and their dependents "is not suffering seriously or generally." Sir GEORGE is quite definite on this point, although he sees fit to reprint a striking paragraph from his last year's survey of the physical effect of unemployment, in which he spoke of the possibility of risk of mental instability in the adult man and prolonged undernourishment of women and children. These words, he adds, seem equally true to-day and are, indeed, confirmed by the data he records. Among men in three localities—Tyneside, South Lancs, and East London—ill-health of a neurasthenic type is on the increase. The commonest ill-effect of unemployment is a slowness of recovery-reaction after illness, and in the older age-periods some general incapacity for work. Women in the North of England seem to be suffering from anæmia as the indirect result of unemployment, but in South Wales there is said to be an " almost total absence " of malnutrition. These findings are based on the personal experience of 66 regional medical officers of the Ministry, all of whom have themselves had long and varied personal experience of general practice; 25 of these officers have personally observed no ill-effects whatever from unemployment, another 25 ascribe certain minor conditions only to unemployment, no more than 16 report substantial ill-effects, and these limited to certain definite areas. But having said this, Sir GEORGE insists that it is necessary to check actual and verified data by the evidence of history. He has found since CHADWICK's classical report of 1842 ample records of the social and medical condition of the people, invaluable as a plumb-line for evaluating experience. Problems raised in the 'forties were answered by reform of local government and poor-law, and of many external conditions of living; the 1904 report on physical deterioration led to public services such as school feeding, school medical supervision, industrial welfare, care of maternity and childhood, health and unemployment insurance. This profound change has proved to be the defence of national health in the last few years of economic depression. The defence may have been imperfect but it has proved substantial.

Apart from this searching study of unemployment, Sir GEORGE reacts sharply to the reiterated assertion of physical deterioration of our race—although he admits that deaths attributed to cancer are increasing, that a large proportion of fatal illness is due to heart disease, that year by year there is a higher percentage of apparently preventable deaths from accident, that large numbers of children still enter school physically and mentally defective, that the physical condition of recruits for the army leaves much to be desired, that maternal mortality is not reduced, and that the nutrition of the people is not so good as it should be. Some of these topics are dealt with in the report, although he disclaims the possibility of a " complete periodic assize " to measure the nation's health. The greatest improvement in mortality over the past three-quarters of a century has been recorded at the ages of 1 to 5 years, and that in spite of the fact that there has been little direct intervention at this age. On the other hand, the boy and girl leaving school at 14 too often decline in physical standard during the next few years, the strain of industrial life coming, it may be, too early upon them. To meet this, Sir GEORGE remarks, the time may have come for some subsidising or constructive action by the State itself. The general nutrition of the people he finds better to-day than at any past period. Happily they are learning to like the " protective foods " such as milk, eggs, fish, fruit, and fresh vegetables of which there has been an enormously increased consumption. The situation, he remarks, does not call for the imposition of a standard dietary. Tuberculosis remains an anxious problem in its effect on women between 15 and 25 years of age, who do not share in the general decline of disease. In a final paragraph Sir GEORGE NEWMAN deals frankly with the arrest of maternal mortality at or about 4 deaths per 1000 births during the last twenty years. Clearly, he says, we must await the slow but sure reaction of the effect of education on each of the five groups—school girls, potential mothers, prospective husbands, midwives, and medical practitioners; but he again draws public attention (on p. 262 of the report) to the counties and towns which are chiefly responsible for the continuance of an exceptionally high maternal mortality, and on the following page he sets out for comparison the ten-year averages of the Queen's Institute and some of the lying-in hospitals and institutions whose death-rate is only a quarter of the general experience. Control of detail, he remarks, is the master-key to the whole problem.

These are but a sample of subjects dealt with in a survey which every thoughtful citizen should read for himself—in spite of the 264 closely written pages, not including the 30 pages of appendices. It is unfortunate that the price of the review should be treble what it was in 1920 and still rising.

ERYTHEMA NODOSUM AND TUBERCULOSIS

Anyone who studies what is written about erythema nodosum will get the impression not only that it is much commoner in some countries than in others but also that its cause or causes differ from place to place. It seems probable, however, that these differences are more often in the eye of the beholder than in the condition itself. As Dr. Gerald Slot pointed out in our last issue there are now four main theories of its causation. Some hold it to be an infectious disease on its own account ("nodal fever"); some regard it as a manifestation of acute or subacute rheumatism; some consider it a symptom of tuberculosis; and some again argue with W. R. F. Collis[1] that it may be produced by various different toxins, being attributable to tuberculosis in one case and to streptococcal infection in another. Dr. Slot, having had good results from anti-scarlatinal serum, thinks it likely that in London at any rate the majority of cases are due to a streptococcus and not to the tubercle bacillus. This opinion will find many supporters, but is offset by the results recorded in another paper which has lately appeared[2] by Dr. L. Forman and Dr. G. P. B. Whitwell of the skin department at Guy's Hospital.

To test the various theories of ætiology Forman and Whitwell have studied 50 cases seen in the department, and have followed up 31 of them. From these "preliminary observations" they deduce that the rheumatic theory, though still prevalent, especially in England, "is undoubtedly a menace to the proper treatment of erythema nodosum." True, a sore-throat sometimes precedes the appearance of the nodes, and this brings the illness into correspondence with rheumatism and streptococcal infection; but they believe it to be merely an activator of tuberculous foci. "Were a streptococcus precipitated into the blood by these sore throats in erythema nodosum one would expect an occasional streptococcal septicæmia to follow, whereas if any grave disease follows the nodes that disease is tuberculosis." Indeed, examination of their cases persuades them to accept Ranke's view that erythema nodosum should definitely be considered a secondary manifestation of tuberculosis. The probable course of events, they say, is as follows:—

> "A primary inoculation of tubercle bacilli occurs, usually in the respiratory tract, but occasionally in the skin or elsewhere. After some weeks the body becomes highly allergic to tuberculin, and should by some chance small numbers of tubercle bacilli enter the blood stream and lodge in the tissues they will by their presence set up an acute reaction in which they are destroyed. If the numbers of bacilli in the blood are numerous, although erythema nodosum may occur early on, the final result is likely to be a miliary tuberculosis and a depressed sensitivity to tuberculin. We suspect that the same depression may subsequently occur in those cases of erythema nodosum, in which there are severe constitutional symptoms or an unusually large number of nodes or a few very intensely inflamed nodes or a severe sore throat."

"Sometimes," they add, "one hears of physicians diagnosing erythema nodosum, but changing the diagnosis to erythema induratum when the nodes persist a long time." The latter is a tuberculous condition seen mostly in young women on the back of the legs, and according to Forman and Whitwell the difference between the two is probably this: the child with erythema nodosum is recently infected and highly allergic, whereas the woman with erythema induratum has been primarily infected many years before. Allergic reaction is slight; the bacillus survives to produce an indolent and fairly typical tuberculous reaction; and the condition is to be regarded as a tertiary lesion, comparable immunologically with phthisis. "If the probable date of primary tuberculosis infection can be determined in erythema induratum it is nearly always many years before, while the incubation period of erythema nodosum is stated to be about seven weeks after infection with the tubercle bacillus according to some observers." The moral drawn from these observations at Guy's Hospital is that special investigation should be made in all cases of erythema nodosum to discover which are likely to develop frank tuberculosis. The patient, if a young adult or child, must be carefully treated until the nodes disappear and then must have a long spell of fresh air and rest. This especially applies to young women.

In these recommendations Forman and Whitwell fall into line with opinion in Norway and Sweden, where erythema nodosum is held to be a very common and early manifestation of tuberculosis. The German school, on the other hand, as represented by Prof. M. E. R. Matthes, is still disinclined to accept this teaching. Matthes's refutation of it may be found in his "Lehrbuch der Differentialdiagnose innerer Krankheiten," and his nonconformity has proved a spur to further research—as witness Dr. C. Giertsen's study[3] of 93 cases seen in a hospital in Bergen between 1924 and 1931. In this material there were only 7 men and 5 children and 87 per cent. of the patients were between the ages of fifteen and thirty. (It was, perhaps, no mere coincidence that as many as 73 of the 88 adults were born in the country as opposed to the town.) Where other observers have followed up their patients to find out how many of them developed tuberculosis, Giertsen has relied on X rays and the Pirquet and sedimentation tests. The radiograms showed considerable adenitis of the hilus of the lung in 80 of the 89 patients examined, and in 32 of these it was the only positive X ray evidence of disease. (In a special chapter there is a discussion of 4 cases in which a *Frühinfiltrat* was demonstrable.) In as many as 48 cases pulmonary infiltration or pleurisy was found within the first month of the appearance of the erythema nodosum, but whereas infiltration round the hilus was seen in 22 of them pathological changes at the apices were rare. The Pirquet tests proved positive in 46 of the 47 patients thus examined—an incidence of positive reactors much higher than that found in various sample tests in Norway. It was the sedimentation tests, however, that proved most valuable in practice, not only at the time of the eruption but at a later stage; and an increased rate of sedimentation more than a month after the nodes came to be interpreted as evidence of active disease of the lungs or pleuræ. The suggestion is accordingly made that the subsequent management of a recent case of erythema nodosum should be largely determined by this delicate and reliable test.

TEMPERAMENT, CONSTITUTION, AND DISEASE

THE attempt to find correlations between temperament and physical states was a part of the Galenic tradition that fell out of favour as the secrets of physiological and pathological processes were revealed by the development of laboratory methods. Such a swing of the pendulum was not new in the history of medicine; the tendency has been for each advance in scientific knowledge to be hailed in turn as containing the final solution of the problem of the mind-body relation. Nineteenth century science, indeed, entrenched itself behind the proposition that it was concerned only with the *how*; consideration of the *why* was dismissed as teleological, and this attitude made us content with the study of mechanism and the exclusion of the study of personality. The period, brilliant in other ways, was marked by the forgetting of clinical observations which, hidden in language of the pre-scientific era, now appear as new discoveries. JUNG's temperamental types, for example, are closely paralleled by the sanguines and melancholics of STAHL—"the last of the Animists"—and KRETSCHMER's work on physique and character, carried out in the modern spirit of accurate observation, is a return to GALEN's attempts to relate these qualities to each other.

The psychological attack upon functional nervous disorders shook our faith in the sufficiency of the study of bodily mechanisms and marked the beginning of a new swing that has not yet reached its full amplitude. We are returning to the conception that temperament, operating through emotional reactions and their physiological concomitants, may play a part in initiating pathological changes, and although this general conception is rarely formulated yet whoever bears it in mind will often recognise clinical examples in current medical literature. The influence of emotion upon gastric secretion and motility, noted in the classical case of ALEXIS ST. MARTIN, had, for example, been scarcely considered in the ætiology of peptic ulcer until DRAPER and TOURAINE made a psychological study[1] of the "ulcer race." These writers showed that ulcer occurred in KRETSCHMER's so-called asthenic type, and that its subjects showed exaggerated fear sense and raised motor and psychomotor activity, and they gave case-histories of ulcer patients which included stormy psychological episodes. The significance of their psychological findings can be estimated only by clinicians accustomed to the systematic examination of that aspect of the patient, but this method of approach may tell us the *why* of those pathological processes that have hitherto been our sole objects of study in this disorder. The same authors have now turned to the study of migraine,[2] a disorder in the accounts of which are often to be found hints of possible psychological causes, and which had already been studied from that point of view by the late Dr. F. G. CROOKSHANK in this country.[3] DRAPER and TOURAINE have studied a series of 50 cases, none being admitted unless all pathological conditions had been excluded as causes for headache. They note the frequent presence of facial characteristics suggestive of pituitary influence upon the growth of the skull, and the tendency of migraine to appear in family groups; but somatic transmission of the disease is rejected in favour of imitation or identification. The patients' intimate surroundings and human relationships were closely studied, and it is claimed that a characteristic constitutional type exists for the migrainous person, in whom intelligence is outstanding but emotional development is retarded, often in the sexual sphere; also that there is a mechanism of psychic forces, involving emotional relationships between the generations, which sets off the physiological disturbance of the migraine attack. What this disturbance may be remains a problem, and doubt arises how the varied factors could act with such physiological specificity as to produce the curiously fixed phenomena of the scotoma and scintillations. The fact remains that in peptic ulcer and migraine these observers have achieved some success in establishing for each disorder a constitutional type and psychological constellation, and though they make no therapeutic claims we may echo their hope that in the psychological approach to the problem of migraine there may be found further opportunities for research and treatment.

MASSAGE DIRECTORIES

THE Chartered Society of Massage and Medical Gymnastics has issued a new register of members, containing about 9250 names of masseurs and masseuses qualified to administer physical treatment under medical direction. In this edition of the register it has been indicated as far as possible which members are established in private practice, and a special section has been added for members who are no longer in practice or whose addresses cannot be verified. The register can be obtained from the secretary, C.S.M.M.G., Tavistock House North, Tavistock-square, London, W.C.1, price 4*s.* We have also received from Mr. J. Stewart Brown (Hygeia, Falmouth), a new edition (August, 1934) of the directory issued by the Private Practitioners' Association of which he is hon. secretary. This is an association of members of the Chartered Society of Massage and Medical Gymnastics who are in private practice, and the directory gives the qualifications of the members, the kinds of treatment undertaken, and the names of those willing to take resident patients or national health cases. A copy of the directory will be sent post free to any medical practitioner who asks for it.

ANNOTATIONS

SEX FACTORS IN INTELLIGENCE

It is a well-attested fact that mental defect occurs more frequently in the male than in the female sex, and an investigation has been made in and around Los Angeles by Dr. A. J. Rosanoff and others[1] with a view to determining whether throughout the whole range of intelligence the superiority of the female is as noticeable as at the lower level. The material examined was 233 pairs of opposite-sex twins who are described as of normal or superior intelligence, the criterion being an I.Q. above 75; a relative excess of cases of higher intelligence among girls was discovered amounting to 22·5 per cent. The method of stating the results, however, is open to criticism, for it masks an important fact brought out in a recent inquiry by Dr. T. A. Danby reported in *Mental Welfare* a few months ago. Dr. Danby found a distinct preponderance of mentally defective boys over mentally defective girls, but no significant difference among the average school population, while among children with an I.Q. of 130 and upwards boys exceeded girls in number to the extent of 22 per cent. Among boys there are, as he said, "more geniuses and more imbeciles." When one looks into the detailed figures of the American inquiry one finds that although I.Q.'s above 130 were relatively rare among the twins, the number of boys at that level of mentality exceeded the girls by 21 per cent. This point seems to have escaped the Los Angeles investigators. They have, however, developed a further line of argument of considerable significance. Having satisfied themselves that sex-linked genetic factors enter into the causation of mental defect, they proceeded with an attempt to discover what other factors are involved. For this purpose a comparison was made between monozygotic and dizygotic twins. In 15 out of 34 cases of monozygotic twins, the I.Q.'s of the two twins differed by not more than five points, indicating, therefore, considerable similarity in hereditary endowment, but in 4 cases there was so great a discrepancy as to make it necessary to suppose that prenatal and intranatal factors were at work. Such factors operate more prejudicially on the male than on the female infant as is shown by the greater mortality in fœtal and early infant life among males. Male life is evidently more vulnerable and the authors conclude that the cerebrum shares that vulnerability; it is thus that they account for the higher incidence of mental defect in males. As further evidence for their suggestion figures are quoted showing that the average I.Q. of 424 first-born boys was 103·7 and that of 448 first-born girls was 107·6. The investigation will stimulate the increasing interest which is being taken in the effect of environmental factors on the production of mental defect. While in the majority of cases there is admittedly a hereditary basis, the possibility should not be overlooked of environmental factors in borderline cases tipping the scale to one side or the other. If the Los Angeles view is confirmed it will serve as a useful reminder that eugenics may be applied to the environment as well as to the stock.

MORPHINE FROM POPPY STRAW

The Advisory Committee of the League of Nations recently became aware[2] of a new process for extracting morphine and other alkaloids from poppy straw and poppy chaff remaining after the ripe capsules have been thrashed to separate the seeds. These parts of the plants have hitherto been regarded as useless and destroyed, or utilised as a poor quality of manure. The discoverer of the new "dry process" is Mr. de Kabay of Hungary, and it has been exploited by the Alkaloida Co., Ltd., in which the principal shareholders are the Royal Hungarian Ministry of Agriculture and the de Kabay family. The process is regarded as a new source of income for agriculture and, owing to the ease with which stocks of the raw material can be accumulated, transported, and stored, the manufacture can be uninterruptedly carried on throughout the year. There are, at the present time, some 8000 hectares of land in Hungary under poppy cultivation, yielding some 13,000 tons of poppy straw annually. One ton of poppy straw can be made to yield 800 grammes of morphine base and 80 grammes of codeine base; thus some 10,000 kilos of morphine and 1000 kilos of codeine could be annually produced. The quality of the alkaloids is pronounced to be the same as that obtained from raw opium and to meet all pharmacopœial requirements. The effect of this new discovery on the supply of morphine for licit, and also illicit, purposes is likely to complicate still further the international control of drugs of addiction. It is reported that in the first three months of this year 40 kilos of morphine, thus made, have been exported from Hungary, and negotiations are in progress for increasing the export trade when the extension of the factories now under construction shall have been completed. The Hungarian Government and the inventor of the process are prepared to enter into arrangements both with private undertakings and Governments for the sale of the secret of the new process to foreign producers under certain conditions. All this makes it important to expedite the summoning by the League of Nations of the projected conference on the production of the raw materials of dangerous drugs.

RADIOGRAPHIC DETECTION OF TUBERCULOUS RECRUITS

The recent progress made by radioscopy in the diagnosis of intrathoracic tuberculosis is given prominence in a report made to the French Academy of Medicine on July 17th by Dr. H. Rouvillois.[1] It may be recalled in passing that as long ago as 1923 Colonel Hauser introduced the systematic radiological examination of recruits in the Swiss army. Elsewhere, isolated industrial, commercial, and university centres, such as that of Munich, have adopted the same principle with impressive results; and some radiological enthusiasts have even been tempted to point the finger of scorn at the older methods of auscultation and percussion. In France, birthplace of Laennec, this mistake has not been made, and in the army at least the radiologist and the clinician work hand-in-hand. The first systematic radiological examinations of French soldiers were undertaken in 1928. From 1932 onwards this system has made rapid progress and in November, 1933, more than 80,000 recruits were examined by a mobile radiological team equipped and organised so as to comb out tuberculous suspects in one barracks after another with a minimum of friction and a maximum of speed and efficiency. This team classifies its material on a broad basis as radiologically healthy, diseased, or suspect; the mobile radiological unit being a large-toothed comb, not designed for hair-splitting, every doubtful case is referred for a later examination at which time and equipment allow of greater finesse. When the findings of the mobile unit are unequivocal, gross lesions being demonstrated, the patient is referred for clinical, bacteriological, and radiographic examination to a special hospital staffed by experts. Hitherto, out of a total of 115,150 recruits examined in the course of the past two years, 1093, or 0·94 per cent., have been combed out, 143 have been found to be suffering from open tuberculosis with tubercle bacilli in the sputum. This is of interest since all the recruits have previously been subjected to clinical examination. The figures indicate that only two-thirds of the tuberculous cases had been discovered in this way, the remaining third being missed until the radiological investigation.

WATER SOFTENING AND HEALTH

CHALK is the subsoil over a large area of south-eastern England and the water which it contains in abundance, although pleasant to the taste and excellent for making tea, is too hard to be convenient for some other domestic purposes. There is consequently an increasing tendency among householders in the home counties to soften the water supplied to them, and a correspondent has asked for guidance as to whether this has any drawback to health. So far as water is used for washing either the person, household utensils, or fabrics, it is undoubtedly advantageous that it should contain little calcium or magnesium salts, since these form insoluble soaps which adhere to the thing washed, carrying with them some of the dirt which should be removed. The classical softening process of Clark in which milk of lime is made to react with the bicarbonates of calcium and magnesium, removing them almost entirely as normal carbonates which are only soluble to the extent of a few parts in 100,000 of water, introduces nothing in place of the alkaline earths it removes. The process requires a fairly precise knowledge of the mineral content of the water to be softened and the reaction is slow, especially if the temperature is low. If the hardness of the water is not due to carbonates but to sulphates or other salts, sodium carbonate must be used as well as lime. The process could be worked in a private house, especially if two cisterns were used alternately, but the average householder would find it rather inconvenient. The growing use of base exchange materials for water softening for industrial purposes has led to their application to domestic supplies, and small appliances in which the water from a tap flows through a layer of one or other of the natural or artificial silicates which readily take up calcium or magnesium from solution in the water, and in exchange part with sodium, are offered for sale—at rather high prices. These materials are rapid in action and efficient as softening agents. The speed of reaction slows down as the exchange approaches completion, and it is necessary, from time to time, to reverse the reaction by passing a strong solution of common salt through the layer of base exchange material, thereby reconverting the calcium or magnesium double silicate into a sodium one. After many cycles of these changes the material needs renewing. The softened water contains sodium salts in amount equivalent to the earth bases removed. Bricks of sodium phosphate, or mixtures of this salt and sodium carbonate, are also used to precipitate insoluble calcium or magnesium phosphate and carbonate. They are effective so long as they last, but in the earlier stages some excess of sodium salts will be present in the softened water and in the later stages the softening is likely to be incomplete. The base exchange method is the only one which can safely be left to itself. Few people are under any compulsion to drink artificially softened water, for there are not many suppliers, whether municipal or private, who soften the water they supply. If they do it seems unlikely that they will come to any harm, for the mere substitution of sodium for calcium and magnesium ions can hardly have any appreciable effect on health, either for good or ill.

MENINGOCOCCAL CARRIERS

SINCE the demonstration in 1901 by Albrecht and Ghon that carriers of the meningococcus occurred this question has received much attention. Thanks very largely to the war time researches of English workers—notably W. M. Scott, J. A. Glover, and M. H. Gordon—precision was given to our knowledge of the meningococcal carriers, and the overwhelming importance of the carrier in the spread of cerebro-spinal fever was firmly established. Recent investigations by Dr. Geoffrey Rake[1] at the Rockefeller Institute bring additional information. The object of his research was to find out the duration of the carrier state, whether remissions of the state occur, and if so whether remissions are associated with any change in type of meningococcus carried, the distribution of types among carriers in a non-epidemic period, and finally the effect of disease of the upper respiratory tract on the carrier state. Observations were made on three groups of persons: a group of 24 adults working on one floor of the Rockefeller Institute, a second group comprising 25 girls aged from 6 months to 14 years who were inmates of a foundling home, and a third group composed of 569 young men in a concentration camp. The findings in the first group are the most important, for they represent the result of weekly swabbings made over a much longer period than has been usual in this type of investigation. Of the 24 persons composing this group—secretaries, technicians, and research workers—13 were examined weekly for twenty months, 2 for fifteen months, 8 for four months, and 1 for seven months. 10 carriers were found in this group, 5 being chronic carriers. 4 of these continued to harbour the meningococcus in the nasopharynx throughout the period of observation and showed no signs of undergoing spontaneous relief when the inquiry was discontinued; the fifth, after carrying the meningococcus for five months without remission, developed a cold with the appearance of a type XIII pneumococcus in the throat in large numbers. This coincided with the disappearance of the meningococcus from the throat, and although unfortunately this person was only under observation for six weeks subsequent to this, he continued free during this period. 3 out of the 4 chronic carriers gave negative swabs from time to time, in one case over a period of four and a half months, but the meningococci always reappeared again in the nasopharynx and, what is particularly interesting, the type of meningococcus carried always remained the same. This observation, as Dr. Rake points out, makes three negative swabs at weekly intervals of little use as the criterion of cure of meningococcal carriers. Of the remaining 5 carriers in the Rockefeller group, 2 were intermittent and the strains carried were not the same, whilst the remaining 3 were transient carriers in whose throats the meningococcus only appeared on one occasion. The carrier-rate in the remaining two groups was 8·0 and 2·1 per cent. respectively, but the difficulty of obtaining satisfactory swabs from children and the fact that none of the persons in the third group was under observation for more than three weeks might readily account for the divergence between those figures and the 41·6 per cent. found in the Rockefeller group.

AN OLD PROBLEM SOLVED

FIVE years ago Dr. Franz Nagelschmidt of Berlin sought to move the hearts of the Tuberculosis Association meeting in Cambridge[1] in favour of Friedmann's turtle-vaccine therapy, his most telling argument being the recital of an experiment conducted by Dr. Eugen Szalai in Pesterzsebet, a small industrial suburb of Budapest. Dr. Szalai claimed that an extraordinary decline in the death-rate from tuberculosis occurred in this area after widespread vaccination with the turtle tubercle bacillus; of 4812 cases of pulmonary tuberculosis treated in the years 1925–27 by this method 12 died, 9 became worse, and the remainder were cured. There was a feeling in this country and on the continent that these results were difficult to reconcile with the results obtained by other workers—that they were in fact too good to be true. A year after the publication of Szalai's paper,[2] Dr. J. Parassin pointed out in the same journal[3] that, Pesterzsebet possessing no hospital of its own, all grave cases of tuberculosis were sent to the hospitals at Pest, thus greatly improving the statistics of the former at the expense of the latter. A complete elucidation of the problem is now to be found in a book by Dr. Friedrich Wolter, director of the Hamburg Epidemiological Research Institute, entitled "Das Tuberkulose-Rätsel von Pesterzsebet und seine Lösung vom epidemiologischen Standpunkt" (Leipzig: Georg Thieme). Wolter points out, first, that the problem can only be solved by statistical methods, and that in the absence of figures for morbidity any mortality-rates lose much of their value—this being especially the case with a chronic disease like tuberculosis, which may last 20 years. Dr. Wolter then shows rather unkindly that the fall in the tuberculosis death-rate in Pesterzsebet was greater in the years 1920–24 when the Friedmann vaccine was not used than in the years 1925–32 when it was. He justifies Parassin's criticism in a table showing that if the number of deaths be calculated with regard to the place in which the patient lived, instead of where he died, the reduction is nothing like so marked. He gives another table comparing the reduction in the mortality-rate in Pesterzsebet with that in five other industrial towns of similar size in Hungary between the years 1920 and 1932. The percentage reduction in 1932 compared with that of 1920 ranged between 72·3 in Czepel (which had no Friedmann vaccination) and 56·7 in Kleinpest, Pesterzsebet coming between with 68·9. In these ways Wolter rules out the suggestion that turtle-vaccine had anything to do with the improvement in the tuberculosis mortality in Pesterzsebet. The reduction he believes to be due to the earlier recognition, earlier treatment, and more adequate after-care of the patients, but most of all to the vastly improved measures of practical hygiene undertaken in the town. Wholesale draining operations, cleansing and clearing the ground, better sanitation, the provision of a safer water-supply, and the planning of healthy homes on the lines of a small garden city—these are the chief factors which have resulted in the improvement. His scholarly work will set at rest the minds of many who could not put aside some striking evidence just because it was a priori improbable. It is also testimony to the fact that the chief factors in the diminution of tuberculosis are the same in Hungary as elsewhere.

PATHOGENESIS OF ANGINA PECTORIS

WITH few exceptions, angina is associated with gross lesions of the coronary arteries, most commonly atheroma in the course of the vessels, much less often with a syphilitic process at their mouths; and it is generally believed that these processes, by limiting the coronary blood-flow to a volume insufficient for the needs of the myocardium, are the root causes of the pain. Whether or not spasm of the diseased vessels or their subdivisions occurs and plays a part in reducing blood-flow is not at all certain, though there is no doubt that the calibre of the vessels is under nervous control. Under physiological conditions the coronary blood-flow stands in a fixed relation to the heart's work, and the experiments of Anrep and Segall showed that when this increases, dilatation of the coronaries occurs as a result of diminished vagal activity. Anoxæmia of the muscle is an obvious consequence of an inadequate coronary flow, and it has been thought by many that this was the cause of angina. This question is discussed by S. Dietrich and H. Schwiegk,[1] and they quote animal experiments in which electrocardiographic changes similar to those occurring in angina pectoris and coronary occlusion result from oxygen deficiency in the inspired air. Again T-wave changes could be brought about in healthy men by artificial anoxæmia, while in anginal subjects there was in addition onset of typical pain. This last was not relieved by vasodilators, though when these were taken as a prophylactic the onset was delayed. On the other hand, pain was quickly relieved by oxygen or ordinary air. These experiments are held to rule out coronary spasm as a factor in pain production. The effect of generalised anoxæmia on the electrocardiogram of normal subjects is also reported on by L. N. Katz, W. W. Hamburger, and W. J. Schutz (Amer. Heart Jour., August, 1934, p. 771), who found depression or inversion of the T wave, and deviation of the ST segment, as has been observed in spontaneous angina. None of these normal subjects, however, experienced any pain. Applying the same method to anginal patients similar changes occurred in the tracings, but in only two of six cases was pain produced. It is to be noted that considerable tachycardia occurs during the experiment, in itself a possible cause of pain. The procedure appears to be risky, and the authors condemn it as a diagnostic test for angina. They conclude that some other factor than anoxæmia is concerned in angina, since it failed to occur in any of their normal subjects and in the majority of their patients. To this may be added the fairly recent knowledge that coronary thrombosis may be accompanied by a variety of symptoms other than pain. Dietrich and Schwiegk reject coronary spasm as a factor in the cardiac pain of effort, yet they appear to countenance deficient dilatation of these vessels (attributed to a failure of vagus inhibition) as a cause of angina resulting from emotion. They also speak of reflex constriction of the vessels resulting from distension of some portions of the gastro-intestinal tract. However, under both these conditions the cardiac load is increased, and, in the presence of some arterial lesion preventing a corresponding increase in blood-flow, there would appear to be adequate cause for cardiac pain, and no necessity to invoke another factor. The fact that changes in the electrocardiogram similar to those occurring in spontaneous angina are produced in normal men when they suffer from oxygen shortage suggests that there is a functional disturbance of the muscle in both cases; yet we do not know the relation between this defect and the sensation of pain, and cannot be surprised that it is not experienced in the normal subject. At the present time the conception of angina as being in some way dependent on a relative ischæmia of the heart muscle rather than purely on an anoxæmia appears more acceptable.

A DIRECTORY OF SOCIAL HYGIENE

THE term social hygiene is sometimes used in a restricted sense to denote the efforts made to eliminate the venereal diseases, sometimes in the wider sense of the application of biology, psychology, and sociology to the promotion of health and racial well-being. It is in the broader sense that the British Social Hygiene Council has construed the term since the change in its official title nine years ago, and evidence of this wider scope is seen in the appearance of a Year-book [1] which is the first comprehensive survey to be made of social hygiene. The book, which is compiled from material made available to the Council by the various Government departments concerned, contains recent information of the incidence of venereal disease, of the means taken to prevent it, and of the channels for its treatment in towns and counties at home and throughout the Empire. This much would already be of much value, but the net is spread to include the wider agencies for the promotion of right thinking and action. Instructive notes on the development of biological education in the colonies are based on replies to a questionnaire recently issued by an advisory committee of the Colonial Office. It is the plan of the Year-book to take one dominion or group of colonies for the subject of a special survey, and Canada, the senior dominion, appears as the first study in this number. The volume also contains some general articles, including one on the methods of propaganda and their results by Mrs. S. Neville-Rolfe and another by Colonel L. W. Harrison on the administration of venereal disease in Great Britain, what has been done and what might be done in the future. Appendices contain a list of voluntary associations, British and international, and a few hints on what to choose for further study, whether in biology, physiology, or the social applications of hygiene.

MONGOLISM AND MATERNAL AGE

MANY years ago it was observed that mongolian imbeciles are often the last children to be born in a long family, a fact which has suggested that the condition may be a product of the exhaustion of the maternal reproductive powers. Evidence since then has accumulated to show that though affected children are not necessarily born at the end of the family, their birth rank is certainly, on the average, significantly later than that of normal children. At the same time it has been clearly shown that though some of these imbeciles have young mothers, the great majority of them are born after the mother has reached the age of 35 years. This is the experience of a recent survey[2] by Dr. K. Rupilius at the University children's clinic at Graz. Which of these two correlated factors, birth order and maternal age, is the more important in the ætiology of the affection has not been determined. Indeed, with a limited amount of material available it is no easy task to disentangle one from the other. To this problem Dr. L. S. Penrose has recently addressed himself.[3] Working in the research department of the Royal Eastern Counties' Institution he has secured the maternal age at birth and the birth order for all offspring in 217 sibships each containing one or more mongolian imbeciles—1031 persons in all, of which 224 were affected. Upon these data he brings a mathematical statistical battery to bear, and his two different methods of approach agree in denying any ætiological importance to order of birth. In fact they show that the numbers of imbeciles in each birth rank are very close to those which would be expected on the assumption that the incidence depends upon maternal age. Another factor which some writers have believed to be of importance is the interval between the birth of a mongolian imbecile and the birth of the child immediately preceding it, an interval which has been found to be on the average unduly long in comparison with that between normal births. According to the careful analysis of this study it is not possible to assign any direct causal significance to this factor either. The underlying influence is again, probably, maternal age, an increase in which tends slightly to lengthen intervals between births.

SCHOOL PHYSIQUE IN AUSTRALIA AND IN ENGLAND

Dr. Jane S. Greig, who is chief medical inspector to the education department of the State of Victoria, has recently paid a visit to this country and compared the conditions [4] she has found among the school-children here and those with which she is familiar. Crippling conditions are less prevalent in Australia; the figures she gives to illustrate this are: congenital hip deformities, 1 in 2000; congenital talipes, 1 in 1000; tuberculosis of bones and joints, 1 in 2000; deformities after infantile paralysis, 1 in 500. The percentage of children in Australia with defective vision is much the same as what it is in England or Scotland, but "in the Old World," Dr. Greig says, "cases of defective vision have to be taken very seriously as the large proportion are due to myopia. This defect . . . is so serious . . . that the children have to be provided with special forms of education. In Australia, on the other hand . . . a country of sunshine, open-air life, and good food . . . progressive myopia is . . . a rarity." While malnutrition has been a problem in the State, "on the whole," Dr. Greig says, "the children have survived wonderfully the ordeal of the period of depression and the consequent unemployment of many fathers of families. Their weight has been maintained to a surprising degree, but I fear that later we will have evidence to show that a large number of children of the unemployed have suffered in stature and are below the average height for their age. This is probably due both to lack of suitable food such as milk and vegetables, and to overcrowding, which is very marked in the more densely populated inner suburbs." It surprises many to know, Dr. Greig goes on, that visible malnutrition is not the first or most noticeable evidence of poverty. "In our experience it is dirt and neglect. Flea-bites, which had become almost a rarity, are becoming prevalent again, for soap and hot water is considered an unnecessary expense when money is scarce." That heights and weights in future will be lower is against general experience. Dr. Greig compares her own figures (for 1922) with those of Bournville, one of England's best, when Australia comes out well. Both sets of findings are, however, below those of Heston (Middlesex), which have been accurately estimated by Dr. Victor Freeman [5] for 1933.

Dr. Freeman has calculated nutrition quotients on Quetelet's formula. He finds that in general the cases deemed on clinical observation to be of subnormal nutrition fell mainly in the group with low nutrition quotients, except with the 12-year-old boys; a discrepancy, he thinks, largely accounted for by the fact that this is a rapidly growing period of life for many boys. The paucity of several types of defect in the Victorian children going hand in hand with good physique is in accordance with a general rule brought out statistically by Dr. Freeman that many important clinical defects diminish in frequency as the nutrition quotient rises. The relationships established appear to justify his claim that weights, heights, and nutritional quotients, when classified in relation to physical defects, may give as reliable a picture of the well-being, or otherwise, of the community as can at present be obtained.

IMPAIRMENT OF ANTITYPHOID VACCINES BY PHENOL

EVIDENCE accumulated from many sources indicates that, among the many antigenic components contained in the typhoid bacillus, the complex polysaccharide that is present at the surface of the bacillary bodies in their normal smooth form plays a predominant rôle in the reactions that establish an active immunity. There have certainly been hints that this is not the whole story; in July last [6] we published a paper by Felix and Pitt, in which they showed that some antigenic component other than the smooth somatic polysaccharide—the O antigen—is concerned in effective immunisation against virulent strains of the typhoid bacillus. But the exact relationship of this new component to the O antigen has not yet been established, and its detection, as Felix himself insists, in no way conflicts with the accepted view that the O antigen itself is an important factor in immunisation.

Another controversy, of interest from the practical point of view, has centred round the antigenic efficiency of the O component as it exists in an ordinary typhoid vaccine. It has been stated by some that while an attack of typhoid fever leads to an abundant production of both O (somatic) and H (flagellar) antibodies, antityphoid vaccination fails to induce the former response and is followed only by the production of flagellar agglutinins, which by general agreement are immunologically ineffective. Other workers have, however, failed to confirm these statements in their categorical form, and it is probably a fair summary of current views to say that antityphoid vaccination is followed by the production of both O and H agglutinins, but that the useful O agglutinins are produced to relatively low titre, and persist in the circulating blood for only a short time, while the useless H agglutinins are produced to high titre and persist for months or years. In our current issue Drs. Stuart and Krikorian record a series of observations from which they conclude that the failure to induce a more satisfactory O response has been due, in part at least, to an inactivation of the O antigen by the phenol added to the bacillary suspension. Employing three vaccines, all killed by heating at 60° C., but differing in that the first received an addition of 1 per cent. phenol, the second 0·5 per cent., while the third was left unphenolised, they inoculated a series of rabbits and men and determined the resulting titre of O and H agglutinins at varying intervals thereafter. Each vaccine induced an abundant production of H agglutinins, nor did the titre differ significantly in the three groups. Each vaccine also induced the formation of O agglutinins; but while the response to the vaccine containing 1 per cent. phenol was relatively poor—titres of 1 : 200 to 1 : 2000 in rabbits and 1 : 100 to 1 : 200 in men—the response to the non-phenolised vaccine was far more satisfactory—titres of 1 : 2000 to 1 : 10,000 in rabbits and 1 : 200 to 1 : 2000 in men. Moreover, tests at later intervals showed that O agglutinins were still present to relatively high titre three months after the inoculation of the non-phenolised vaccine, while these antibodies had disappeared, or sunk to a very low titre, in the rabbits or men injected with the vaccine containing 1 per cent. phenol. The vaccine containing 0·5 per cent. phenol, which was tested only in rabbits, gave intermediate results.

The importance of retaining the antigenic activity of particular bacterial components in any preparation used for active immunisation is receiving added emphasis with each increase in our knowledge; and the demonstration that phenol, so commonly used as an antiseptic addition to immunological reagents, may seriously impair the activity of some of them should be carefully noted, and its possible implications further explored.

PROF. F. A. E. CREW, director of the Institute of Animal Genetics at Edinburgh, will deliver the Lloyd Roberts lecture at the Royal Infirmary, Manchester, on Tuesday, Nov. 6th, at 4.15 P.M.

THE hundredth anniversary of the foundation of the University of Durham College of Medicine at Newcastle-upon-Tyne will be celebrated at Newcastle on Oct. 4th and 5th. A convocation will be held in the chapter house of Durham Cathedral at which the honorary degree of doctor of civil law will be conferred on Sir Hilton Young (Minister of Health) and Sir Holburt Waring, P.R.C.S.; of doctor of hygiene on Sir Francis Dyke Acland (chairman of the Dental Board) and Dame Janet Campbell, M.D.; of doctor of surgery on Major General J. A. Hartigan (director-general, A.M.S.), Mr. J. W. Leech, M.S., M.P., and Mr. William Robinson, M.S.; and of master of arts on Dr. W. D. Arnison.

NATIONAL SMOKE ABATEMENT SOCIETY.—The sixth annual congress of this society will be held in Glasgow under the presidency of Dr. H. A. Des Voeux from Sept. 27th to 29th. Among those who will read papers is Dr. J. Johnstone Jervis, medical officer of health for Leeds, who has chosen as his subject slum clearance and smoke prevention. The address of the society is 36, King-street, Manchester 2.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XIX.—PROGNOSIS OF PARALYSES IN CHILDREN

(EXCLUDING POLIOMYELITIS)

THE paralyses met with in childhood form so miscellaneous a group that much subdivision and classification are necessary before prognosis can be adequately considered. Moreover, it is particularly in cases of this kind that the prognosis as regards life and as regards the course of the disease show so little correspondence. In many of them, although the outlook is often dismissed—in a sense accurately—as "hopeless," in that the disorder is not amenable to treatment, yet its course is so benign that questions as to the child's present and future régime need consideration, and indeed are of great importance. From the viewpoint of prognosis the paralyses of childhood may be divided into two groups, according to whether the lesion on which they depend is *progressive* or is *residual*. It is important to remember that the lesion and not the clinical condition is referred to; paralyses, even though occasioned by a purely residual lesion, may deteriorate under unfavourable conditions, and give the impression that the disease is progressive. This is exemplified by a diplegic whose mental condition does not permit of suitable treatment, and it has led to an erroneous idea that spastic palsies in general are progressive.

Progressive Paralyses

The progressive paralyses which most frequently raise practical questions of prognosis are the myopathies and the abiotrophies. There are also certain toxic and degenerative conditions in which extrapyramidal syndromes predominate, and a group of fatal degenerations of infancy and early childhood. Progressive paralyses in children nearly always result from familial diseases.

Myopathies.—The commonest type is the one in which the prognosis is most unfavourable—i.e., pseudo-hypertrophic muscular atrophy. The patient —almost always a boy—shows evidence of the affection about the age of five; it may not be until a year or two later that the diagnosis can be made with certainty. Once this has been done the prognosis leaves little room for doubt. The muscular weakness, aggravated by lordosis, scoliosis, and other postural defects which it is impossible to combat, will increase steadily and somewhat rapidly, so that in the course of three or four years the child will become crippled or bedridden. This state of affairs is usually not of long duration; these children lack resistance to disease and seldom live beyond childhood or early adolescence. The outlook is so bad that no useful purpose is served by making preparations for the future or pressing education. Much sacrifice and disappointment will be saved if this fact is stated candidly at the outset.

In other forms of myopathy the prognosis is different, and cannot be stated so confidently. In the *facio-scapulo-humeral* type the onset is in early childhood, but it runs no constant course, and in some cases it seems to become more or less stationary in later years. In the rare *juvenile* (*Erb*) type the outlook is better still, owing to the later age of onset. Neither of these types have any great tendency to shorten life, so that education and vocation must be considered. Each case must be judged individually, but it should be borne in mind that such atrophy as has taken place will be permanent, and that at any rate *some* deterioration of function in the affected part is to be expected.

Cases of myopathy are seen which represent a mixture of these types, and in them the prognosis may be difficult. In general, the more pseudo-hypertrophy is present the worse is the outlook.

Abiotrophies.—These are represented most typically by Friedreich's disease, in which there are hypotonus and ataxia without muscular atrophy, and by neural muscular atrophy (Charcot-Marie-Tooth), in which muscular wasting is the salient feature.

It is always a difficult matter to convey to parents an idea of what may be expected for a child affected by *Friedreich's disease.* In the first place, the expectation of life is extremely uncertain. These children resist infections badly, and probably about half those seen in hospital practice fail to reach adult life. On the other hand, if care and home conditions are good the probability is that they will do so, and they have a good chance of surviving three or four decades. Once the years of puberty are passed the disease seems to progress much more slowly, or even to become stabilised. These children's future is greatly complicated by the mental factor. Though not actually defective, they are nearly always below the average in mental powers, particularly in concentration and initiative. It is therefore unwise to suggest that they shall compensate for their physical limitations by engaging in intellectual occupations. A considerable number of them, however, do earn their livings in the less skilled forms of employment.

In the *Charcot-Marie-Tooth* type of atrophy the prognosis is decidedly better than in Friedreich's disease, although the wasted appearance of the legs suggests a more severe disablement. Individual cases vary considerably, and it is well to warn parents that there is some danger of the child becoming seriously crippled, as well as of the mischief spreading to the hands. But mostly the disease runs a very benign course; the patients survive adolescence and succeed in earning their livings under the limitations imposed by their disability. Their mental powers are in no way below the normal. On re-examining one of them after an interval of a year it is often impossible to detect any extension of the disease. Hence the orthopædic surgeon is justified in undertaking more radical measures for prevention or correction of deformities, and the prognosis is improved thereby. In the majority the power of walking will be preserved, although it may be somewhat of a labour, particularly in going up stairs and inclines.

In the group of progressive degenerations in which extrapyramidal syndromes predominate there is little scope for treatment; prognosis is, therefore, the principal question on which advice will be sought. While in all of them the prognosis as regards function is bad, the prognosis as regards life varies considerably in the different forms. In *hepato-lenticular* degenerations (Wilson's disease, pseudo-sclerosis) the children are cachectic as well as crippled; many of them die in childhood and comparatively few survive adolescence. The outlook for their bodily activities is entirely bad; they become disabled by rigidity and contractures. Some degree of dementia is likely to ensue. These cases are, however, rare in comparison with the *athetoses*, of which at any rate a large number are progressive. In them the general health is not impaired, and life is not endangered, except in that the child may be prevented by them from leading a healthy life and susceptibility to disease be thereby increased. Most of them survive adolescence, and they are commonly met with in the twenties and thirties, but their expectation of life is probably well below the average. From the point of view of their activities the outlook depends very largely on whether the athetoid movement and spasmus mobilis are unilateral or bilateral. In double athetosis it is very bad; walking is always difficult and may become impossible, and it is extremely difficult to prevent contractures and joint changes. In all but the mildest cases it is impossible to train the hands to any useful activities. On the other hand, in hemi-athetosis it is often surprising how much the child learns to overcome the disability, both in walking and in the use of the hands. It is worth while persevering in manual training, and at a later stage some assistance may often be obtained from operative measures. There is no essential mental defect in athetosis, and many of these children are remarkably intelligent. Some are defective as the result of associated cerebral lesions, and in them the prognosis is bad from all points of view.

Of other severe paralyses of early childhood—Hoffmann-Werdnig disease, amaurotic idiocy, Schilder's encephalitis—little need be said. They are invariably fatal, the first two usually within a year and the last within two or three.

Paralyses due to Residual or Recoverable Lesions

The most important of these are diplegia and hemiplegia.

Diplegia is merely a syndrome and may be due to a variety of causes. Some cases are progressive and usually die in infancy. But most are not progressive, and in them the prognosis is of great practical importance. In my view it is more favourable than has been generally recognised, but it depends almost entirely on the treatment provided. In these children the power of standing and walking does not develop spontaneously, and cases which are left to their own devices nearly always deteriorate.

Certain complications of diplegia render the prognosis unfavourable whenever they occur. These are frequent convulsions persisting beyond infancy; a true degree of amentia, apart from retardation; severe athetoid movements. In the absence of these complications the main points in prognosis are the severity of the spasm and the age at which suitable treatment is begun. If a case of moderate severity is seen during the second year the outlook may be presented as follows.

Under continuous treatment it is likely that the child may be taught to walk in a frame by 3½ or 4 years, to push a doll's perambulator by 4 or 4½, and to walk alone by 5 or 6. It must not be expected to talk before 4, and there may be some dysarthria for several years more. Only in a few cases will the gait become quite normal, but in many it will eventually approximate to the normal. It is impossible to assess the mental possibilities at this age, and one must be prepared for some disappointments in this respect. A greater proportion of these than of normal children will die of intercurrent disease, but the percentage is not a very high one.

When these patients are seen later in childhood, after being allowed to drift into contracture, or being treated by faradism, the prognosis is much worse. Nevertheless, provided that the mental state is not one of apathy, some improvement can nearly always be obtained.

In *hemiplegia* the prognosis is much better than in diplegia. One side of the body develops its activities normally and the child usually learns to walk spontaneously, though with a limp. The arm, on the other hand, may become useless. If early treatment is instituted one may expect to render the affected leg almost normal. In the arm, supination will probably be incomplete, and power less than in the other, but the resulting disability may be quite a slight one.

Of other non-progressive paralyses *amyotonia congenita* and *diphtheritic neuritis* may be taken as examples. In the former the prognosis should be guarded owing to the high mortality from respiratory disease. But a good prospect of recovery may be held out for those who escape this danger.

In diphtheritic paralysis the prognosis is entirely good, complete recovery occurring without special treatment.

Out-patients,
Children.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. W. J. Morris to *Valiant*.

Surg. Lt.-Comdrs. R. R. Baker to *Drake* for R.N.B. and to *Hermes* (on recommg.); R. L. G. Proctor to *President* for course; J. M. Sloane to *President* for course; and G. A. Miller to *Pembroke* for Harrier, for trials.

Surg. Lt.-Comdr. (D.) W. E. L. Brigham to *Tamar* for Hong-Kong Hospital.

Surg. Lt. S. J. Savage to be Surg. Lt.-Comdr.

Surg. Lts. D. A. Hovenden to *Encounter* and to *Drake* for R.N.B.; T. F. Davies to *Drake* for R.N.B.; J. W. L. Crosfill to *Dolphin*; S. Gay French to *Drake* for R.N.B., and to *Hermes* (on recommg.); and C. Ommanney-Davis to *President* for course.

Surg. Lt. (D.) A. M. Watson to *Drake* for R.N.B.

Surg. Lts. (Short Service) E. D. Caldwell, P. K. Fraser, A. J. Glazebrook, W. A. S. Grant, D. P. Gurd, E. James, R. M. Kirkwood, J. W. Rhys, R. F. Stenhouse, and G. D. Wedd.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. A. C. Howard has resigned.

Proby. Surg. Sub-Lts. J. B. W. Hayward to *Drake* for R.N.B.; and W. H. Osborn to *Cairo*.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. G. W. W. Ware, D.S.O., having attained the age for retirement, is placed on ret. pay.

Maj. C. Crawford-Jones to be Lt.-Col.

Lt. T. D. Phelan to be Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS

Maj. W. T. Gardiner, M.C., having attained the age limit, retires, and retains his rank, with permission to wear the prescribed uniform.

ROYAL AIR FORCE

Squadron Leader (Hon. Wing Comdr.) E. Huntley, O.B.E., relinquishes his temporary commission on completion of service and is permitted to retain the honorary rank of Wing Commander.

Flight Lt. (Hon. Squadron Leader) E. E. Isaac, M.C., relinquishes his temporary commission on completion of service and is permitted to retain the honorary rank of Squadron Leader.

Flight Lt. F. W. P. Dixon to No. 33 Squadron, Bicester.

Dental Branch.—Flight Lts. W. D. Guyler to R.A.F. Depôt, Uxbridge; V. H. Weekes to Station Headquarters, Upper Heyford.

INDIAN MEDICAL SERVICE

The undermentioned appts. are made: To be Lts. (Temp. Commn.): Manohar Singh Chadha, Wahajuddin Ahmad Mirza, Abdul Haq, and Maung Maung Gyi.

Lt.-Col. I. D. Jones retires.

BRITISH MEDICAL ASSOCIATION

MEETING IN BOURNEMOUTH

SECTION OF NEUROLOGY, PSYCHOLOGICAL MEDICINE, AND MENTAL DISEASES

At the final meeting of this section, Mr. NORMAN DOTT (Edinburgh), vice-president, being in the chair, Prof. DAVID WATERSTON (St. Andrews) opened a discussion on

Pain

Interest in pain, he said, was not confined to the medical world; philosophers and ecclesiastics had pondered over it. Much of the discussion had dealt with its "protective" aspect, but he did not think any good purpose was served by philosophising about this. Pain in some instances served a useful purpose by warning against agencies to be avoided or by deterring the sufferer from attempting physical exertion which would be harmful to the condition underlying the pain. But this principle was not a universal one. The sufferer from renal colic was warned by his pain neither what to avoid nor what to do to ease it. Moreover, pathological changes might take place in the body—*e.g.*, severe arterial degeneration—without a hint of pain. Like other forms of sensation, pain could be defined only in terms of itself, just as visual phenomena could be described only in terms of sight and were unappreciable by those who had never seen. Pain was different from a mere unpleasantness of sensation. It was so varied in its forms and arose apparently from so many different causes that it might appear almost hopeless to discover the underlying mechanism. We did not know what were its nerves or, indeed, whether it had its own nerves or not, nor whether the "centre" was in the thalamus, if there was a "centre." The ordinary means of physiological experiment were scarcely applicable to the study of pain; man himself must undergo experiment. It was difficult to imagine that pain was ever due to impulses along nerves of other forms of sensation.

The mechanism of pain production might be studied in two successive steps. The first was to determine the tissues and organs that could give rise to pain, and the second the effective stimulus in each of them. It was well recognised that different structures were entirely different in their pain responses. In a case of prolapse of the rectum, the prick of a pin near the anal orifice was painful but on the mucous membrane no pain whatsoever was elicited. The problem of visceral pain presented special features, and would not be understood until we knew more about "somatic" pain. His own experiments were devised to test whether pain could be produced by direct mechanical stimulation of different tissues. The stimulus used was a sharp needle. When the needle was inserted no pain arose from the epidermis; the dermis gave an immediate and acute response; subcutaneous tissue was less responsive but nevertheless in subcutaneous tissues there was a pain mechanism; fibrous tissues were responsive, especially the aponeurosis of muscle. The walls of veins were almost insensitive, but arteries gave a very acute, severe, and sickening response. Striated muscle gave a dull sensation like pressure. Periosteum often gave no response and bone was insensitive to this kind of stimulation, but stripping periosteum from bone was definitely painful. The response of muscle was specially instructive, yet severe pain could be produced from muscles which contracted without having a proper blood-supply, and Sir Thomas Lewis had shown that the pain was due to the production locally of a chemical stimulus which he termed the "p substance." There were reasons for supposing that a chemical agent might be the stimulus for pain in other tissues.

The term "referred" pain was not a good one, since all pain was referred by the sufferer to some place. The point of distinction between the two kinds of pain was that in one the pain was localised by the sufferer at the place where the disordered process was at work, while in the other it was referred to some distant region. For the former he suggested "homotopic," while for the latter, in contrast, we might apply the term "heterotopic." There were difficulties in accepting Mackenzie's theory in all its details. The close similarity between the area of pain and tenderness due to local causes and one of visceral pain and tenderness made it extremely probable that the same underlying condition was present in both of them. The speaker had found that an area of muscular pain and tenderness might be abolished by the local injection of a small amount of normal saline, which presumably helped to get rid of the "p substance." Dr. Forman had found that normal saline injected into the painful and tender areas of "heterotopic" visceral pain acted in the same way and gave relief. He thought it would be found that in such areas there was formed the same pain-producing substance as that formed in areas of pain from local conditions.

Mr. JOHN MORLEY (Manchester), who confined his remarks to abdominal pain, said that the gastro-intestinal tract was insensitive to mechanical stimuli which produced pain when applied to the surface of the body, but the parietal peritoneum was acutely sensitive. Certain features of the visceral afferent nerves justified us in regarding them as different in function from the somatic sensory nerves. He did not believe that visceral pain was referred to the abdominal wall by means of a spinal reflex. In any case of early acute appendicitis we could predict with the greatest confidence the exact position in which the inflamed appendix would be found by noting the point of maximum deep tenderness and muscular rigidity. If this pain was referred from the viscus it would certainly be constant in position and not vary as it did with the position of the appendix. It was important to realise that pain produced by stimulation of the parietal peritoneum was not felt in the peritoneum itself but was radiated to the more superficial branches of the somatic sensory nerves which supplied the affected area of the peritoneum.

Dr. MACDONALD CRITCHLEY (London) discussed the psychological concomitants of pain and susceptibility to pain. Preoccupation with the pain was a very constant feature, but other concomitants varied with the circumstances. The patient's sense of time was disorganised. Mental depression and pain hardly ever went together. In certain patients pain seemed to give rise to stimulation of the special senses and most commonly aroused the sense of colour. Susceptibility to pain was increased by refinement and education. There were rare individuals who seemed to have no susceptibility to pain. They were naturally analgesic. One such man appeared on the stage as elicited. The spasm occurring in an artery already partly occluded by atheroma probably interfered with the flow and led to local thrombosis.

Dr. H. McPHEDRAN (Toronto) drew attention to other lesions which gave rise to pain in the chest simulating coronary disease, notably lesions of the gall-bladder. The history in these cases frequently gave a clue to the origin of the pain. Two cases which he had recently seen with abscesses in teeth made him wonder whether infection had some bearing on sudden coronary occlusion.

Dr. GRANT, in replying, said that he could not agree with Prof. Duguid that atheromatous arteries were not narrowed; and he mentioned the effects of disease in the arteries of the limb where reduction of the circulation could be proved. Turning to Dr. Bourne's remarks he said that the angina of effort and that of thrombosis were both associated with cardiac changes which could be demonstrated post mortem. Cases did arise in which infarcts of the heart were present without atheroma of the arteries, and in such cases spasm probably played a part, but a diagnosis of spasm should not be made too lightly.

Dr. JOHN McMICHAEL (London) read a paper on

The Pathological Basis of Splenic Anæmia

He suggested that splenic anæmia as first described by Gretsel must have included a variety of separate pathological states, including acholuric jaundice, Gaucher's disease, and even aleukæmic leukæmia. He had found that a group of 96 cases of clinical splenic anæmia included achlorhydric microcytic anæmia, leuco-erythroblastosis, and reticulo-endotheliosis, but by far the most common condition was hepato-lienal fibrosis, which includes both cirrhosis of the liver with splenomegaly, and pre-cirrhotic splenomegaly. The spleen in the latter condition was characterised by the effects of venous congestion in addition to proliferative changes.

PUBLIC HEALTH

The Major Fevers of Children: their Recent Trend

IN an analysis based upon the Registrar-General's statistics for England and Wales during the past 75 years the health department of the League of Nations[1] considers the trend of mortality of the four major acute specific infections of childhood: diphtheria, scarlet fever, [illegible] measles. Two main points emerge [illegible]: (1) the great decline in the total number of deaths caused by these diseases; and (2) the alteration in the proportion of deaths due to each of them. If the death-rate of children under 15 from each of these diseases be taken as 100 for the quinquennium 1856–60, and compared with the rates for the quinquennium 1926–30, the decline in the death-rate from diphtheria is 78 per cent; from scarlet fever, nearly 98 per cent; from whooping-cough and measles, 72 per cent. and 68 per cent. respectively; and from all four together, nearly 82 per cent. Diphtheria antitoxin was introduced in 1895, and it is therefore not surprising to learn that an accelerated fall in the death-rate from this disease dated from that year, but no such specific cause can be assigned for the great decline in the number of deaths from scarlet fever. An antitoxin was not available until about 1925, whereas Hilda M. Woods[2] showed that about 1880 "some change occurred and mortality definitely declined and has continued to do so." For the quinquennium 1926–30 the death-rate from scarlet fever among children under 15 was 5·5 per 100,000, compared with 220 for the quinquennium 1856–60. Woods points out, however, that the present low level may be merely the trough of a wave. The decline in the mortality from whooping-cough also commenced about 1880 and has also been continuous; that from measles fluctuated until 1915, but since then has shown a rapid decline. In the earliest registration years scarlet fever caused nearly 40 per cent. of the total deaths attributed [illegible] these four major infections; from 1916 onwards [illegible] proportion has fallen to 6 per cent. The share [illegible] diphtheria until 1890 averaged about a fifth, but sin[illegible] then it has risen to about a [illegible]er. In the midd[illegible] of last century whoopin[illegible]d measles wer[illegible] each responsible for about [illegible]e, whereas now the share of each exceeds a third. Thus although the actual number of deaths caused by these two diseases has fallen very greatly during the past three-quarters of a century, their relative lethality amongst the four specific infections has become enhanced.

There is no evidence that the decline in mortality from diphtheria and scarlet fever has been coincident with any comparable decrease in prevalence, in spite of a high hospitalisation rate for both diseases over many years. Diphtheria in 1933 was very prevalent in Great Britain, especially during the last quarter, and in some parts of the kingdom was of a severe clinical type possibly associated with the *gravis* strain of the bacillus. In England and Wales[3] there were 47,435 notifications and 2646 deaths; in Scotland[4] 8843 notifications and 356 deaths. In England and Wales the number of notifications of scarlet fever was the highest since 1921, "but the number of deaths substantially less than in that year"; in Scotland the number of notifications (38,887) "far exceeded the highest number recorded during the last 30 years." The disease was accountable for 729 deaths in one division of the kingdom and 310 in the other.

Diphtheria is definitely preventable and the recent figures are a reproach. Scarlet fever is also preventable, and it may be noted that in Zetland the county medical officer is of opinion that a scheme of Dick-testing and immunisation which had been introduced in recent years "contributed in no small measure to the abatement of the scarlet fever outbreak." Active immunisation is the only feasible way of reducing the incidence of these two diseases. Diphtheria takes a constant toll of some 3000 children's lives annually. Scarlet fever, although a shadow of its former self, is responsible for an enormous amount of illness even in inter-epidemic phases, whilst its periodical epidemicity results, as it did last year, in the resources of public health authorities being strained to breaking point owing to the insistence of the public upon hospitalisa[illegible] which, more often than not, is unjustifiable upon [illegible] preventive or curative grounds. Diphtheria and [illegible] fever are compulsorily notifiable and although [illegible]usion of "[illegible]riological diphtheria" tends to [illegible]e real f[illegible] in the one case and the [illegible] of c[illegible] unrecognisable types [illegible] ggerate it in the other, the ratio of morbidity to tality can be assessed with fair accuracy. On the r hand, neither the morbidity nor the true mor- y from whooping-cough or measles is really wn. Notification of these diseases, if in force at all, cal and usually partial, and it is well recognised in measles, especially, death is apt to be ascribed roncho-pneumonia to the exclusion of the ante- nt specific infection. Last year measles in Great ain was in its inter-epidemic phase, and although experience of Scotland was exceptionally favour- —there were only 36 deaths—the disease was the stered cause of death of 1937 children in England Wales. We learn from the English report that prevalence of scarlet fever, already noted, con- ed in the early part of 1934, and then coincided a substantial increase in the prevalence of, and, btless, deaths from measles. It is evident too the League of Nations report that the biennial rge of measles did not spare Scotland in the first ter of this year, since partial notification revealed 5 cases and there were 89 deaths.

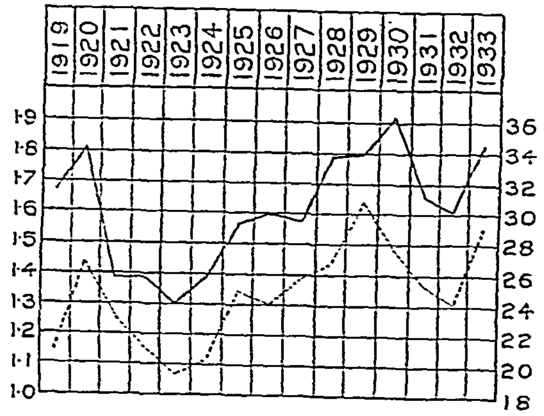
he ravages of measles, given an adequate supply of alescent or adult immune serum, can at least be gated, but even if allowed to run its course tenuated these ravages are not so severe in relative s of either morbidity or mortality as those of oping-cough with its long clinical course. In land and Wales last year 2270 deaths were ascribed hooping-cough, a death-rate of 5·6 per 100,000, st in Scotland it is recorded that the 762 deaths the disease were equivalent to a death-rate of er 100,000; 98 per cent. of these deaths occurred ngst children under 5 years of age. P. Stocks M. Karn[5] showed that in 1929 no less than 1141 hs from whooping-cough occurred in the area of administrative county of London alone, all ngst children under 10 years of age. This was valent to 13 per cent. of the mortality from all es at these ages. Stocks found that the London was exceptionally high, but there is evidence that oping-cough when epidemic is everywhere to be ded even more than measles. Recent work upon vaccine prophylaxis of this disease is at least nising, and it is to be hoped will be repeated upon dequately controlled scale in this country; but, e writer of the League of Nations report concludes, prophylactic campaign, even if limited to the ation of mothers, in the absence of specific unisation, cannot be started well and successfully ied out unless the importance of measles and oping-cough is realised." This unfortunately, only in this country but in most others, is far being the case.

Puerperal Fever and Erysipelas

the latest fascicle[6] of the L.C.C. report for 3, which deals with vital statistics and public th administration, Sir Frederick Menzies again rs to the upward movement of maternal mortality particularly to the correspondence in the move- t of the mortalities from puerperal fever and from ipelas among women over 20 years of age, matters which some space was devoted in his report for 3. Attention is drawn to the fallacies arising from expression of maternal mortality as a fraction of ch the numerator includes deaths at all stages of nancy of women, whether married or unmarried, the denominator only births after the twenty- th week of gestation. Statisticians are fully alive to the difficulty, but so far no better means of arriving at a measure of maternal mortality for practical purposes and general use has been devised. Sir Frederick advises London authorities to show deaths due to abortion or miscarriage separately from those associated with live or stillbirths, and, so long as no attempt is made to draw conclusions from local annual rates derived from these subdivided and necessarily small figures, the proposal ought to meet with acceptance. He also emphasises the greater risk attendant upon stillbirth than live birth and the consequent need for still further classification of statistical records. He appears to adhere to the view which he expressed in 1928 that a falling birth-rate tends to be associated with an increase in the maternal death-rate. The Registrar-General however maintains[7] "that no excuse for the lack of improvement in the maternal mortality-rate can . . . . be found in the falling birth-rate," since the decline in the relative numbers of children born in the birth ranks of high order (fourth or later confinements, presumably) compensates for the increase of the proportion of first confinements.

In London as elsewhere, puerperal sepsis accounts for about 40 per cent. of the maternal deaths, and the report points out that deaths from this infective cause are subject to greater fluctuation than those of non-septic origin. The variation of the puerperal fever death-rate in correspondence with the death-rate from erysipelas is strikingly illustrated by the figure which we reproduce from the report. The importance and wide diffusion of infection with hæmolytic streptococci has been amply demonstrated, but on general epidemiological grounds one would expect that infection of the community generally should have a bearing on the occurrence of puerperal sepsis almost, if not quite, as great as infection of the women over 20 years, unless the theory of autogenous infection is accepted. In fact, the death-rate from erysipelas at all ages closely follows the same course.



A comparison between the incidence during the years 1919–33 of (black line) puerperal fever death-rate per 1000 births and (dotted line) erysipelas death-rate per 1,000,000 among females aged 20 and over. Since stillbirths were not registrable until 1928 it must be taken that the puerperal rates are based on live births.

The Single Abattoir

In a report to the Belfast public health committee, Dr. C. S. Thomson illustrates the value of having only one abattoir in a city, and that one a municipal abattoir under the supervision of the M.O.H. An animal was killed at Hillsborough, Co. Down, some elicited. The spasm occurring in an artery already partly occluded by atheroma probably interfered with the flow and led to local thrombosis.

PUBLIC HEALTH

The Major Fevers of Children: their Recent Trend

In an analysis based upon the Registrar-General's statistics for England and Wales during the past 75 years the health department of the League of Nations[1] considers the trend of mortality of the four major acute specific infections of childhood: diphtheria, scarlet fever, whooping-cough, and measles. Two main points emerge from this analysis: (1) the great decline in the total number of deaths caused by these diseases; and (2) the alteration in the proportion of deaths due to each of them. If the death-rate of children under 15 from each of these diseases be taken as 100 for the quinquennium 1856–60, and compared with the rates for the quinquennium 1926–30, the decline in the death-rate from diphtheria is 78 per cent; from scarlet fever, nearly 98 per cent; from whooping-cough and measles, 72 per cent. and 68 per cent. respectively; and from all four together, nearly 82 per cent. Diphtheria antitoxin was introduced in 1895, and it is therefore not surprising to learn that an accelerated fall in the death-rate from this disease dated from that year, but no such specific cause can be assigned for the great decline in the number of deaths from scarlet fever. An antitoxin was not available until about 1925, whereas Hilda M. Woods[2] showed that about 1880 "some change occurred and mortality definitely declined and has continued to do so." For the quinquennium 1926–30 the death-rate from scarlet fever among children under 15 was 5·5 per 100,000, compared with 220 for the quinquennium 1856–60. Woods points out, however, that the present low level may be merely the trough of a wave. The decline in the mortality from whooping-cough also commenced about 1880 and has also been continuous; that from measles fluctuated until 1915, but since then has shown a rapid decline. In the earliest registration years scarlet fever caused nearly 40 per cent. of the total deaths attributed to these four major infections; from 1916 onwards the proportion has fallen to 6 per cent. The share of diphtheria until 1890 averaged about a fifth, but since then it has risen to about a quarter. In the middle of last century whooping-cough and measles were each responsible for about a fifth share, whereas now the share of each exceeds a third. Thus although the actual number of deaths caused by these two diseases has fallen very greatly during the past three-quarters of a century, their relative lethality amongst the four specific infections has become enhanced.

There is no evidence that the decline in mortality from diphtheria and scarlet fever has been coincident with any comparable decrease in prevalence, in spite of a high hospitalisation rate for both diseases over many years. Diphtheria in 1933 was very prevalent in Great Britain, especially during the last quarter, and in some parts of the kingdom was of a severe clinical type possibly associated with the *gravis* strain of the bacillus. In England and Wales[3] there were 47,435 notifications and 2646 deaths; in Scotland[4] 8843 notifications and 356 deaths. In England and Wales the number of notifications of scarlet fever was the highest since 1921, "but the number of deaths substantially less than in that year"; in Scotland the number of notifications (38,887) "far exceeded the highest number recorded during the last 30 years." The disease was accountable for 729 deaths in one division of the kingdom and 310 in the other.

Diphtheria is definitely preventable and the recent figures are a reproach. Scarlet fever is also preventable, and it may be noted that in Zetland the county medical officer is of opinion that a scheme of Dick-testing and immunisation which had been introduced in recent years "contributed in no small measure to the abatement of the scarlet fever outbreak." Active immunisation is the only feasible way of reducing the incidence of these two diseases. Diphtheria takes a constant toll of some 3000 children's lives annually. Scarlet fever, although a shadow of its former self, is responsible for an enormous amount of illness even in inter-epidemic phases, whilst its periodical epidemicity results, as it did last year, in the resources of public health authorities being strained to breaking point owing to the insistence of the public upon hospitalisation which, more often than not, is unjustifiable upon either preventive or curative grounds. Diphtheria and scarlet fever are compulsorily notifiable and although the inclusion of "bacteriological diphtheria" tends to dilute the real fatality-rate in the one case and th frequency of clinically unrecognisable types

PANEL AND CONTRACT PRACTICE

Off with their Heads!

the course of his eighth presidential address to anitary Inspectors' Association on Sept. 4th onard Hill, M.B., F.R.S., spoke of the need for ncy and economy in the medical services paid y the State. In these respects he contrasted nce practice unfavourably with the work done spitals.

a general hospital," he said, "a patient is first y a receiving room medical officer, who sifts out ture of the case, and if the trouble be more than sends the patient, in accordance with his diagnosis, the physician, the surgeon, the eye specialist, &c. . . . mplete a diagnosis the patient has the advantage ts made in the bacteriological and biochemical ments and of examination by X rays. To aid his ry there are available the skill of the surgeon and ethods of physical medicine, manipulative surgery, ge, electricity, irradiation with light and heat, and s medicinal baths. It is not possible for [illegible] n, er qualified, to carry out anything lik [illegible] he of diagnosis and treatment. Even if he has the edge he has not the room, the expensive apparatus, e skilled assistance required."

me 80 per cent. of the troubles which lead nts to consult their panel doctor there is nothing s the matter, continued Sir Leonard; "a encouragement and nature will put things right; tle of medicine plays its part, and faith-healing the rest." But serious cases may be missed: ample, there is the abdominal pain that may be o appendicitis, and the cough that may be due berculosis. Again there is diabetes, which may erlooked, and may also be inadequately treated. ugh want of proper control "many cases of tes arrive at the hospitals in a state of coma. the statistics of the Registrar-General do not that fall in the death-rate for diabetes which d have resulted through the discovery of insulin." e panel system, Sir Leonard thinks, should be ced by one in which all medical officers paid by State are attached to hospitals, clinics, and nsaries. "The panel doctor waits for the sick me to him; he cannot go into the factories and a holiday for those who need it or make changes nditions which will lead to the prevention of se." In speaking of sickness benefit he repeated harge that "an undue proportion of sicknesses on a Saturday, and an undue proportion begin Monday."

is comprehensive indictment of the present m will find supporters both within and without profession; and it is perfectly proper that those engaged in insurance practice should sometimes to prove that they see most of the game. Not body, however, has Sir Leonard Hill's enthu- for hospitals, clinics, and dispensaries as an native to the family physician. And is the ment provided by hospitals always so much rior? As at present constituted they are largely d by junior men who are gaining experience e going out to practise on their own responsibility metimes as panel doctors—without the shelter ded by the name of a great institution. Anyone has been resident in them will remember errors dgment or practice which never came to light; yet all their privacy there are sometimes complaints. pitals, in fact, make mistakes like everybody but there are no medical service subcommittees quire into them. They have come to occupy sition of great privilege, and it is galling to etent practitioners to find that what a junior nurse at a hospital says about the condition of a patient—"he ought to have been sent to hospital before . . . &c."—is always accepted by the public. At the same time there are signs that the approved societies are now beginning to realise that certificates obtained at hospitals have no more intrinsic value than those of external practitioners—and sometimes not so much.

As for the old remark about illness ending on Saturday and beginning on Monday, Sir Leonard Hill must remember that all the professional bodies from the Insurance Acts Committee downwards have done their best to persuade doctors to sign patients off the funds as soon as they are well. But anyone who has tried to do it knows the difficulty that immediately crops up. Employers are very loath to restart a man at work in the middle of a working week. Suppose that a cut finger is definitely dry for the first time on Wednesday, with the scar healed but tender. The new week starts on Friday. It would be interesting to hear how often Sir Leonard would sign the man off on Wednesday, knowing that the employer would not have him back till Friday—especially if the patient told him the scar was still tender and painful. The fact that illness often starts on the beginning of the week is usually due to the desire of the man to carry on as long as possible; he works the last part of the week when he ought to have ceased earlier. It really seems to have very little to do with the merits of the panel system.

It is true, of course, as Sir Leonard Hill says, that a large proportion of patients have nothing serious the matter with them; but he is surely aware that a primary object of the Act was to induce people to consult their doctors in the earliest possible stage of an illness, before serious trouble arises; and according to him they are doing it. He produces no evidence that serious cases are missed, and the statistics of complaints made to the medical service subcommittee show that errors of diagnosis are not at all common—a conclusion which was amply borne out by the report of the last Royal Commission.

A Dilemma

Two weeks ago in this column we printed the draft letter regarded by the Insurance Acts Committee as a proper one for the secretary of an approved society to send to the insurance practitioner who has certified one of its members as being incapable of work. We noted the difficulty of answering such a letter without infringing professional secrecy. The doctor who considers his reply merely as another report to write may find himself on the horns of a dilemma. If he answers "yes" the case will be referred to the regional medical officer and the doctor lays himself open to the question why he has not himself referred it before. The society's letter is, however, designed to avoid references. If he says "no," but fails in "other observations" to convince the society of the futility of a reference, he must tell the patient that he informed the society that a reference was not necessary but was overruled. Actually the only possible answer is "yes," but to the society alone. For whereas the patient stands to lose sickness pay if found capable and has all the trouble and inconvenience of attending the centre for examination, and whereas the doctor risks having his judgment reversed—to say nothing of the extra work of writing reports and the bad mark if they do not arrive in time—the society may gain up to 15s. a week through cessation of sick pay, at a cost of

1s. 6d. for the reference. The advantage is in fact wholly on the side of the approved society. In regard to the "other observations," if the reply is limited to an estimated prognosis of the return to work made in agreement with the patient, the doctor will probably be on safe ground in giving this help to the society, but the form of words used should be not such as to brand him as being professionally incorrect if subsequent facts do not bear out his estimate. In any case he would need to be very careful not to give the society any information which might be damaging to the patient, without his consent. This is probably the reason why the diagnosis of gastritis or anæmia is often used in the certification of pregnant young girls at the present time. If the patient discloses the condition to the society it does not matter, but if the doctor does so, even on the certificate which is handed to the insured person to give to the local agent, in a small village area the news would be around directly and the doctor would be blamed by the public although not legally culpable. It may require all Dr. Dain's persuasive eloquence to convince the panel conference that the letter should be agreed to in its present form.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

HOUSING AND TUBERCLE

THE Royal Sanitary Association of Scotland, which held its diamond jubilee this year at Stirling, has come to be accepted by the local authorities as setting the general standard for sanitary work in the country and providing an occasion for ventilating the large problems of public health. Its history has been bound up intimately with the development of the public health authorities. At this congress discussion turned on tuberculosis. In his presidential address Mr. Allan W. Ritchie commented on the importance of colour in house decoration; former drab, heavy, dust-collecting draperies and dismal wall colourings had given place to surfaces of lighter and brighter hue. Industrious housewives had demonstrated the uplifting effect of harmony in colour, but much remained to be done by the effective use of colour—flowers, shrubs, hedges, and trees—in dispelling the gloom of urban conditions. He wished to correct an impression which had gained an astonishing currency (e.g., the bath used as a coal bunker *statim*) that slum-dwellers transferred to a new housing scheme took no more than a year or two to reduce their new dwellings to a level with the old. The proportion who failed to respond to their new surroundings was actually not more than 4 or 5 per cent.

A sketch of the working of the Glasgow tuberculosis scheme for the last 20 years was given by Dr. R. J. Peters. The annual cost of this scheme, about £235,000, was, he said, relatively high because of the liberal hospital accommodation needed to counterbalance the low standard of housing and the overcrowding in the city. In Glasgow each tuberculosis case cost the ratepayers about £100 for treatment and supervision. Sanatorium and municipal hospitals had in the past resulted largely in divorcing tuberculosis from general medicine. But now with the clinic system the work of tuberculosis officers was broadening out to an extent undreamt of when the schemes were inaugurated. Prof. Carstairs Douglas congratulated Stirling county and burgh on their milch herds. Of 132 biological tests on individual cows from Stirling he had, up to June last, only found two positive. Dr. G. V. McMichael (Paisley), presid elect, spoke of the need for a definite policy on hou tuberculous families in industrial areas. Of cases investigated during the last five years 63 cent. shared a bed, another 21 per cent. shared a ro and only 15 per cent. were the sole occupants of room. In the light of such conditions his l authority decided to make a special effort, and du the last three and a half years 182 tubercu families, or 21 per cent. of the registered cases, been rehoused. In future housing schemes 15 cent. of the houses were to be allocated to tubercu families, the rents being kept below the usual £12, and £16 respectively for 2, 3, and 4 apartment hous

AUSTRALASIA

(FROM OUR OWN CORRESPONDENT)

ROYAL AUSTRALASIAN COLLEGE OF SURGEONS

THE annual report of the Council of the Ro Australasian College of Surgeons which has been published announces the election of Mr. H. Devine, of Melbourne, as vice-president, to fill vacancy caused by the retirement of Sir Alexan MacCormick. Mr. Alan Newton, of Melbourne, appointed censor-in-chief, in place of the lat Hamilton Russell. The Council further reports creation of training posts for young surgeons assistants to in-door surgeons at various hospit and the establishment of a hospital for post-gradu teaching. This hospital, to be known as the "Fri George Hospital," Melbourne, was formerly homœopathic hospital, and its change of title scope is the result of negotiations between the coun of the College and the authorities of the hospit The College building in Melbourne will be opened Sir Holburt Waring, the president of the Ro College of Surgeons of England, in March, 19 when the next annual general meeting of the Coll will be held. At the last meeting, held in Adelai from Feb. 28th to March 3rd of this year, about o hundred Fellows from all States of the Commonwealt attended. It was opened by the Governor of Sou Australia, and after the formal admission of 15 ne Fellows an address on the origin of the College, i aims and its objects, was delivered by the presiden Sir Henry Simpson Newland.

PRIMARY FELLOWSHIP EXAMINATION IN AUSTRALIA AN NEW ZEALAND, 1934

Candidates for the primary examination for th diploma of Fellowship of the Royal College of Surgeon of England will be able to sit for it in Melbourne i November and in Dunedin, New Zealand, in Decembe next. This is the second occasion on which th examination will have been held in Australia. Pre viously only graduates were allowed to take th examination, but now special arrangements hav been made to allow senior students to do so. Th date of the examination coincides with the latte part of the examinations in anatomy and physiolog at the University of Sydney, and the faculty o medicine of this university has agreed to make specia arrangements for those students who wish to sit fo the primary examination at Melbourne, when Mr G. Gordon Taylor and Prof. G. A. Buckmaster will act as examiners in respectively anatomy and physiology. Special classes have been arranged in both Melbourne and Sydney by the local post-graduat committees. It is understood that there will be about 60 candidates for the examination from Australia and 25 from New Zealand.

CORRESPONDENCE

ERYTHEMA NODOSUM

To the Editor of THE LANCET

—My experience with erythema nodosum of reptococcal type answering at once to a single f antistreptococcal serum is in complete agree-with that of Dr. Slot in your last issue (p. 600). e other hand, I must challenge his remarks on equency of streptococcal erythema nodosum as ed to tuberculous erythema nodosum. Certainly ldren the latter is many times as frequent, and uite an exception to find a case of streptococcal ema nodosum in childhood. Before treating iven case, it is wise to do a Mantoux tuberculin /1000) and, if possible, a streptococcal endotoxin utaneous test. The underlying cause of the ular case then becomes obvious and the priate cases for antistreptococcal serum can be l out.—I am, Sir, yours faithfully,

DONALD PATERSON.

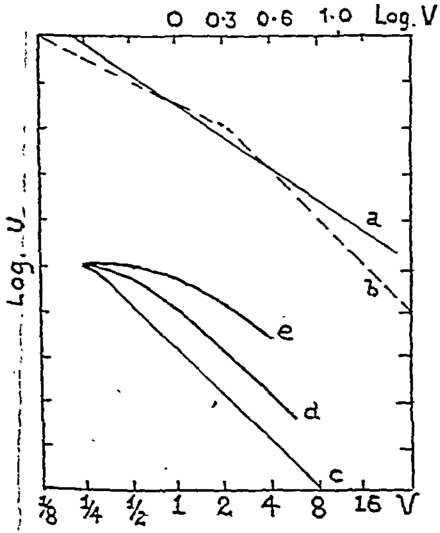
shire-place, W., Sept. 15th.

THE UREA-CLEARANCE TEST

To the Editor of THE LANCET

Dr. Hinden's paper on the urea-clearance our issue of Sept. 8th leads us to draw attention mpler method of evaluating results—viz., e use of graphs.

ence Ambard's and van Slyke's tests are on an assumed normal relationship between -urea concentration in milligrammes per litre (B), ry urea concentration (U), and the secretion-in cubic centimetres per minute (V). It is ised that, when kidney efficiency and B are ant, V varies reciprocally as some power of U. can be put to the proof by the usual method of sis. Given a series of data satisfying the above



U (urinary concentration of urea) plotted against $\text{Log}_{10}V$ m. urine per minute): (*a*) on the basis of Ambard's mula, assuming a normal fixed value for the blood-urea, $V' = K_1$; (*b*) on the basis of van Slyke's formula, assuming ormal fixed value for the blood-urea, $U^2V = K_2$ (when $V < 2$); $= K_3$ (when $V > 2$). (*c*), (*d*), and (*e*) are curves from the ters' observations, showing the effect of increasing the oad" of the

aph of log U : log V should be haracteristic slope.

ding respectively to Ambard's ke's law (*b*) are shown in the accompanying Figure. For different fixed values of B, the graph as a whole will move vertically upwards and downwards. On the other hand, observations[1] suggest that the natural graph is seldom linear, but varies both in form and in situation with the load imposed upon the kidneys (represented by B). In the Figure *c*, *d*, *e* show the type of change to be expected as the load increases. Further, as kidney efficiency declines, the situation of the curve tends to fall and the horizontal flattening to become more pronounced. For clinical purposes, therefore, a series of normal curves for different values of B would provide a more reliable standard than a rigid algebraic formula, and since the coördinates could be calibrated directly in plain figures (as the Figure shows for V), calculation of logs would be unnecessary. The criterion of normal relationship would then be whether the readings for secretion-rate and urinary urea concentration fall on the corresponding normal curve.—We are, Sir, yours faithfully,

A. R. MCCLURE,
C. P. STEWART.

RADIOLOGY IN GENERAL PRACTICE

To the Editor of THE LANCET

SIR,—From the standpoint of a qualified radiologist doomed to general practice I hasten to refute Dr. Monteith's letter in your last issue, and to give whole-hearted support to the statement uttered at the recent B.M.A. discussion that "the general practitioner who purchased an X ray outfit was likely to become a menace to his patients." As a student in 1925 I heard Dr. W. J. O'Donovan, dermatologist to the London Hospital, describe cases of lupus and other skin diseases which he had seen converted to epithelioma by ardent practitioners possessing X ray outfits. The mere installation of an X ray outfit never brings automatically to the installer a sound knowledge of radiology. One might as well purchase a copy of the Koran and automatically consider oneself to be a Mohammedan mullah.

During eight years of general practice I have seen the following mistakes made by well-qualified medical men who considered themselves fit without adequate training to interpret radiograms.

1. Describe as fractures the overlapping shadows of the metatarsal and metacarpal bones.
2. Fail to recognise a crack in a bone, where there was no displacement or deformity (several cases).
3. Consign to institutions for surgical tuberculosis, as tuberculous hips and spines, cases where the radiograms were quite normal.
4. Read into normal radiograms the tentative clinical diagnoses.
5. X ray cases of pregnancy and fail to interpret twins owing to improper technique in radiography.
6. Misuse the X ray apparatus by imagining that the X ray will *directly* reveal carcinoma in such glandular tissues as the breast and the liver.

Finally during a long association with manufacturers of X ray apparatus, I have culled the information that some general practitioners install X ray outfits to attract attention much in the way that the chemist puts large bottles of coloured water in his shop window. The exhibition of the apparatus is calculate to elicit praise and advance prestige where no is due. I am, Sir, yours faithfully,

Pinwell, Slough, Sept. 15th. N. C. HYPHER

"NATURE AND NURTURE"

To the Editor of THE LANCET

SIR,—In a recent notice of my book your reviewer expresses alarm lest my antipathy to eugenics, and repeated emphasis on the interaction between the gene and its environment, may promote the belief that human genetics is a purely academic pursuit which has no practical contribution to make to preventive medicine. The object of the William Withering lectures was to look beyond the false antithesis which has been endorsed by philanthropic environmentalism and eugenic calvinism. In its place I tried to put the modern view which envisages the gene as an agent in the process of development interacting with the environment at every stage. Far from robbing the pursuit of human genetics of any social utility this conception enlarges our appreciation of the constructive contribution which it may make as our knowledge advances.

The eugenic view is that the practical importance of human genetics resides in selection—that is to say, discouraging persons with certain genes from parenthood by legislative acts or social pressure. This would restrict the practical usefulness of human genetics to extreme disorders, and I cannot believe that the busy house physician to whom your reviewer refers is likely to be encouraged to undertake searching inquiry into the genetic factors in disease if sterilisation is the only object in view. The alternative view which is implicit in every page of my book is that the more we find out about the hereditary background of disease the better shall we be able to prescribe a regimen of healthy living. I doubt if your reviewer would wish to increase the difficulty of maintaining a population which already has a gross reproduction-rate below unity by advocating the sterilisation of people who have the misfortune to be suffering from an infection of the frontal sinus. At the same time, I feel confident that he would not dismiss the possibility that genetic factors play some part in deciding whether one individual is more likely than another to get such a disorder.

From the narrow standpoint of eugenics knowledge of that kind would be utterly useless. From the standpoint which I have presented it would be an essential piece of practical information. If we had such knowledge we should be in a position to warn people who are liable to suffer in that way, and advise them about the necessary steps to take in order to avoid trouble for themselves.

I am, Sir, yours faithfully,

LANCELOT HOGBEN.

University of London, Department of Social Biology,
Sept. 17th.

URETERO-COLOSTOMY

To the Editor of THE LANCET

SIR,—Owing to absence from London I have only just seen Mr. John Everidge's account of his technique in uretero-colostomy in your issue of Sept. 1st (p. 483). He concludes by saying:

> "This technique of delivery of the catheter appears simple and easier than other methods in use in Coffey No. 2—i.e., by attachment to gauze packing in the bowel, manipulation of the catheters through a sigmoidoscope other rigid tube, as suggested by Nitch and Green-mytage, which remain in situ during the operation."

is suggests that I advocated packing the rectum h gauze. As a matter of fact I have never used method, as I considered it too complicated and thy, and Coffey, who originated it, gave it up e before his death. In the method I described a lead tube (not a sigmoidoscope), curved to fit hollow of the sacrum, is passed by an assistant wit altering the position of the patient, after the abd has been opened and the operative field prep This serves as a support on which the peritoneal muscular coats of the bowel can be divided easily. The tube is then drawn down until the e. mucous membrane of the rectum is stretched its opening. The mucous membrane is punctured a tenotome and the catheter, attached to the u in accordance with the Coffey No. 2 technique, through the opening and down the tube, to be gr. by the assistant and pulled further down until ureter is drawn into the bowel to which it (the is attached by a suture which does not enter lumen of the bowel. The method is therefore st aseptic, and was specially devised for this pu

I cannot agree with Mr. Everidge's claim that method is simpler or easier, and it is certainly completely aseptic, for he first passes a straight (the sigmoidoscope), then a rubber bag, then i the bag, then deflates it, and finally passes withdraws a needle via the peritoneal cavity, t the contaminated wall of the bag. All s interested in this operation have been endeavo to simplify it and lessen its dangers, but with deference to Mr. Everidge's well-known skill ingenuity I do not consider his operation fulfil desiderata. In the endeavour to meet them m I have reverted to the Mayo modification of Coffey No. 1 operation, which is simple, rapid in my experience, more satisfactory than the with catheters. The only disadvantage is t not applicable to simultaneous bilateral tr tation.

I am, Sir, yours faithfully,

Harley-street, W., Sept. 15th. CYRIL A. R. N

MEDICAL NEWS

Chemists' Exhibition

The forty-third Chemists' Exhibition will be held at new hall of the Royal Horticultural Society, Grey street, London, S.W., from Sept. 24th to 28th.

Society of Public Analysts

The next meeting of this society will take place Wednesday, Oct. 3rd, at the Chemical Society's Burlington House, Piccadilly, London, W., at 8 P when Dr. G. Roche Lynch will read a paper on the mination of lead in biological material with sp reference to bone. The hon. secretary is Dr. Lynch may be addressed at the department of chemical patl St. Mary's Hospital, London, W.2.

Royal Sanitary Institute

The institute has arranged a sessional meeting Finchley on Friday, Oct. 5th. At 3 P.M. the members inspect the Finchley open-air swimming pools in the North-road, and at 5 P.M. papers will be read on Finchley swimming pools by Mr. P. T. Harrison, and the purification of swimming-bath water by Dr. A. Turner, the medical officer of health.

A sessional meeting will also be held at Sunderland Friday, Oct. 12th, when Dr. A. Stuart Hebbleth the medical officer of health, will op vermin and slum clearance. A sec anæmias and preventive medicine is t Dr. H. A. Cookson, the borough pathologist.

Opening of the Medical School

The inaugural address at G school will be delivered by Mr. C. F Oct. 3rd, and not as stated in our before the address, Lord Nuffield

OBITUARY

ILLIAM HENRY TRETHOWAN, M.B.Lond., F.R.C.S. Eng.

HE sudden death of Mr. W. H. Trethowan at the ht of his professional career has come as a shock to his colleagues and to his many friends outside pital circles. He left for his annual holiday in early part of August, and died after a short ss on Sept. 12th while he was on a visit to Sweden. illiam Henry Trethowan was a Cornishman of d personality. He was born at Cawsand in 1882, son of Mr. W. H. Trethowan, and was educated the High School, Devonport, and Plymouth hnical College. He went to Guy's in 1901 with unior entrance scholarship which was of great help to him, his financial resources being slender. He qualified M.R.C.S. Eng. in 1906, and in the same year was awarded the gold medal in the final M.B., B.S. Lond. examination. He held a succession of junior resident appointments at Guy's, among which was the post of house physician to Dr. Newton Pitt. In 1908 he was appointed resident medical officer to Bright ward (for paying patients) for two years before becoming resident surgical officer. He took Fellowship of the Royal College of Surgeons 1912, and in the same year was appointed geon in charge of the newly constituted depart- nt for orthopædic surgery at Guy's. From s time on his interest in orthopædics increased til this branch of surgery became his life work. ring the war he served, as a captain R.A.M.C. (T.), the Military Orthopædic Hospital, Ducane-road w the Hammersmith Hospital), as one of the team ich, under the inspired direction of Sir Robert nes, made history in their specialty. In 1919 Mr. ethowan was elected surgeon to the Royal National thopædic Hospital, and in October of the same ar he was invited by the Metropolitan Asylums ard to become consulting orthopædic surgeon to een Mary's Hospital for Children, Carshalton, to al particularly with the cases of deformity and vanced disease of bones and joints which at that ne were seeking treatment at this hospital in reasing numbers. The facilities for observation d prolonged treatment under almost ideal condi- ns appealed to him and, notwithstanding the ny other calls on his time, he accepted the extra rk and continued it when the hospital was taken er by the L.C.C., paying a fortnightly visit of veral hours' duration greatly to the benefit of ndon's crippled children.

MR. TRETHOWAN

In his earlier years Mr. Trethowan had shown no ecial aptitude or inclination for surgery, and deed it was his intention to become a physician. He was also interested in midwifery, and this interest was fostered by his term as resident obstetrical officer at Guy's. A voracious reader, he found it easier to gather his knowledge from books than from observation of bedside practice, and his unusually good memory made it easy for him to recall and apply what he had read. He was not one of those who had a natural clinical instinct, and he often spoke in after years of his early struggles to acquire this important sense. That he surmounted his difficulties and later developed keen clinical acumen is a testimony to his hard and persistent work. Mr. Trethowan's admiration of the work of Sir Arbuthnot Lane greatly influenced his early tendencies and practice.

As a teacher Trethowan was stimulating and forceful. His boundless enthusiasm for orthopædics was infectious, and his views, sometimes unorthodox, were often expressed with vigour and conviction. His out-patient department at Guy's was always crowded, and no student who attended was likely to forget his graphic and lucid teaching. His examination of a case was thorough and careful, though his notes and findings were dictated in rapid and indeed torrential sentences. His arguments were often enlivened with quotations or deliberate misquotations, and on the blackboard which was always at his side in the department he drew adept diagrams, as well as giving personal demonstrations of some peculiar or typical gait.

As an operator he was expert and facile; his craftsmanship was superb, and his technique impressive. No detail was omitted, and yet his surgical work, although never appearing to be hurried, was actually performed with unusual rapidity and great deftness. He was especially interested in the management of difficult fractures, and was a master of the art of bone-grafting, displaying the utmost ingenuity and skill in the selection, adaptation, and insertion of grafts. The deformities of the foot and their correction was another branch of orthopædics which especially engaged Mr. Trethowan's attention. In all departments his methods were bold and determined. His private practice and his hospital work occupied most of his time. He wrote comparatively little, and seldom took part in public discussion. He contributed a chapter on orthopædic surgery to Choyce's "System of Surgery," an article on the treatment of simple fractures to Jones's "Notes on Military Orthopædics," and to the Robert Jones Birthday Volume which appeared in 1928, a paper on fracture-dislocation of the ankle-joint. In the series on Modern Technique in Treatment, published in THE LANCET from 1923 to 1928, he was represented by an article on the treatment of hammer-toe.

As a man, he was kind-hearted and generous to a fault. Everyone at Guy's knew that "Treth" was always ready to help and advise his colleagues and was particularly appreciative of the difficulti of his juniors. He was frank in criticism of wh he did not like, but his comments were nev wounding. His æsthetic sense was acute, and was quick to perceive the humour of any situat which others were inclined to take too seriou Trethowan's leisure was given over to music. younger days he was a member of the choral s of the hospital. Later in life he delight larly in playing the organ, and he lived Hospital for many years after his means justified removal to a more salubrious residential quarter in order to stay near the chapel organ. When he did move to Hampstead he built himself an organ in his own house. His family life meant much to him; he is survived by his wife and two boys.

JAMES HUNTER, M.D. R.U.I.

Dr. James Hunter, who died at Invercargill, New Zealand, on July 14th, after some months of illness, was born at Hunterstown, near Doagh, Co. Antrim, Ireland, in 1862, the son of Robert and Barbara Hunter. He was educated at the Methodist College, Belfast, where in 1881 he obtained the gold medal in mathematics. In the study of medicine at Queen's College, Belfast, James Hunter had a distinguished undergraduate career, winning a succession of scholarships and the class prizes in anatomy and surgery. He graduated as M.D., M.S., in the Royal University of Ireland in 1888, and after some infirmary experience in Belfast and a clinical assistantship at the Soho Hospital for Women, went to New Zealand and entered upon country practice at Winton, in the province of Southland. In 1892 he moved to the town of Invercargill in Southland, and there he spent his life. His professional skill and his quiet kindness earned him a considerable general practice, and his leisure was devoted to the study of certain of the basic sciences in which he maintained an active interest. In busy routine work he was a persistent student, and made time to keep abreast of progress in medicine. The year 1898 he spent in Ireland, Berlin, and Vienna in post-graduate study, being attached in Vienna to Hajek's clinic for the study of disease of the ear, nose, and throat. He last visited England and Northern Ireland before his retirement in 1924. In earlier days he was a keen fly fisherman, and, after giving up practice, he spent the summer months at Ulva, Stewart Island, where, in surroundings still in their natural state, he followed his interest in botany and developed the study of New Zealand's native trees and birds. Dr. Hunter married in 1903, and is survived by his wife, two daughters, and one son.
